B1/P1001

A Case Study on Genomic Imprinting Facilitates Learning of an Abstract Topic

L. K. Goudsouzian[1], S. M. Lo[2]; [1]Biology, DeSales University, Center Valley, PA, [2]University of California at San Diego, La Jolla, CA.

Genomic imprinting is a form of non-Mendelian inheritance. Students in molecular biology and genetics college classrooms can struggle to understand genomic imprinting, in part because both high school and college instruction in genetics has traditionally prioritized lessons on Mendelian patterns of gene inheritance. We hypothesized that the use of a case study would help students better learn the topic of genomic imprinting. We wrote an interrupted case study which focused on genomic imprinting. The case study consists of three short popular news articles which relate to the topic of genomic imprinting. Each article is followed by a set of 2-4 questions. Students read each article and discuss its associated questions in small groups, then with the entire class, before moving on to the next article. We deployed the case study in an intermediate-level molecular biology course at a small, liberal-arts university. We assessed student learning and attitudes towards the case study (total of 50 pre/post matched pairs). In four true-false assessment questions, our results showed that students' performance on after the case study was significantly higher than their performance before the case study (McNemar's test for dichotomous paired nominal data, pre vs. post case study, p ranging from < 0.05 to < 0.0001 with odds ratios ranging from 5.39 to 17.48). Students also self-reported increased knowledge on concepts related to genomic imprinting (two items on a four-point Likert-like scale, pre vs. post case study, Wilcoxon rank-sum test for non-parametric data, $p < 0.0001$ for both items, Cohen's d effect size = 2.22 and 2.81). Finally, students were likely to agree that the case study was beneficial to their learning and was an enjoyable classroom activity (five items, post only, at least 3.28 ± 0.70 on a four-point Likert-like scale). We conclude that the case study is an effective way to instruct students about this challenging topic.

B2/P1002

MIRIC (Mentoring the Integration of Research Into the Classroom) Network affinity groups produce diverse resources for CURE development

M. J. Wolyniak[1], L. F. Barton[2], K. K. Resendes[3], J. N. Fitz Gerald[4], N. A. Najor[5], E. J. Sandquist[6]; [1]Hampden-Sydney College, Hampden-Sydney, VA, [2]Austin College, Sherman, TX, [3]Westminster College, New Wilmington, PA, [4]Rhodes College, Memphis, TN, [5]University of Detroit Mercy, Detroit, MI, [6]Weber State University, Ogden, UT.

An effective way to engage students in science education is through course-based undergraduate research experiences (CUREs) at all levels of the curriculum. While a proven high-impact pedagogical practice, CURE implementation can be a daunting task. Long-term mentorship in a community of practice dedicated to CURE development is an outstanding way for current and future faculty to overcome barriers to creating CURE experiences tailored to their own unique classroom needs. The Mentoring the Integration of Research Into the Classroom (MIRIC) Network is an initiative of the Council

on Undergraduate Research (CUR) Biology Division that trains current and future instructors on how to effectively implement CUREs into their classes. MIRIC is a supportive community for novice and experienced CURE instructors seeking to develop and strengthen their work with authentic research experiences in the classroom. To this end, MIRIC invites its mentee and mentor participants to join discussions on topics including "starting from scratch", inclusive CURE design and implementation, CURE sustainability, and extending the CURE model to K-12 classes to hone their skills on a specific aspect of CURE development of particular interest to them. Here we highlight the work of our affinity group work to date and showcase our diverse projects and products which may be shared with or used by other potential CURE instructors. Survey data from MIRIC participants indicate the network has been successful in giving participants the skills and the support necessary to develop effective CUREs that address the specific needs of their classrooms. Collectively, this affinity group approach for group mentoring has been effective in helping MIRIC mentees to develop the skills and confidence necessary to implement an effective CURE.

Creative activities promote student motivation and engagement in a large cell biology course

I. Bouhdana, M. Denis, G. J. Brouhard; McGill University, Montreal, QC, CANADA.

Student motivation and engagement are foundational to academic success but can be difficult to achieve in large enrolment cell biology courses. In social cognitive theories of motivation, students are motivated when they perceive value in an educational activity, and motivation can feed forward on three distinct dimensions of student engagement, namely behavioral, cognitive, and emotional engagement. This engagement, in turn, is critical to academic success. A key to stimulating student motivation is creativity. We wondered whether creative activities would have a positive impact on student motivation, engagement with course material, and academic performance in a 500-student undergraduate cell biology course at McGill University. Students were given assignments with the option to choose between four creative activities: (1) 3D printing a protein structure based on a PDB file; (2) baking cookies or other pastries shaped like a protein of interest; (3) creating a freeform visual art submission, such as a painting; or (4) making a meme about course material. Students who did not wish to submit creative activities could opt out by completing a self-graded quiz instead. We hypothesized that the creative group would report greater motivation and engagement that would feed forward into improved performance on course examinations. Twice during the semester, we collected quantitative and qualitative survey data from students designed to measure their levels of behavioral, cognitive, and emotional engagement; we then correlated this data with exam performance. Our results indicated that students who participated in creative activities perceived them as valuable and reported higher levels of behavioural and emotional engagement with course content relative to students who took self-graded quizzes. However, contrary to our hypothesis, students who took self-graded quizzes reported significantly higher levels of cognitive engagement with course material and outperformed other students on course examinations. Our results suggest that creative activities are motivational and engaging to cell biology students but must be designed to promote cognitive engagement in order to improve academic performance. Future implementation of creative activities should consider student motivations for engaging in these activities as the basis for their design and intentionally include a cognitive engagement component.

B4/P1004

Using molecular biology preprints to engage undergraduates in the scientific community and enhance their scientific literacy: evidence from a new curriculum on preprint peer review

G. McDowell[1], S. Fankhauser[2], M. Balgopal[3], **R. S. Lijek**[4]; [1]Lightoller, LLC, Chicago, IL, [2]Oxford College, Emory University, Oxford, GA, [3]Colorado State University, Fort Collins, CO, [4]Mount Holyoke College, South Hadley, MA

Science education focuses on how experiments are carried out and the knowledge generated by the resulting literature, but misses an opportunity to engage students in the critical validation process that translates one into the other - the peer review of scientific manuscripts. Peer review is integral to the scientific process and so we envision a paradigm shift that makes teaching peer review integral to science education (McDowell et al., MBOC, 2021). Explicit teaching about peer review unmasks part of STEM's "hidden curriculum": untaught knowledge that is required for success and which disproportionately hinders minoritized students. Few training opportunities exist in peer review and none are designed for or tested in undergraduates. With NSF support, we created and are evaluating a curriculum in which biology undergraduates learn about the importance and mechanisms of peer review, then write and publish their own reviews of manuscripts in prepublication ("preprints"). Preprints are widely available online for free throughout biology, and their use in molecular biology has exploded in recent years, making this curriculum broadly applicable. By having students authentically review works-in-progress created by practicing scientists, they meaningfully contribute to the scientific literature and community. Using COVID19 preprints also motivates students who might be otherwise disconnected by the pandemic to re-engage in a meaningful way. Our research asks: does this preprint peer review curriculum improve students' scientific literacy? Does it enhance students' sense of belonging in the scientific community? We tested these hypotheses using validated pre-post surveys (e.g. TOSLS, PITS) and thematic analysis of students' writing. Here, we present the first of three years of data collection at Mount Holyoke, a small liberal arts college for women and gender minorities. Ongoing work includes scale up of the curriculum at Colorado State and Emory Universities and dissemination of the resulting evidenced-based curriculum suitable for diverse settings (McDowell et al., Learned Publishing, 2022). Using this curriculum to enhance students' scientific literacy and sense of belonging in the scientific community has the potential to broaden participation and prepare students for success in the STEM workforce and create a scientifically-literate public.

B5/P1005

Fictional Case Study Effects Student Learning about Immune Cell Memory

K. M. Cooper; Molecular, Life, and Health Sciences, Loras College, Dubuque, IA.

In an immunology class there are many opportunities to connect basic cellular principles to diseases and medicine, making undergraduate students potentially more likely to care about and remember the concepts. However, finding medical case studies to teach basic immunological principles is challenging, as many are too complex for an introductory-level immunology class and more appropriate for graduate or medical students. A simple fictional case study was designed to actively engage students in discovering what hemolytic disease of the newborn is, how it can be prevented, and how the preventative treatment is based a general principle of immunological memory where naïve B cells do not activate if antibody is already present on the antigen they recognize. Students were given pretests, posttests, and surveys about their impressions of the case study and their learning. Data from two

different cohorts of students showed student interest and engagement, though the topic was still challenging for them to fully understand. Additionally, general ideas for writing approachable case studies related to the cell biology of the immune system are shared.

B6/P1006

Supporting Faculty in CURE Implementation: Resilience and Growth of the Genomics Education Partnership Community

A. L. Goodman[1], **M. S. Santisteban**[2], C. S. Silver Key[3], J. Siders[4], C. Reinke[5], W. Leung[6], S. Gehrke[7], L. K. Reed[8]; [1]Chemistry and Biochemistry, California Polytechnic State University, San Luis Obispo, CA, [2]University of North Carolina at Pembroke, Pembroke, NC, [3]North Carolina Central University, Durham, NC, [4]Ohio Northern University, Ada, OH, [5]Linfield University, McMinnville, OR, [6]Washington University in St. Louis, St. Louis, MO, [7]University of Washington, Seattle, WA, [8]The University of Alabama, Tuscaloosa, AL.

Early participation in undergraduate research promotes persistence in STEM and other positive student outcomes (Rodenbusch et al., 2017), yet Primarily Undergraduate Institutions (PUIs) often lack the resources required to provide broad access to research. The Genomics Education Partnership (GEP, https://thegep.org/) is a community of 261 faculty members from 215 institutions across the United States and its territories. The Partnership is dedicated to facilitating equity in undergraduate biology education by providing centralized resources to empower faculty to engage their students in experiential learning and Course-based Undergraduate Research Experiences (CUREs) in genomics and bioinformatics. In the past four years, our community has undergone substantial changes: a transition from centralized to distributed leadership, the development of focused growth efforts to recruit faculty from Minority Serving Institutions (MSIs) and Community Colleges (CCs), and a switch in modality from in-person to virtual New Member Training. To assess how these changes have impacted our community, we created surveys and interview protocols based on the study of other communities of practice in STEM education (Kezar and Gehrke, 2015), and used them to collect quantitative and qualitative data. **Outcomes:** Our community has grown from 118 to over 260 active members in the last two years. The rapid growth and transition to virtual communications have been augmented by the activities of regional nodes that hold in-person and online activities, such as student research symposiums, faculty meetings, and training for new members and teaching assistants. Preliminary analysis of the survey responses from 124 faculty (60% response rate at the time of survey) suggests that the GEP model serves a wide range of faculty — including those who were newly-trained and long-time members, those who seek innovative genomics curriculum, and those who focus on engaging students in genomics research projects. We are analyzing faculty implementation reports to characterize the patterns of CURE adoptions for faculty trained in different modalities and teaching at different types of institutions. **Broader Impacts:** Characterizing the development and functioning of a distributed faculty community supporting the transformation of STEM education practices can provide a model for other faculty communities focused on education reform. The GEP provides the opportunity for faculty and students at CCs, MSIs, and other PUIs to engage in scientific research and gain professional development. Supported by NSF IUSE-1915544 and NIH IPERT-R25GM130517.

B7/P1007

Case study exams decreased test anxiety in a general biology class

D. S. Alves[1], C. D. Kilgore[2]; [1]Biochemistry and Cellular and Molecular Biology, University of Tennessee, Knoxville, TN, [2]Teaching and Learning Innovation, University of Tennessee, Knoxville, TN.

Case studies are stories often used as an educational message and the purpose of this activity goes beyond just telling a history to students, it inspires and engages students to process the information and reflect in depth about the subject. In the present work, students from an introductory biology course (Bio160 at the University of Tennessee) were exposed to a case study in an innovative quiz format. Bio160 is a large size introductory class for major and non-major students, in which students often report negative emotions associated with perceived difficulty. Based on student feedback, the most common negative emotion reported was anxiety that often manifested during tests, exams and quizzes. Anxiety can also affect student retention, and in science classes, it can lead undergraduate students to leave their major (England et al., 2017). The main goal of our project is to understand the impact of using a case study exam on student test anxiety. The case study used in the present work was related to cell cycle (mitosis and meiosis). Students' knowledge in cell cycle was evaluated by using a quiz format that was delivered during the presented story. In order to address the possibility of students having anxiety from the exposure of an unknown test format, students were introduced to similar case studies twice before the exam. Student feedback indicated that the case study test format motivated them to learn something new about chromosomal/genetics sex definition and that they were inspired to think outside the box regarding the subject tested during the quiz. Finally, the results indicated that students experienced a significant decrease on test anxiety when exposed to this innovative test format.
References: England, B. J., Brigati, J. R., and Schussler, E. E. (2017). Student anxiety in introductory biology classrooms: Perceptions about active learning and persistence in the major. PLoS ONE, 12(8), e0182506.

What Do Biology Students Do When They Need Academic Help? An Examination of Student Help-Seeking Behaviors

S. N. Ewell[1], R. Dunk[1], A. Radocha[1], R. Youngblood[1], S. Ferdous[1], A. Chen[2], Y. Mehari[1], A. Peart[1], M. Seibenhener[1], C. J. Ballen[1]; [1]Auburn University, Auburn, AL, [2]University of California, Irvine, Irvine, CA.

Self-regulated learning behaviors have been identified as a key factor in facilitating STEM persistence (Park et al., 2019). Self-regulation is a predictor of student academic performance and encompasses a variety of skills including help-seeking behaviors (Karabenick & Dembo, 2011). Help-seeking is a self-regulated learning behavior that allows learners to acquire content knowledge and skills necessary for academic success (Micari & Calkins, 2021). However, due to various barriers, many students do not seek help when needed. Currently there is a lack of in-depth literature that holistically examines the academic help-seeking processes of undergraduate students enrolled in biology coursework. To characterize the help seeking processes of students enrolled in undergraduate biology courses, we distributed a voluntary survey across three lower-level biology courses and three upper-level biology courses during two semesters at two R1 universities that asked students to indicate their attitudes toward help-seeking and classroom factors that encourage student help-seeking (n=1,023). We found that across all courses, ~51.2% of students perceived that they needed help to understand course content. We then ran an EFA model which independently verified the existence of two factors in our

questionnaire data: the perceived benefits of help seeking, and avoidance of help seeking (Pajares et al., 2004). Quantitative analyses revealed several individual characteristics predicted students' perceptions of help-seeking. For example, mixed-model analyses indicated that STEM majors were more likely to seek help, and persons excluded because of their ethnicity or race (PEERs) were less likely to seek help. However, neither of these factors had an impact on the perceived benefits of help seeking, which varied based on the individual course. On average, students in some courses perceived benefits more than students in other courses in our study. Next, we coded open-ended responses using thematic analysis. We found that across all classes, students preferred to use informal sources of help (e.g., classmates). Finally, we found that the following instructor behaviors encouraged student help-seeking behavior: instructors who explicitly encouraged question asking, structured class time for questions, provided positive feedback to questions, and cultivated a positive classroom environment. Additionally, we found that large class sizes, perceived negative attitude of the instructor, and rapid coverage of course material all discouraged help-seeking. Together, these data allow for understanding of student help-seeking processes in large enrollment biology classes and provide intervention targets for students who may struggle with obtaining help when needed.

B9/P1009

Supporting the Social-Emotional Health of CAMP Program Students in STEM

S. W. Lee[1], S. Dingwall[2], **R. A. Cardullo**[2]; [1]University of California, Irvine, Irvine, CA, [2]University of California, Riverside, Riverside, CA.

Minoritized students find it challenging to be accepted in the science, technology, engineering, and mathematics (STEM) environm. Minoritized students are more likely to persist in STEM if they feel a sense of belonging. California Louis Stokes Alliance for Minority Participation (CAMP) is a program that aims to support and increase the number of minoritized STEM graduate students and professionals. CAMP exists at all nine undergraduate University of California (UC) campuses and at various California State Universities, California Community Colleges, independent colleges and universities, and national laboratories. CAMP support of students is multifaceted, including research opportunities, financial support, academic advising, career counseling, professional development workshops, graduate school admission and preparation, and social activities. A key component of the CAMP program is getting undergraduate students involved in faculty-mentored research. Trust in faculty research mentors is associated positively with increased motivation and career expectations in students. Across all nine undergraduate UC campuses, we investigated the social-emotional health (Co-Vitality survey) of CAMP students who were involved in research and its correlation with perceptions of trust in their faculty research mentor. Co-Vitality of CAMP students correlated moderately with trust in their faculty research mentor. There was no correlation between Co-Vitality of CAMP students and trust in their college. This study suggests that faculty research mentors represent a source of support for their students' social-emotional health.

B10/P1010

Socially Relevant University Biology Course for Non-majors

A. Campbell, A. McDonnell; Davidson College, Davidson College, NC

Although biology education researchers focus most of their attention on courses designed for biology majors, most university students are not science majors. These non-major students often must take one

science course in order to graduate. Courses required of non-majors often are referred to as general education (GenEd) requirements or institutional service courses. GenEd biology courses typically mirror the content of courses designed for majors but "softened" to reduce the stringency of the content. Rather than presenting non-majors with a survey of biology reminiscent of high school courses that pushed them away from science, we designed a topics course that connected socially relevant topics with biology. The course described here, *Biology For Life*, used two guiding principles. First, we chose topics inherently interesting to college students. Topics included weight regulation, artificial sweeteners, pandemics, vaccines, race and race-based medicine, sex determination, sleep, GMOs, marijuana, alcohol, and climate change. Second, we presented students with data taken from peer-reviewed publications so they could build analytical skills and quantitative literacy. We wanted students to develop skills and understanding that would serve them after college (for life) and not just enough to pass examinations. In addition, students learned about logical fallacies used in arguments and how to draw argument maps. These two tools reinforced the major lessons from each chapter and helped students improve their ability to distinguish valid from fallacious arguments. Formal and informal course evaluations underscored very strong student enthusiasm for the course. However, four students felt the course was overly political and biased. This and other criticisms have been addressed for the next iteration of the course. The course also included a laboratory component which focused on quantitative literacy and Microsoft Office proficiency to provide marketable skills students could use in their post-university careers. In its first iteration, the course was offered 100% online due to the pandemic though it will be taught in person whenever possible. The entire GenEd course will be published as a combined electronic textbook and lab manual to facilitate adoptions by others who teach online or in person.

B11/P1011

S-STEM Scholarship Program: Exploring the Effects of Psychosocial Factors on STEM Persistence at an HBCU.

C. Carter, M. Van Stry; Lane College, Jackson, TN.

Lane College, founded in 1882 by former slave Bishop Isaac Lane, has strong history of educating underserved, minority students through student-center approaches. The Lane College S-STEM program aims to increase the number of low-income students entering STEM fields by providing scholarships, co-curriculum and high impact program activities to support Lane College students majoring in biology, chemistry, computer science, mathematics, or physics. These activities include development and implementation of new first-year STEM courses, including CHE 110 Scientific Literacy and Critical Problem Solving and PHY 111 Galileo and the Church. We have successfully recruited 2 cohorts of S-STEM scholars who have participated in several project activities including bi-weekly cohort meetings, undergraduate research projects, community outreach, internships, mentoring, and professional development. For the research project, we are exploring the development of non-cognitive factors known to impact student persistence in STEM (Grit, Self-efficacy, Growth Mindset, etc.) as S-STEM scholars matriculate through the program. Our initial measures of Grit and Growth Mindset for cohort 1 do not show a significant difference between S-STEM scholars and the control group of academically talented Power of Potential scholars. However, we have experienced low student participation in surveys during the period of remote instruction in response to the COVID-19 pandemic. For cohort 2, we measured self-efficacy for students in cohort 2 using the self-efficacy formative questionnaire developed by Gaumer Erickson and colleagues. Our data for the five students cohort 2 who completed the survey show an average score of 80.8% for focus, 60.8% for steps, and overall 72.5%. These initial data suggest

that the students will benefit from targeted instruction aimed at developing growth mindset and self-efficacy.

B12/P1012

Using *C. elegans* to study novel RNA interference phenotypes to promote inquiry-based learning in an undergraduate Cell and Molecular Biology course

J. Sullivan-Brown, A. Durkan, C. Byrnes, E. Cooper, A. Hally, J. Sowa; West Chester University of Pennsylvania, West Chester, PA

Inquiry-based undergraduate laboratories are designed to introduce students to the excitement of making novel scientific discoveries and perform independent research. Our objectives were to provide undergraduates with opportunities to gain genuine experiences in contributing to fundamental scientific knowledge by characterizing novel RNAi phenotypes of relatively understudied genes in the worm *Caenorhabditis elegans*. In our efforts to create these experiences, we designed labs for an upper-level Cell and Molecular Biology course at a primarily undergraduate institution in which students characterized the RNAi phenotypes of the potential oncogene DCAF13 (DDB1 and CUL4 associated factor 13). We discovered that when *dcaf-13* is disrupted in *C. elegans*, the worms showed a significant effect to larval development as measured by determining overall length of worms at 48 hours of development. In addition, *dcaf-13*(RNAi) worms display either a failure or delay of reaching the L4 or adult stages. Our data also indicates that *dcaf-13*(RNAi) did not affect embryonic development in *C. elegans*; however, egg-laying was significantly decreased in *dcaf-13*(RNAi) worms suggesting a general role in fertility. We were able to publish this work in *microPublication Biology*, with student authors from the Cell and Molecular Biology course and continue to use this study as a platform for novel discoveries.

B13/P1013

Self-regulated learning skills are linked to academic success: is it all "wrapped" up in reflection?

A. Ratnayake, A. Bansal, N. Wong, T. Saseetharan, S. Prompiengchai, A. Jenne, J. Thiagavel, **A. Ashok**; University of Toronto-Scarborough, Toronto, ON, Canada

Metacognition is the process of accurately monitoring one's comprehension and study strategies to enable effective self-regulated learning (SRL). SRL promotes autonomy, and purpose, which are components of intrinsic motivation shown to drive academic achievement. Our goal was to use a student-partnered approach to investigate the value of reflective tools to hone metacognitive skill development in students. We hypothesized that by using tools that allow reflection and refinement of students' study strategies, we could promote SRL and academic success in a foundation biology course. Undergraduate students in a semester-long second-year biology course were provided with three reflection survey instruments at three critical time points. Each survey included prompts aimed to encourage students to devise a study plan, reflect on the effectiveness of their plan, and identify areas for improvement as they prepared for evaluations. Student responses were systematically analyzed using a qualitative data analysis approach and were correlated with their academic performance. Our study sought to investigate the role of metacognition, motivation, and behavior in student course performance by (i) identifying the most utilized self-regulated learning strategies in order to better support student learning in the future, (ii) investigating the role of reflection in enhancing metacognitive processing and academic performance, and (iii) understanding whether students created and/or

modified their study strategies as an outcome of self-regulation. Our results suggest that students were able to demonstrate metacognitive awareness, as they accurately reported on the effectiveness of the study strategies they employed throughout the semester and indicated a shift from passive to active reviewing techniques in future study planning. Students perceived the reflection instruments beneficial in identifying areas of improvement and developing long-term study habits. Students who found the instruments to be effective also demonstrated improved performance on course assessments, suggesting a strong correlation between metacognitive axes and academic performance. Finally, students reported using the resources provided (ie. tipsheets and videos) to create or modify study plans in preparation for the semester ahead; employing the resources in this manner was correlated with improved academic performance. We conclude that reflection plays a central role in promoting metacognitive development, which, through impacts on motivation and behavior, augments self-regulated learning and enhances academic performance. Our study supports the recommendation that systematic use of reflection tools can support student learning in foundation biology courses.

B14/P1014

Linking research in cell biology and genetics courses through a single research topic on ABCD1 overexpression

K. Kandl, J. Porterfield, L. Bowers, S. Fruehling, A. Walter, L. Listenberger; St Olaf College, Northfield, MN

Authentic mentored undergraduate research is known to improve student learning and engagement. Course-based undergraduate research experiences (CUREs) allow more students to participate in research early in their academic careers. However, a single semester of research embedded in a laboratory course may not be enough to support student engagement with a complex problem. We are expanding the CURE concept by linking research projects across two distinct yet interdependent courses required for the Biology major, Cell Biology and Intermediate Genetics. Each course enrolls 130-150 students per year and may be taken in either order. During the fall 2021 and spring 2022 iteration of our linked CURE model, students in Cell Biology and Intermediate Genetics courses studied the effect of overexpressing ABCD1, a peroxisomal long chain fatty acid transporter, on the expression of other genes in lipid metabolic pathways (Intermediate Genetics) and on cell growth, metabolism, and lipid storage (Cell Biology) in the freshwater ciliate, *Tetrahymena thermophila*. Results from the Laboratory Course Assessment Survey, show that students beginning in either course reported similar satisfaction in terms of collaboration, discovery and relevance, and iteration, suggesting that the linked CURE model is effective whether students' first introduction to the research topic is from a genetics or cell biology viewpoint. Students obtained meaningful results that they shared in a poster session, and these results are being used to drive additional independent research projects in our labs. As we implement this approach in all sections of Cell Biology and Intermediate Genetics, Biology majors will have a year-long research opportunity using multiple approaches to address a single question. We will present logistical considerations for implementation such as faculty buy-in and scheduling considerations for sharing of information between students in these courses. Importantly, this approach is adaptable to different questions and model organisms, providing a template for sustainable research opportunities.

B15/P1015

Promoting Student Engagement and Academic Success in Introductory Cell Biology by Utilizing a Concepts Enhancement Learning (C.E.L) Lounge

K. Baker, G. Weber, M. Gobbett; University of Indianapolis, Indianapolis, IN

In an effort to overcome student disengagement and underpreparedness, exacerbated by remote learning during the pandemic, a pilot program, the Concepts Enhancement Learning (C.E.L) Lounge, was implemented in Introductory Cell Biology. The goal of the C.E.L Lounge is to provide engaging activities that not only promote students' "hands-on, minds-on" learning but to develop their abilities to learn course content and adapt to traditional academic expectations. Students had a weekly opportunity to assess their understanding of course material by voluntarily attending the C.E.L. Lounge, completing the supplemental learning activity, and answering the associated questions. Activities included models, manipulatives, and images of cellular processes. Students were welcomed and encouraged to work together; as a result, students also engaged in peer instruction. Completion of C.E.L. Lounge activities was positively correlated with overall course grades. Furthermore, students' perceptions indicated that they felt the activities were not only engaging, but more importantly, increased their understanding of lecture material and helped them be better prepared for exams, thus promoting their overall academic success in the course.

B16/P1016

Design2Data CURE Biotechnology Students develop employable technician skills while Engaging in authentic research experiences

C. E. Rolle, K. Mennes, N. Campbell; Capital Community College, Hartford, CT

The Design2Data with β-Glucosidase CURE uses a crowdsourcing approach to engage undergraduate students in design-build-test experiments to functionally characterize the effects of single amino acid mutations. CUREs are a meaningful for students who would not otherwise engage in authentic research as a part of their biotechnician skills training. Students began the D2D CURE in a biotechnology course and continued as an independent research project. Target amino acids were identified in the protein structure using Foldit. Plasmids containing the mutants were generated using Kunkel mutagenesis. The recombinant proteins were expressed, purified, and their enzymatic activity characterized. None of the mutations impacted protein induction and expression. The enzymatic activity and thermostability of the mutants were evaluated. This data will contribute to the D2D database to address current predictive limitations of protein modeling software. Given that Capital Community College is a designated MSI and HSI, as well as over 70% female students, the addition of the D2D CURE to the Biotechnology AS Degree Program should contribute to the diversity of the STEM pipeline in the region.

Science Education: K-12

B17/P1017

A STEAM lesson plan diversifies middle school student conceptions of scientists

J. Gardiner[1], C. Meaders[2], S. Wynns[3], S. Nigam[4], J. Harris[5]; [1]Fox Chase Cancer Center, Philadelphia, PA, [2]Cell and Developmental Biology, University of San Diego, San Diego, CA, [3]Cabrillo National Monument, San Diego, CA, [4]University of California San Diego, San Diego, CA, [5]Xavier University, New Orleans, LA.

Role model interventions that are tied to place-based-learning and classroom curricula may be effective tools for promoting diversity in science, technology, engineering, and mathematics (STEM). To evaluate this premise, we developed a sixth-grade lesson plan that focused on teaching environmental conservation and highlighting diverse women in STEM. Our curricula used a three-touch educational model consisting of comic-based lesson plans, a local “field trip” to Cabrillo National Monument, trading cards featuring 19 diverse women scientists, and a conservation capstone poster presentation - all aligned to Next Generation Science Standards - to create a meaningful experiential and project-based curriculum. To evaluate the program, we used a mixed-methods, change over time model, including the Draw-a-Scientist test (DAST) to assess if student perceptions of scientists were altered from the curricula. Overall, thirty-three students completed the DAST before and after participation. We used inductive coding of student drawings and responses to questions about their drawings and coded for six types of scientist stereotypic features. We found that science stereotypes held by students decreased from an average of 3.03 (SD = 1.26) per pre-drawing to an average of 2.24 (SD =1.37) per post-drawing, and that this decrease was significant ($p = 0.008$). We conclude that by using innovative tools such as art and comics for STEM education/outreach that feature characters representing a diverse array of scientists with intersectional identities, educators can help shift student perceptions on who can be a scientist, potentially increasing diversity in STEM fields.

B18/P1018

Share Your Expertise and Enthusiasm with Teachers: Organize a Workshop for Teachers to Build Inexpensive Microscopes for Classrooms

B. Goldstein; University of North Carolina at Chapel Hill, Chapel Hill, NC.

To get low-cost microscopes in front of kids and teachers, I've been running microscope-building workshops for elementary school teachers. In this poster, I’ll share what I do so that others can duplicate and/or build upon what I’m doing. I use a modified version of Kenji Yoshino's microscope design, which he described in an Instructable entitled "$10 Smartphone to digital microscope conversion!" This is a simple and clever design for a microscope that takes advantage of ubiquitous smartphone cameras. The microscopes are mostly transparent, making their inner workings obvious to teachers and students. And all of the parts are readily available from hardware stores or online, so teachers or students can make more anytime if they wish. Based on feedback from teachers, I enlarged Kenji's design to accommodate iPads and other tablets, which are available in many elementary schools, and I've made other minor improvements. Teachers have reported back that groups of students interact with each other around each microscope as they look at the smartphone or tablet screen together — a big improvement over microscopes in which students might see only their own eyelashes, and in which only each student would know what they saw. For the workshops, I prepare enough materials for each teacher to build their own microscope to keep in their classroom. A workshop with about a dozen or

more teachers can equip a school with a complete set to move from classroom to classroom. Most of the workshops last 90 minutes, during which three things happen: (1) the teachers assemble the microscopes, (2) they develop expertise using the microscopes as they take pictures of things they brought with them, and they collect images to share (see image galleries at www.diymicroscopes.org), and (3) teachers brainstorm about how they'll use the microscopes to best match their curriculum needs and students' interests. My current work includes bringing workshops to high poverty school districts in North Carolina and to statewide teachers conferences, and working collaboratively to assess outcomes. At this poster there will be some of the microscopes for anyone to try, and I'll share a protocol that you can use to get started running your own workshops with teachers at local schools. And I'll be happy to talk with people about collaborating or helping you get started running workshops on your own.

B19/P1019

Engaging high school students in summer research with cell biology and environmental science connections

E. L. Behnfeldt, S. Fromherz; Biology, Saginaw Valley State University, Univ Ctr, MI.

Summer research for high school students can foster interest in science and STEM careers. However, the pre-requisite background needed for cell biology research, and distractions of summer may challenge sustained student interest. As part of a broader program at Saginaw Valley State University, Michigan, a regional public primarily undergraduate university serving a high proportion of students from rural and underserved backgrounds, we developed and, in the summer of 2021, implemented research projects for four area high school students in a mentored team setting. The team consisted of two high school teachers, two undergraduates and an SVSU professor team leader. Projects broadly centered on plastic waste, a topic area likely of high relevance in students' daily lives. We bridged from environmental science to cell biology with experiments on the impacts of microplastics on the phagocytic pathway in a model unicellular ciliate, *Tetrahymena pyriformis*. Over the course of 6 weeks, students collected and studied local aquatic microbiota, helped develop and carry out authentic research projects in *Tetrahymena*, and prepared and presented research posters for a wider community audience. We used microscopy workstations equipped with large screen monitors and video cameras, as well as dyed polystyrene beads, to readily capture and quantitate data, and to easily share real-time microscopic images with the larger group. Initially we used pulse-chase experiments to introduce methods before helping students to develop and carry out authentic and feasible projects. For example, one student quantified vacuole size as a function of microplastic size. Qualitatively, we observed significant learning gains by the students in research skills such as experimental design and analysis, microscopy, math, teamwork, and communication. Furthermore, the group experience benefited mentor team members in multiple ways. We will describe the structure and benefits of the mentored team structure, microscopy workstations, exercises to support student growth and confidence in cell biology research, and representative projects and data. Our results suggest that summer research projects connecting cell biology with the environment, carried out in a small group setting with diverse mentors, can provide positive learning experiences for high school students and may foster careers in STEM.

Gaining STEAM!: Illuminating Research Through Art

J. Gardiner[1], K. Tran[2], K. Montgomery[3]; [1]Fox Chase Cancer Center, Philadelphia, PA, [2]University of Pennsylvania, Philadelphia, PA, [3]University of California San Francisco, San Francisco, CA.

Public access and exposure to scientific research is limited due to both restrictive paywalls and technical language written for specialists. While effectively communicating discoveries to non-specialists is imperative, it is no trivial task. Thus, **developing alternative approaches to disseminate discoveries to non-specialist audiences is essential to ensure broader populations can actively engage in scientific discourse.** The combination of art and storytelling in comics break down complex concepts while simultaneously providing an engaging medium. When applied to science, this makes the subject more approachable, memorable, and enjoyable. **To this end, we developed** a community-based science communication (SciComm) project, "*Gaining STEAM!"* which addresses two hurdles within science engagement and communication: 1) providing SciComm training for scientists to engage with non-experts and 2) facilitate discourse between scientists and the community about scientific research. **This was accomplished through**: developing workshops for scientists on effective science communication through storytelling and comics, collaborations with local artists to create comic books based on the scientist's research, and a public comics showcase displayed through posters. Surveys distributed at the *Gaining STEAM!* showcase revealed that 70% of non-UW-Madison affiliates were unaware of university sponsored research. Strikingly, 55% of UW-Madison affiliates were also unaware of research projects conducted at their university. **100% of individuals surveyed** indicated that the use of comics improved their comprehension of the scientist's research. **Collectively, these findings support the use of comics as a tool for improved science communication and public engagement with STEM.**

A SEPA partnership to enhance middle school STEM education

R. Sloboda[1], M. Tine[2], V. May[3], A. Skinner[4], L. Foster-Johnson[5], M. Fenzel[6], K. Price[6]; [1]Biological Sciences, Dartmouth College, Hanover, NH, [2]Sociology, Dartmouth College, Hanover, NH, [3]Thayer School of Engineering, Hanover, NH, [4]Guarini School of Graduate and Advanced Studies, Hanover, NH, [5]Geisel School of Medicine, Hanover, NH, [6]Montshire Museum of Science, Norwich, VT.

Providing young students with a solid understanding of science and the scientific process through their exposure to scientific thought and analysis is crucial for their life-long science comprehension and its relevance to the world around them. Loss of interest in learning STEM and perhaps having a future career in STEM has been shown to begin in the middle school years and is much more acute in low-income rural communities where there are few resources, such as equipment, teacher support, and collegial interaction. Our SEPA project involves Dartmouth faculty, graduate students, and science education experts from the Montshire Museum of Science working with middle school science teachers to co-develop hands-on, NGSS-aligned, science units that 6th-8th grade teachers in low-income rural communities can use to enhance the STEM engagement and learning of their students. At this point in our five-year project, we have worked with 6th and 7th grade teachers at four under-resourced schools in VT and NH. Our poster provides links to the curricular units we have developed, which are freely available to any teacher interested in using them. Initial assessments of the impact of these units on those involved indicate the project has had positive effects on several groups. Teachers reported enhanced self-confidence when teaching science, more confidence in the application of NGSS to their

classes, and more confidence in the inclusion of engineering design in developing hands on, instructional activities for their students. Similarly, the graduate students enhanced their science outreach skills and improved their self-efficacy. However, after engagement with the units we developed, the impact on the STEM attitudes of students in our 6th and 7th grade target classes was mixed. Students who expressed an interest in science at the start of the school year sustained a positive attitude towards STEM, but STEM attitudes remained low for those students who initially expressed less interest in science. Our results thus far suggest that interventions in middle school may be ineffective, because by the time students have reached middle school their level of interest in science as a field of study and as a career path may have already been fixed. Thus, efforts to impact positively the level of interest middle school students have for STEM needs to begin earlier, e. g. when they are in the elementary grades. Our work is supported by a Science Education Partnership Award (SEPA) from NIGMS of the NIH.

Science Education: Graduate and Medical School

B22/P1022

Evidence that Video Didactic Preparation can Augment Problem Based Learning in Medical Education

K. L. Hamilton[1], P. Horneffer[2], T. P. Stein[3], G. S. Goldberg[3]; [1]Georgetown University, Washington, DC, [2]All American Institute of Medical Sciences, St Elizabeth, JAMAICA, [3]Rowan University, Stratford, NJ.

Problem based learning (PBL) utilizes a self-directed strategy. Group participation is needed for this process to succeed. Students without a background in biology or medicine can feel overwhelmed by the complexity of the subject matter and unable to participate in the group learning process. We incorporated curated educational videos in the PBL curriculum to help address this situation. First year medical students participated in this study in the form of a typical PBL session. They were then assessed on basic and clinical science knowledge and their learning experience. Student basic science and clinical knowledge were similar between the experimental and control groups. However, the experimental group scored 13% higher in their learning experience, and 400% higher in their perception of feeling prepared and participating in the group PBL experience with $p<0.05$ by t-test ($n=13$). Results from this study indicate that videos can be utilized to enhance the PBL process.

Communicating scientific concepts through art

B. E. Mierzwa[1,2]; [1]Ludwig Institute for Cancer Research, San Diego, CA, [2]Department of Cellular and Molecular Medicine, University of California, San Diego, CA.

Creativity is an integral part of both science and art, and using it to combine these two seemingly different disciplines creates unique and effective ways to communicate scientific information, both inside and outside the scientific community. Along my classical academic career path, I have been exploring the visual aspect of science communication using hand-drawn illustrations, science fashion, and interactive media. My drawings aim to convey complex biological concepts using both abstract imagery and real scientific data. Each illustration requires breaking down the essence of scientific findings and translating them into aesthetic visuals using metaphors that describe complex biological processes in intuitive ways. This form of visualization provides a powerful tool to facilitate communication between researchers from diverse fields, spark fascination and curiosity for science, as well as inspire our next generation of scientists. Here, I will share my journey towards combining science

and art, highlight the impact of artistic practices on my own research and communication, and discuss avenues for scientists to explore this emerging field.

B24/P1024

Evaluating the feasibility, utility, and impact of engaging in mentorship assessment to improve doctoral mentoring relationships

H. N. Fedesco, **E. L. Dolan**, E. Kraner; Biochemistry & Molecular Biology, University of Georgia, Athens, GA.

A doctoral student's relationship with their research advisor is thought to be the most influential factor in the quality and success of their training experience, but these relationships are not always positive. We hypothesize that doctoral mentoring relationships can be enhanced by improving student-advisor communication. Communication scholars have identified a set of behaviors used in close relationships, called relational maintenance strategies, which help to sustain or increase relational quality. Examples include being open and positive about the relationship, which can enhance relationship satisfaction, commitment, and trust. Furthermore, research on mentoring shows that, when relationship quality is high, mentees are more likely to persist and succeed. With this in mind, we sought to create a mentoring assessment structure that would foster openness and positivity in student-advisor relationships. We developed a survey based on established measures of mentoring support, administered the survey to student-advisor dyads, and provided a report to each dyad along with tailored feedback and talking points. We studied the experiences of students and advisors as they completed the process to assess the feasibility, utility, and impact of engaging in mentorship assessment. First, we recruited 12 life science doctoral student-advisor pairs, who completed the survey and received a report. Then we interviewed a subset of them to understand their experiences and gather feedback for improvement. We revised and repeated the survey and reporting process with new pairs and conducted additional interviews, including interviewing 11 international students from 7 countries to gain insight into cultural issues that may influence whether and how students engage in mentorship assessment. We then conducted qualitative content analysis of the interviews to describe student and advisor experiences with and outcomes from the mentorship assessment. Students and advisors reported that they were able to send relational maintenance messages. International students also had positive reactions, indicating comfort with the process. Students and advisors both noted relationship improvements such as gaining new insights, improving communication, and more openly discussing needs. Students noted positive outcomes such as greater accountability, a more manageable workload, and improved clarity about expectations. Advisors reported that they felt validated about their mentoring efforts. Students and advisors reported only a few neutral/negative outcomes, largely related to the time and effort spent completing the survey.

B25/P1025

Investigating the Relationship Between Metacognitive Awareness and Metacognitive Accuracy in Introductory Biology Students

J. Wollesen, M. Aranda; SOUTHERN ILLINOIS UNIVERSITY EDWARDSVILLE, Edwardsville, IL

Introductory biology courses are often difficult for students because they require students to have metacognitive awareness, which is the ability to monitor one's learning. Perceptions of learning are used to predict performance on tasks, which demonstrates metacognitive accuracy. Higher awareness is

thought to correlate with higher accuracy; however, previous studies examining this relationship have been inconclusive. We hypothesized that that these inconsistent findings are due to additional variables, such as mindset and locus of control. It is crucial to understand the relationships between these variables because they can influence student success by helping students develop self-regulatory skills. Three research questions guide this study: 1. To what extent does metacognitive awareness correlate with metacognitive accuracy and exam scores? 2. To what extent do mindset or locus of control affect the relationship between metacognitive accuracy and exam scores? 3. To what extent do measures of awareness, mindset, locus of control, or accuracy change after students take exam 1? To measure these variables, students completed a survey before and after their first exam. Accuracy was measured comparing predicted to earned exam scores. We did not find the expected correlations between metacognitive awareness and metacognitive accuracy or exam scores. We did, however, find correlations to be present between metacognitive awareness, mindset, and locus of control. No significant difference was observed in responses collected before and after the first exam. Further analyses of these data will examine possible differences in relationships among variables between different groups of students, such as high, mid, and low performers. We also plan to examine patterns of study strategy use among students and compare these to measured levels of metacognitive awareness and accuracy. This study sought to further investigate the relationship between metacognitive awareness and metacognitive accuracy by examining two additional student characteristics: mindset and locus of control. These components, along with metacognitive skills such as awareness and accuracy, can impact student success. We believe this information could inform teaching practices by allowing instructors to identify and assist students in developing self-regulatory skills.

Lessons learned from teaching science virtually to medical and graduate students during the COVID-19 pandemic

S. B. Lovitch[1], A. Jambhekar[2]; [1]Brigham and Women's Hospital, Boston, MA, [2]Harvard Medical School, Boston, MA

At the onset of the COVID-19 pandemic, science educators at all levels were asked to rapidly pivot from in-person to virtual teaching and adapt their curricular materials to a virtual format, often with little to no experience or guidance. While improving conditions have since allowed for resumption of in-person instruction, many institutions have elected to retain elements of virtual or hybrid instruction. Therefore, review of the lessons learned from the virtual education experience of 2020-21 is warranted, in order to identify effective tools and approaches, and to recognize potential pitfalls and consider strategies to avoid them. We reviewed our experience teaching virtually in three courses with distinct learner populations and educational goals, based on analysis of anonymized student evaluation data and comments as well as personal experience. The courses analyzed are *Foundations of Medicine*, a course for first-year medical and dental students covering basic science content; *Developing and Communicating Scientific Investigations*, a course for first-year PhD students in Systems, Synthetic, and Quantitative Biology; and *Pathology of Human Disease*, a course for second- and third-year PhD students in the Leder Program in Human Biology and Translational Medicine (a translational science-focused track open to students in various PhD programs). Several virtual education strategies were particularly effective and well-received by the students, including use of polling and interactive annotation; use of the chat function in Zoom as a non-disruptive venue for asking questions and providing mutual support; and use of breakout groups where students could easily share electronic

materials, including those generated during the course of the discussion. The most frequently encountered pitfalls were inability to complete sessions within their allotted time; to monitor multiple small-group discussions simultaneously; to practice and evaluate oral presentation skills; and to identify struggling students due to lack of non-verbal cues, exacerbated by students' reluctance to activate video. Ultimately, virtual education proved to be an effective, but intrinsically limited, venue for conveying scientific content to medical and graduate students, and could be significantly improved by applying the lessons learned from the COVID experience.

Imaging Technologies, Single Molecule Imaging, and Super-resolution

Label-free morphological and biochemical characterization of pancreatic secretory cells

V. Loconte[1], A. Deshmukh[2], J. Cuala[2], B. Vanslembrouck[1], K. Chang[2], K. White[2]; [1]Dept of Anatomy, University of California, San Francisco, San Francisco, CA, [2]University of Southern California, Los Angeles, CA.

The dysfunction of α and β cells in the islet of Langerhans can lead to different types of diabetes1. The maintenance of the cell well-being is usually accompanied by rearrangements in the cellular ultrastructure, which can alter intracellular connectivity and cell functional activity2. High-resolution techniques such as electron and fluorescent microscopy have been able to distinguish single components in the islets; however, both methods require extensive cell manipulation to reconstruct the whole three-dimensional (3D) cellular architecture3,4. To address this challenge, we used a high-throughput label-free approach, which allows us to recognize α and β cells from mouse islets based on their subcellular features using soft X-ray tomography (SXT)5. SXT captured the 3D ultrastructural reorganization of a single cell without staining and slicing, preserving high spatial resolution (50 nm) and short time of collection (<10 min)6. For both mouse α and β cells, we mapped cell, vesicle, and nuclear volume, as well as vesicle diameter, and vesicle X-ray absorption, and determined univocal features that can be used to identify cell types without the need of additional labels. We identified significant larger cell volume and vesicle diameter for β cells as compared to α cells, whereas we observed higher vesicle molecular density for α cells. All together, these features provided hallmarks that can be used to distinguish among the two cell types in the mouse islets and across different species. Finally, we were able to define structural heterogeneity in both α and β cells, showing different cell subpopulations. Collectively, our method can be applied to systems that require low levels of manipulation and high resolution, and allows to map and quantitatively describe cellular phenotypes and their impact in healthy and diseased conditions. Laboratory Cryo Soft X-ray Tomography for 3D Imaging of Whole Cells

K. Fahy[1], P. Sheridan[1], F. O'Reilly[2], **T. McEnroe**[1], W. Fyans[1]; [1]SiriusXT, Dublin, IRELAND, [2]UCD Dublin, Dublin, IRELAND.

Analysis of three-dimensional biological cell samples is critical for understanding the mechanisms of viral disease and for the development of novel therapeutics. Soft X-ray microscopy (SXM) is the unique technology that can image whole intact cells in 3D under normal and pathological conditions without labelling or fixation, at high throughput and spatial resolution [1-4]. The main challenge of SXM is that the photonic illumination required for imaging has heretofore only been available at synchrotron labs [5] and access is limited. SiriusXT has developed a lab-scale SXM for fast and inexpensive three-dimensional imaging of whole cells that can be readily performed in a laboratory. The capabilities of this compact imaging device, combined with complementary light and electron microscopy approaches, is currently being demonstrated through a series of virology use cases to generate new scientific knowledge on the viral life cycle and host cell response to viral infection [6]. Our studies will allow demonstration of the benefits of the lab-based system relative to both synchrotron based SXM as well as other imaging modalities. However, the most comprehensive view of the complex structure of cells is unlikely to come from a single microscope. We will facilitate correlation of SXM with light and electron microscopy by integration of a fluorescence microscope, dual modality of sample presenting scheme, including EM grids, and an automatic data analysis pipeline. In this paper, we will present tomography data from whole single cells, and discuss the sample preparation and data analysis workflows employed by the microscope.

Figure 1: Slice through a reconstructed huh-7.5 cell cryo preserved and imaged in the laboratory soft x-ray microscope. Whole cell imaging with natural contrast allows the immediate identification of many cellular organelles.

Development of POLArIS, a versatile probe for multi-color/multi-target orientation imaging in living cells

K. Sato[1], N. Nakai-Kadowaki[1], A. Sugizaki[1], K. Chiba[2], K. Saito[1], M. Kawagishi[1], Y. Tomabechi[3], S. B. Mehta[4,5], H. Ishii[4,6], N. Sakai[3,7], H. Ka[1], M. Shirouzu[3], T. Tani[4,8], S. Terada[1]; [1]Tokyo Medical and Dental University, Tokyo, JAPAN, [2]Ochanomizu University, Tokyo, JAPAN, [3]RIKEN Center for Biosystems Dynamics Research, Yokohama, JAPAN, [4]Marine Biological Laboratory, Woods Hole, MA, [5](present address) Chan Zuckerberg Biohub, San Francisco, CA, [6](present address) National Institute for Physiological Sciences (NIPS), National Institutes of Natural Sciences, Okazaki, JAPAN, [7](present address) RIKEN SPring-8 Center, Sayo-gun, JAPAN, [8]National Institute of Advanced Industrial Science and Technology (AIST), Ikeda, JAPAN.

Monitoring the orientation of biological molecules in living cells is a key approach to understanding the mechanisms of the emergence/dissolution of molecular architectures. Fluorescence polarization microscopy (FPM) can visualize the dipole orientation of fluorescent molecules and has been used for analyzing the architectural dynamics of biomolecules. To monitor the orientation of molecules of interest using FPM, they need to be labeled with fluorophores in a sterically constrained manner so that the fluorophores do not freely rotate. Recently, we reported a versatile probe for such labeling using fluorescent proteins, POLArIS (Probe for Orientation and Localization Assessment, recognizing specific Intracellular Structures of interest) (PNAS 2021). Original POLArIS is a recombinant binder affimer rigidly connected to a green fluorescent protein mutant and can target specific biomolecules of interest by combining with evolutionaly molecular engineering. We have later developed nanobody-based POLArIS, which is compatible with animal immune libraries, with color variations of cyan/green/yellow/red fluorescent proteins, enabling multi-color orientation imaging for multiple targets (BBRC 2021). As an initial test case of POLArIS, we developed POLArIS^{act}, which specifically binds to F-actin in living cells. Localization analysis using fluorescently labeled phalloidin in fixed cells and co-expression with other genetically encoded F-actin probes indicated that POLArIS^{act} is an excellent F-actin probe. FPM analysis confirmed that POLArIS^{act} can monitor the orientation of F-actin both *in vitro* and in living cells. We microinjected the mRNA of POLArIS^{act} into starfish oocytes and observed the actin dynamics during early developmental processes using FPM. We found that actin filaments radially extend from centrosomes during mitosis in early embryos. Detailed microscopic observation revealed that the distribution of the radially extended actin filaments is very similar to that of astral microtubules. We named this actin-based structure FLARE (FLuffy And Radial actin-aster associated with mitosis in Embryo).

Paired-objectives photon enhancement (POPE) Microscopy

M. Tingey[1], S. Junod[1], B. Zhang[1], A. Ruba[2], W. Yang[1]; [1]Biology, Temple University, Philadelphia, PA, [2]School of Engineering and Applied Science, University of Pennsylvania, Philadelphia, PA.

The first two authors contributed equally to this work.

Fluorescence microscopy techniques are widely employed for the visualization, localization, and observation of structures and dynamics in biological samples. In order to obtain optimal image resolution, collecting the maximum number of photons from each fluorophore is essential. Historically, researchers have addressed this need by increasing the excitation energy, engineering higher numerical aperture (NA) objectives, improving the quantum yield of fluorophores, and/or escalating the quantum efficiency of detectors. While these approaches have led to great advances in the field of microscopy, they cannot proceed linearly in a limitless manner. We noticed that more than half of photons are lost as fluorophores emit in a direction other than the objective of either an upright or inverted microscope. To collect these lost photons, we have developed a new system called paired-objectives photon enhancement (POPE) microscopy to increase photon capture of a fluorophore by nearly two-fold. This system captures these lost photons by aligning an 8f optical system and mirror directly opposite the lower objective of an inverted microscope, thereby reflecting more emitted fluorescence back through the lower objective and into the detector. Through the additive effect of the initial fluorescence and the reflected fluorescence combining, the number of photons captured nearly doubles. This improved photon budget allows a microscopy imaging system to have better optical resolution, higher sensitivity, and/or faster detection speed. This new technique has been demonstrated in confocal light microscopy,

epifluorescence microscopy, and super-resolution light microscopy; and can, in theory, be applied in a modular fashion to any and all other fluorescence microscopy methods.

B32/P1031

Multiplexed spatiotemporal tracking of RNA dynamics in live mammalian cells using fluorescence lifetime imaging microscopy

N. Sarfraz, E. Braselmann; Chemistry, Georgetown University, Washington, DC.

RNA localization, biomolecular association, and dynamics are all linked and closely influence RNA function.[1] For quantitative insight into these processes, it is essential to visualize RNAs live and track responses to cellular perturbations.[2] In this study, we established FLIM for live RNA tracking. Our genetically encoded RNA FLIM sensor builds upon the Riboglow platform.[3,4] Riboglow consists of a small molecule fluorescent probe that binds a genetically encoded RNA tag and changes fluorescence upon binding.[3,4] This prompted us to hypothesize that fluorescence changes in the probe could lead to significant changes in fluorescence lifetime (τ). We assessed the τ of the probe in live cells in the presence vs. absence of tagged RNA. As hypothesized, we observed differences in τ that lead to substantial fluorescence contrast between cells with vs. without RNA. The cellular contrast for FLIM measurements was robust and superior in direct comparison with fluorescence intensity-based contrasting.[4] We have demonstrated tagging of coding and non-coding RNAs in mammalian cells. Importantly, the RNA tags in FLIM-Riboglow may be varied to yield unique fluorescence lifetimes in the same laser channel. We successfully identified two different RNAs, enabling quantitative assessment of spatiotemporal RNA dynamics live.[4] Recently, we have expanded the platform to include another tag, producing a significantly different lifetime thus expanding our tracking capabilities to three RNAs for multiplexed RNA detection. Current efforts are underway to expand multi-parameter RNA tracking capabilities and establish physiologically relevant RNA tracking in diverse mammalian model systems.

B33/P1032

A novel sub-precision detection method (MCS-DETECT) identifies shape complexity of mitochondria-ER contacts (MERCs) in 3D STED super-resolution microscopy

B. Cardoen[1], K. Vandevoorde[2], G. Gao[2], P. Alan[2], W. Liu[2], A. Vogl[2], G. Hamarneh[1], I. R. Nabi[2,3]; [1]School of Computing Science, Simon Fraser University, Burnaby, BC, CANADA, [2]Life Sciences Institute, Department of Cellular and Physiological Sciences, University Of British Columbia, Vancouver, BC, CANADA, [3]School of Biomedical Engineering, University Of British Columbia, Vancouver, BC, CANADA.

With the inter-organelle distance of mitochondria-ER contacts (MERCs) below the resolution of 3D fluorescence and super-resolution microscopy, identification and morphological analysis of MERCs is restricted. We illustrate how a novel Membrane Contact Site detection algorithm (MCS-DETECT) is able to accurately reconstruct sub-precision MERCs from 3D STED super-resolution microscopy and describe their morphological diversity. Our approach reconstructs the sub-precision MERC interface using a windowed Spearman correlation of the 2nd intensity differential, making the approach robust against inherent fluctuations in fluorescence markers across channels and datasets. To enable quantitative analysis, we compute shape features of the produced contacts, as well as a confidence map to report on reliability of contact detection. We validate MCS-DETECT by a parallel electron microscopy (EM) study of elongated ribosome- studded MERCs (riboMERCs), present in HT-1080 but not COS-7 cells. MCS-DETECT reconstructs large, tubular riboMERCs selectively in HT-1080 cells and identifies morphological

differences between riboMERCs and large contacts induced by expression of an ER-mitochondria linker in COS-7 cells. MCS-DETECT registers decreased large riboMERCs in Gp78 knockout HT-1080 cells, and increased riboMERCs, that retain the elongated, tubular morphology, upon overexpression in COS-7 cells of wild-type Gp78 but not a Ring finger mutant Gp78 lacking ubiquitin ligase activity. Gp78-dependent riboMERCs present complex tubular shapes that intercalate between and contact multiple mitochondria. MCS-DETECT applied to whole cell 3D super-resolution microscopy therefore shows that Gp78 ubiquitin ligase activity regulates the formation of novel tubular shaped riboMERCs.

MINFLUX facilitates the analysis of macromolecular complexes via light microscopy

C. A. Wurm, M. Velasco, K. Bahlmann; Abberior Instruments America, Jupiter, FL.

Cells assemble macromolecular complexes into scaffoldings that serve as substrates for catalytic processes. Although dimension of these scaffolds varies, their investigation is often hampered by the available resolution of the applied (light) microscopes and/or the molecular specificity of the available labeling technology.
MINFLUX nanoscopy is capable of resolving structures as small as 1 - 2 nm [1]. For this, single fluorophores are localized by reading out their fluorescence signal at pre-defined positions in its vicinity. 3D MINFLUX nanoscopy allows researchers to investigate the arrangement of molecules in biological samples with a localization precision < 3 nm in all three dimensions. By combining MINFLUX nanoscopy with conventional confocal microscopy, structures of interest can be identified using reference marker proteins whereupon the protein of interest is analyzed at a molecular level. Colocalization studies can take advantage of the resolution in the nanometer range using two-color MINFLUX imaging.
At the basis of a current research project, we will exemplify the possibilities of the current MINFLUX nanoscopy and how MINFLUX can be applied to overcome the limitations of alternative technologies.

Molecular architecture of clathrin plaques and pits defined by super-resolution network analysis (SuperResNET)

I. Khater[1], **T. Wong**[2], C. Hallgrimsson[1], S. Moparthi[3], S. Vassilopoulos[4], G. Hamarneh[1], I. Nabi[2]; [1]Simon Fraser University, Vancouver, BC, CANADA, [2]University of British Columbia, Vancouver, BC, CANADA, [3]Sorbonne Universite, Paris, FRANCE, [4]Sorbonne Université, Paris, FRANCE.

SuperResNET is an integrated software that performs a set of processing operations to quantify and visualize 3D point clouds generated by single-molecule localization microscopy (SMLM) data. SuperResNET is equipped with computational modules to correct for multiple-blinking of single fluorophores, filter-out noisy events, segment clusters of localizations, extract various cluster features, and apply machine learning-based grouping to identify the biological clusters. SuperResNET was previously applied to caveolin-1 labeled cells, identifying the structure of caveolae and three distinct non-caveolar scaffolds. Here, application of SuperResNET to clathrin labeled HeLa cells identifies three groups: Class I: larger plaques; Class II: intermediate sized hollow pits and vesicles; and Class III: smaller oligomers. Cos7 cells present reduced number of plaques and treatment with the clathrin endocytosis inhibitor pitstop decreases plaque number in HeLa cells. Consistently, large clathrin plaques are not

observed by platinum replica electron microscopy in pitstop-treated cells. A second grouping of Class II pits based on shape features distinguishes larger, spherical and more hollow structures from smaller, elongated and more compact structures that accumulate upon pitstop treatment. Association of clathrin pits with plaques together with loss of plaques upon pitstop inhibition of clathrin endocytosis supports clathrin plaques as a reservoir for clathrin-dependent endocytosis. SuperResNET 2D and 3D visualization tools help detail the structural transition of clathrin budding from flat lattices into curved pits representing a powerful tool for analysis of the molecular architecture of subcellular, macromolecular organelles and structures.

High resolution imaging reveals microclustering and large-scale reorganization of Fcγ receptors during Rituximab-mediated phagocytosis of B lymphoma cells

S. Jo[1], **B. L. Scott**[2], N. P. D. Nurmalasari[2], B. R. Fischer[1], Y. M. Loyd[2], R. B. Anderson, III[2], A. D. Hoppe[1]; [1]Chemistry and Biochemistry, South Dakota State University, Brookings, SD, [2]Nanoscience and Biomedical Engineering, South Dakota Mines, Rapid City, SD.

Antibody dependent cellular phagocytosis (ADCP) is an important effector mechanism by which professional phagocytes remove infected or immunologically aberrant cells during adaptive immune responses or treatment with therapeutic antibodies. ADCP has largely been studied using small and rigid particles such as silica beads that display immobile antigens. However, infected host and malignant cells are large and most transmembrane protein antigens on their surface are mobile or transiently confined by their actin cytoskeleton. Here, we studied ADCP of B lymphoma cells by macrophages using high resolution imaging to visualize the clustering of Rituximab (anti-CD20) with respect to the macrophage membrane and recruitment of Spleen Tyrosine Kinase (SYK). We found that Fcγ receptors (FcγR) on the macrophage surface initially form microclusters, recruit SYK, and undergo large-scale reorganizations at the phagocytic synapse prior to and during engulfment of the target cell. Using CRISPR-Cas9, we created SYK knockout macrophages that were unable to complete phagocytosis. Instead, Rituximab accumulated in large patches at the base of forming phagosomes that were subsequently internalized by trogocytosis and the phagocytic cup receded. This result is consistent with SYK kinase activity being necessary to trigger redistribution of Rituximab-FcγR during engulfment thereby preventing antigenic modulation of the target. To manipulate antigen mobility, we presented IgG on supported lipid bilayers (SLB) with different lipid compositions to generate either fluid or immobile bilayers. SLB-coated beads with mobile bilayers produced more total tyrosine- and SYK- phosphorylation during internalization than immobile bilayers indicating that microcluster rearrangement enhances FcγR signal amplification. Finally, using CRISPR knockouts and drug inhibition, we found that FcγR microcluster reorganization during frustrated phagocytosis requires the WAVE2 complex and Arp2/3 in addition to SYK. Taken together, we conclude that FcγR microclustering and antigen mobility promotes FcγR-SYK signaling and the reorganization of these microclusters is important for minimizing antigen modulation and promoting successful ADCP.

De novo spatial proteomic profiling of immune synapses using a machine learning-guided microscope

Y. Liu, **W. Chong**, C. Huang, Y. Lin, Y. Chen, C. Cheung, H. Chang, C. Chung, C. Chang, J. Liao; Syncell Inc., Taipei, TAIWAN.

The spatial proteome of the immune synapse (IS) between a target cell and a lymphocyte provides valuable insights for mechanistic studies in immuno-oncology and therapeutic applications. Unfortunately, the low abundance of IS and the lack of an absolute IS marker for IS enrichment before mass spectrometric (MS) analysis create barriers for an efficient IS proteomic profiling. Here, we made use of Microscoop^{TM}, an integrated platform combining microscopic imaging, machine learning-based algorithm and photochemical labeling, to achieve spatial specific enrichment of IS proteins. Raji B cells, which served as the antigen-presenting cells (APCs), was incubated with Jurkat T cells to induce IS formation. Multiple immunofluorescence images of CD3, a common IS marker, were first applied to train an image progressing algorithm with convolution neural network-based deep learning. Microscoop then automatically performed multiple rounds of fluorescence imaging, deep learning-driven pattern generation, and photochemical labeling to biotin-tag sufficient number of immune-synapses. Subsequent protein enrichment by streptavidin pull-down and MS analysis allowed identification of IS specific proteins. Using Microscoop, we successfully labeled and isolated proteins from spatially reorganized interfaces between T cells and APCs. Following proteomic analysis, several hundreds of proteins were identified, including the proteins, such as the tyrosine protein kinase LCK, that are known to be specifically associated with T-cell receptor (TCR) and involved in TCR signaling. More interestingly, we identified several novel proteins at the ISs, including proteins that are implicated in phosphatidylinositol signaling. Our data showcases the Microscoop technology as an efficient and innovative approach to unravel spatial proteome of complex biological targets. We also revealed novel factors that potentially regulate immune response at the APC-T cell interfaces, thus shedding light on immune checkpoint signaling and tumor immunotherapy.

Validating AI pipelines for single cell image data

A. Asmar, Z. Benson, M. Halter, A. Plant; NIST, Gaithersburg, MD.

Measurements of dynamic changes in single cells over time provides insight into the coordinated fluctuations in gene expression within individual cells in a population. Time lapse imaging is the primary method for obtaining single cell dynamics, and we have developed an imaging workflow to capture large-scale, ultra-fast time-lapse imaging of cells. A total of more than 12 x 10^6 induced pluripotent stem cells (iPSC) can be imaged approximately every 3 minutes in phase contrast over many hours using continuous motion microscopy. Corresponding fluorescence images are acquired at 30min intervals, and together these data provide a training set for UNet inferencing that allows segmentation and tracking of unlabeled parent and daughter cells in iPSC colonies. Because our interest is to monitor and analyze intracellular single cell dynamics over a large number of cells, and because we are interested in probing these dynamics under different culture conditions as populations evolve in time, we are particularly interested in verifying the accuracy of our algorithmic workflows. The large size of the datasets precludes establishing ground truth with manual methods. We investigated the application of a reporter cell line to automatically validate our lineage tracking workflow. Using a multi-color “Rainbow” reporter line, where a mixed population of cells are differentially tagged using single or multiple constitutive

fluorescent proteins, we can establish ground truth for lineage tracking. Each cell/lineage can be assigned a unique RGB value and then compared with the output from the tracking of unlabeled cells. This workflow provides large-scale data acquisition, algorithm development and implementation, and system validation that allows us to segment and track millions of cells over short intervals and long times. This approach allows us to accurately determine division times within the population, and to quantify intracellular fluorescent biomarker fluctuations over multiple generations.

REPORTING OF MICROSCOPY METADATA - HOW TO IMPROVE QUALITY AND REPRODUCIBILITY IN BIOIMAGING

M. Hammer[1], A. Rigano[2], J. Ryan[3], D. Grunwald[1], J. Lacoste[4], R. Nitschke[5], B. Schroth-Diez[6], C. Brown[3], **C. Strambio-De-Castillia**[2]; [1]RNA Therapeutic Institute, University of Massachusetts Medical School, Worcester, MA, [2]Program in Molecular Medicine, University of Massachusetts Medical School, Worcester, MA, [3]Advanced BioImaging Facility - Department of Physiology, McGill University, Montreal, QC, CANADA, [4]MIA Cellavie, Montreal, QC, CANADA, [5]Life Imaging Center, University of Freiburg, Freiburg, GERMANY, [6]Light Microscopy Facility, Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, GERMANY.

Biology increasingly relies on microscopy techniques that push the boundaries of spatial and temporal resolution to dramatically improve fundamental understanding of life and advance therapeutic solutions. Drivers of innovation such as new fluorescence techniques and detection systems have led to the routine use of complex microscopy assays, optical components, mechanical parts, and imaging conditions. As a result, microscopy has evolved from a simple instrument that provided qualitative results to a quantitative measurement tool with a variety of possible measures such as distances, times, or intensities.

Rigorous science requires that all relevant information (i.e., metadata) about an experiment be reported using the FAIR (Findable, Accessible Interoperable, and Reusable) principles. However, it is often difficult for microscope users to decide what information about their microscope is essential, and users often feel overwhelmed by the amount of technical information required to meet FAIR imaging standards. International bioimaging organizations such as BioImaging North America (BINA), Canada Bioimaging, the Royal Microscopy Society, German Bioimaging, Euro-Bioimaging, France Bioimaging, and Global BioImaging have recently joined forces with individual imaging scientists, microscope manufacturers, and standards organizations to form QUAREP-LiMi (www.quarep.org), support biomedical researchers, and provide a forum for building broad consensus on quality control, reporting, and reproducibility in microscopy.

Here we present the recently released tiered system of microscopy metadata specifications originally developed by the NIH-funded 4D Nucleome (4DN) Initiative and BINA to extend the Open Microscopy Environment (OME) data model (i.e., the basis for the popular Bio-Formats image data exchange format). Because this 4DN-BINA-OME (NBO) metadata model correlates experimental design complexity with reporting depth on microscope hardware, acquisition settings, and calibration control, it has found favor in the international imaging community and is currently being further developed to incorporate instrument manufacturer input as part of QUAREP-LiMi.

To extend the impact of the NBO-QUAREP specifications, the talk will introduce the Micro-Meta App and MethodsJ2 software tools developed to enable biomedical researchers to properly report microscopy metadata and improve the quality and reproducibility of their imaging experiments regardless of their

imaging experience. Micro-Meta app enables researchers to capture detailed metadata about microscope hardware and acquisition settings. MethodsJ2 is a Fiji/ImageJ plugin that collects image metadata from image files and the Micro-Meta App to generate methods text for publication.

Aberration-corrected STED Microscopy with MATRIX Detection for Neuroscience Research

M. Velasco[1], K. Bahlmann[1], M. Meschkat[2], J. Matthias[2], C. Wurm[2]; [1]Abberior Instruments America, Bethesda, MD, [2]Abberior Instruments, Goettingen, Germany

Stimulated Emission Depletion (STED) microscopy is a well-established super-resolution imaging technique that enables the visualization of nanoscale structures in biological specimens. Among the super-resolution modalities, STED microscopy stands out due to its compatibility with challenging specimens such as biological tissue, a prevalent specimen type in neuroscience despite its complexity. In tissue samples, acquiring STED images with high signal-to-noise is challenging for two reasons. First, improving resolution results in a reduction of the volume of the effective point-spread-function, which leads to dimmer images. Since the STED effect is applied in the focal plane, the in-focus signal decreases, while the background signal from the rest of the sample has the same strength as in conventional confocal microscopy. This translates to a decrease in the signal-to-background ratio, especially in thick tissue samples where the out-of-focus background contribution is high. Second, thick tissue samples typically have non-constant refractive index maps that lead to optical aberrations that compromise the quality of the STED doughnut. This is especially true for the three-dimensional (3D) STED doughnut, and the outcome is a depletion profile that switches off fluorescence entirely rather than just confining it to a sub-diffraction-limited sized spot. This effect worsens deeper in tissue as optical aberrations accumulate, and it imposes a practical limit on the imaging depth of conventional STED microscopy in tissue. We present two approaches that work in-tandem to improve STED imaging in tissue. The first approach is MATRIX detection, which harnesses the power of an array-based detector to discriminate in-focus signal from out-of-focus background without the losses experienced with pinhole detection. MATRIX detection can thus significantly increase optical sectioning and signal-to-background ratios. MATRIX detection can also be combined with adaptive optics, which (in our implementation) relies on a deformable mirror to introduce phase distortions that negate those induced by the specimen. In this way, optical aberrations can be corrected and super-resolution can be maintained even when imaging deep in tissue. The unprecedented combination of MATRIX detection and adaptive optics is powerful and allows for deep-tissue super-resolution imaging experiments where nanoscale structures can be visualized with more native context. We will present the intuitive and user-friendly implementation of MATRIX detection and adaptive optics on a state-of-the-art Abberior Facility Line STED microscope, and we will demonstrate how aberration-corrected STED microscopy with MATRIX detection can be applied in a range of neurobiological specimens.

Characterization of *C. elegans* autofluorescence using spectral scanning and Fluorescence Lifetime Imaging Microscopy (FLIM)

E. Cameron, **H. Hulsey-Vincent**, L. Dahlberg, D. Galati; Western Washington University, Bellingham, WA

C. elegans produce a disruptive amount of autofluorescence during imaging. The greatest signal comes from granules in the gut, and a lesser amount from the cuticle. This autofluorescence has been

characterized at low spatial resolution using spectral scanning and at high spatial resolution using band pass filters. However, it has not been characterized at high resolution spectrally and spatially. We performed high resolution spectral scans of the gut granules at 405 nm, 488 nm, 561 nm, and 647 nm excitations. This revealed distinct spectral populations, with the most prominent at 405 and 488 nm.
In addition to measuring spectral differences, we used Phasor-Fluorescence Lifetime Imaging Microscopy (FLIM) to characterize differences in photon emission lifetime. The cuticle and gut granules were characterized at 440 nm and 488 nm excitations. The cuticle had a single photon decay population at both 440 and 488 nm excitation, while the gut granules had three distinct photon decay populations at both 440 nm and 488 nm excitation.
Cuticle autofluorescence hinders detection of fluorescent proteins at low levels. Using Phasor-FLIM, the auto fluorescent cuticle and GFP tagged proteins exhibit distinct lifetime populations. We demonstrate that by using Phasor-FLIM, the dim fluorescent signals which would typically be lost to noise caused by autofluorescence of the cuticle or gut granules can be separated and quantified. Further studies involving C. elegans may use Phasor-FLIM masking to distinguish between autofluorescence background and true fluorescence of commonly used fluorescent proteins and dyes.

B42/P1041

Multi-scale Unet: Incorporating machine learning to improve automated cell segmentation in time-lapse images to facilitate linage tracking of primary human hematopoietic progenitors

K. M. Ta[1], E. Thompson[1], S. Boobalan[2], **E. McEwen**[3], C. Monterosso[3], J. Duncan[1], D. Krause[1], V. Scanlon[3]; [1]Yale University, New Haven, CT, [2]University of Connecticut, Storrs, CT, [3]UConn Health, Farmington, CT

Multi-parameter single cell imaging analyses permit novel and robust dissection of the temporal molecular mechanisms governing stem and progenitor cell fate. Given our ability to acquire high throughput image acquisitions, downstream analyses become the bottleneck of projects. An accurate automated analysis is necessary for high throughput imaging. Previously established cell imaging analysis algorithms heavily rely on manual curation of both cell segmentation and linking cell tracks on a per cell basis, or require heavy feature engineering and parameter tuning to achieve reasonable results, rendering these tools very time and labor intensive.(Magnusson et al., 2015; Qin et al., 2020; Zargari et al., 2021) Our goal is to improve the automation of cell segmentation in brightfield (automatically identify individual cells and their membrane boundaries) by taking advantage of the recent successes in data driven deep learning tools. To achieve this goal, we compared several automated cell segmentation algorithms (Baxter, Unet, DeepSea) as well as our novel Multiscale Unet algorithm on their ability to identify individual cells over multiple time frames and then ran the resultant segmentation files through the automated tracking component of the Baxter algorithm. We utilized our time-lapse image data set and ground truth tracking of primary human Megakaryocytic-Erythroid Progenitor cells (CD34+Lin-CD135-cD45RACD110+CD38midCD41-) (Scanlon et al., 2022) to assess the automated performance of each algorithm. Specifically, we compared the resultant cell counts in a consistent field of view at given time points, the positions of the centroids of the segmented cells, and compare lineage trees representing the heritage of each progeny. The Multiscale Unet segmentation algorithm gave the closest automated results compared to the ground truth dataset. These results deliver a major step forward in automated image analyses of high throughput image sets, and facilitate accurate, robust, and timely results regarding the temporal molecular mechanisms that lead to cellular behavioral phenotypic changes, such as lineage commitment of progenitor cells. Results from these types of analyses could lead to improved understanding of steady state hematopoiesis as well as pathogenic changes in

progenitor cells leading to cytopenias or cancer and may illuminate novel druggable targets that instruct progenitor cell fate.

Green genetically encoded voltage indicators for rapid and prolonged two photon voltage recording *in vivo*

M. A. Land[1], E. N. Zaabout[1], X. Lu[2], S. Yang[2], Z. Liu[2], X. Dong[1], A. J. McDonald[1], Y. Gou[1], V. Villette[3], S. Lai[1], M. M. Pang[4], S. Su[4,5], C. Cai[6], E. Froudarakis[1,7], N. Zhou[1], S. S. Patel[1], C. L. Smith[1], P. Bizouard[3], J. Bradley[3], T. R. Clandinin[4], A. Giovannucci[6,8,9], A. S. Tolias[2,1], J. Reimer[1], S. Dieudonné[3], F. St-Pierre[2,1]; [1]Baylor College of Medicine, HOUSTON, TX, [2]Rice University, HOUSTON, TX, [3]PSL Research University, Paris, France, [4]Stanford University, Stanford, CA, [5]Columbia University, New York, NY, [6]University of North Carolina at Chapel Hill, Chapel Hill, NC, [7]Foundation for Research and Technology Hellas, Heraklion, Greece, [8]North Carolina State University, Chapel Hill, NC, [9]UNC Neuroscience Center, Chapel Hill, NC

Monitoring neural activity on the millisecond time scale in genetically defined cells is a goal of neuroscience, but remains challenging to perform *in vivo*. A limitation of current techniques is not being able to quantitatively monitor neuronal electrical (voltage) dynamics with single-cell or subcellular resolution from large and genetically defined populations of neurons. Genetically Encoded Voltage Indicators (GEVIs) are a promising tool to bridge this gap. GEVIs are fluorescence-emitting protein sensors that report membrane potential (voltage) dynamics as changes in brightness. However, current GEVIs suffer from low sensitivity to voltage changes and are relatively dim, limiting our ability to image smaller transients and voltage dynamics in deeper layers of the cortex. GEVIs also suffer from poor photostability severely limiting their ability to be used for behaviorally relevant time scale. These issues are further exaggerated when trying to image under two-photon microscopy, a method of choice for deep-tissue imaging. Here, we report novel GEVIs optimized for long-term *in vivo* imaging under two-photon illumination. Our sensor design is based on the published ASAP family of sensors in which a voltage-sensitive domain is coupled to an extracellular circularly permuted GFP. Using high-throughput multi-parametric screening under two-photon illumination we tested mutations at amino acid positions that are structurally and evolutionary important in ASAP. Using a holistic metric we identified top sensors with improvements in sensitivity, brightness and/or photostability for further combinatorial screening. From these combination screens we identified a champion sensor called Jellyfish-derived Electricity-reporting Designer Indicator for 2-Photon microscopy (JEDI-2P). JEDI-2P is brighter, has improved photostability, greater sensitivity and faster kinetics than other leading sensors. JEDI-2P has been shown to report light-evoked responses in axonal termini of *Drosophila* interneurons. Using both resonant-scanning and ULoVE random-access microscopy, we show that JEDI-2P can also detect voltage dynamics of individual cortical neurons in awake behaving mice for more than 30 min. Additionally, JEDI-2P can be used to robustly detect spikes at depths exceeding 400 µm in pairs of neurons. Further screening has identified a new generation of sensors with improved response amplitude and kinetics compared with JEDI-2P. These new sensors have been cloned into a variety of vectors and are available for *in vivo* beta testing. We anticipate that development of our advanced GEVI toolbox will enable more robust high-throughput and real-time neural recording.

B44/P1043

Scalable 3D printed inserts for increased stability of hepatic intravital microscopy

M. Cornelius; National Institute of Health, Bethesda, MD

Confocal-based intravital microscopy (IVM) of the liver allows direct visualization of dynamic processes to evaluate hepatic function and dysfunction. Specifically, qualitative, and quantitative parameters can be extracted with high spatial and temporal precision. However, preserving tissue physiological conditions while achieving stability on the microscope stage remains challenging. This is magnified in murine models for non-alcoholic fatty liver disease (NAFLD), and Type II diabetes (T2D) where increased weight and hepatic lipid content negatively impact stability. We developed novel intravital microscopy inserts to address these limitations, allowing improved tissue access and enhanced stabilization. The production process of this prototype platform is based on 3D printing of the insert in a single-step process, which includes scalable sizes to accommodate small to large-size mice. The feasibility of production and the advantages of this customizable and versatile design are shown and discussed in this paper. Our design represents a significant step forward in facilitating intravital imaging of metabolic dynamics in physiology, NAFLD, and T2D, using IVM in living mice

Keywords. 3D printing, hepatic lobule, hepatocyte, intravital microscopy, mouse liver, glucose uptake

Isotropic, One-step 12-fold modified Expansion Microscopy (mExM)

R. X. Norman[1], J. Loi[2], M. Saotome[3], E. E. Recchia[1], Q. Rosemarie[2], S. L. Lesko[4], S. Patel[2], N. Sherer[4], B. Sugden[2], M. E. Burkard[1], A. Suzuki[2]; [1]Medicine, University of Wisconsin-Madison, Madison, WI, [2]McArdle Laboratory for Cancer Research, University of Wisconsin-Madison, Madison, WI, [3]School of Medicine and Health Sciences, University of North Dakota, Grand Forks, ND, [4]Institute of Molecular Virology, University of Wisconsin-Madison, Madison, WI.

Macromolecular complexes are integral to cellular functions and many of them are smaller than the resolution limit of fluorescence microscopy. Super-resolution methods including STED, SIM, and STORM improve the resolution limit but are insufficient to resolve many of these structures and require specialized equipment, dyes, and mathematical processing. Expansion microscopy is an alternative super-resolution method, where the sample is embedded in polymers, and it expands upon the addition of water. The resolution of ExM can be improved by the expansion factor as it is independent of the microscope optics. In this study, we used N,N-Dimethylacrylamide (DMAA), and Sodium acrylate as monomers and polymerized the hydrogel without requiring any specialized equipment. We also designed a reusable imaging chamber and mounting media to reduce the drift of the hydrogel and photobleaching respectively during imaging. As isotropic expansion is critical to prevent sample distortion and has not been addressed in previous studies, we determined the isotropy of both the hydrogel and the embedded sample. We found that the hydrogel stably expanded ~12-folds isotropically in three dimensions. To validate the 3D isotropic expansion of specimens, we measured nuclear sizes and volumes in multiple cell lines including human organoids. We chose the interphase nuclei since it is the largest organelle and has unique features such as nuclear membranes and a conserved 3D architecture. We found that our optimized method achieves 12-fold isotropic expansion of nuclei in various monolayer cells and organoids. Next, to validate the preservability of nuclear structures after expansion, we determined the 3D chromatin conformation using the Pore-C method. We found that the 3D organization of chromatin is not disrupted upon expansion suggesting that our 12x mExM method

preserves the chromatin at the microscopic and molecular levels. To examine the structural preservation and resolution, we imaged microtubules (~25 nm width) and centrioles (~250 nm) using mExM and confirmed that these structures are well preserved after 12-fold expansion. The thickness of microtubules using mExM was ~29 nm compared to ~257 nm pre-mExM. In further validations, we found that our method was able to preserve RNA transcripts at the HIV-1 genome integration site in a cell. Additionally, our method could visualize single Epstein-Barr Virus (EBV) particles in a lytic host cell. The EBV envelope diameter measurement was comparable between mExM and electron micrograph, showing the strong potential of this method in studying nanometer-scale structures. Since this method uses commonly available reagents and equipment, we think that it could also serve as an economical super-resolution method for a wider scientific audience.

B46/P1045

Deformable Phase Plate: a New Technology for Plug-and-Play Adaptive Optics

S. M. Weber, P. Rajaeipour; Phaseform GmbH, Freiburg i.B., Germany

Adaptive optics (AO) comprises a set of powerful opto-electromechanical techniques that enable dynamic correction of optical imaging errors. Despite their proven advantages for various microscopy techniques in life sciences, especially for deep tissue imaging, the widespread use of AO is still hindered by extreme complexity and integration costs. These disadvantages are mostly related to the main elements of AO systems, typically deformable mirrors (DM), and the wavefront metrology methods. The integration of such hardware into microscopes usually requires significant modifications or, in most cases, the development of new setups taking into account the AO design constraints. The Deformable Phase Plate (DPP) described in our poster presentation is a refractive counterpart of DMs, able to compensate for high-order aberrations, enabling higher contrast, sharper images and tighter focal spots for multiphoton microscopy. Its transmissive working principle combined with sensorless aberration measurement techniques enables plug-and-play AO systems. Like a lens in a conventional cage, DPP can be inserted into the beam path of microscopes to provide dynamic correction of system- and sample-induced aberrations. In our contribution, we will demonstrate the use of DPP to compensate for sample-induced aberrations in the illumination path of a two-photon microscope for focusing deep into biological tissue. By dynamically measuring and correcting aberrations using DPP, we show that it is possible to significantly improve the quality of the images obtained while simplifying sample preparation. AO is progressing daily to become accessible to a wider range of users, and our DPP technology, commercialized by the spin-off Phaseform from Freiburg in Germany, has the potential to play a signifcant role in this development.

B47/P1046

Chemigenetic fluorescent biosensors for imaging and screening signaling protein activity

L. W. Miller; University of Illinois-Chicago, Chicago, IL

Genetically encoded, Förster resonance energy transfer (FRET) biosensors enable live-cell optical imaging of signaling molecules. Small conformational changes often limit the dynamic range of biosensors that combine fluorescent proteins (FPs) and sensing domains into a single polypeptide. To address this, we developed FRET and lanthanide-based FRET (LRET) biosensors with two key features that enhance sensitivity and dynamic range. For one, alpha helical linker domains separate FRET partners and ensure a large conformational change and FRET increase when sensing domains located

near each terminus interact. We have demonstrated that linkers increase dynamic range in a length-dependent manner. Another key feature that enhances sensitivity is the incorporation of luminescent Tb(III) complexes as FRET donors. The long excited-state lifetimes (~ms) of Tb(III) and Tb(III)-sensitized FP emission signals favor time-resolved luminescence (TRL) detection strategies that nearly eliminate non-specific fluorescence background. TRL plate readers and microscopes use pulsed light to excite specimens and detect long-lived signals after a brief delay (~µs) that allows short-lived (~ns) fluorescence to decay. LRET biosensors enable medium (96-well) and high (384-well) throughput TRL assays of protein-protein interaction inhibition in cell lysates or intact cells. This presentation elaborates the technology and presents data on cellular imaging and screening with sensors that measure Rac1 GTPase and PP1 phosphatase activities.

Exploring cellular context with plasma-focused ion beam scanning electron microscopy

G. Perumal, R. Vernon, R. Chalmers, A. Rigort, J. Mitchels; Thermo Fisher Scientific, Hillsboro, OR.

Focused ion beam and scanning electron microscopes (FIB/SEM)can be used to obtain three-dimensional volumetric data from biologicalspecimens. The unique combination of an imaging and precision manipulation toolallows sequentially removing material with the ion beam and imaging the milledblock faces by scanning with the electron beam, an approach known as FIB/SEMtomography. This technique can be applied to both resin-embedded samples andcellular specimens which have been preserved by cryo-fixation. Forcryo-imaging, the FIB/SEM instrument needs to be equipped with a cryo-system toenable imaging of samples that have been cryo-immobilized (vitrified) by eitherhigh-pressure freezing (HPF) or plunge-freezing methods. Here we demonstrate how biological samples can be imagedusing multi-ion plasma FIB (PFIB) technology. We exploit the fast materialremoval capabilities of the plasma beam for the newly developed spin millmethod, which is suitable for processing and imaging large sample areas onresin-embedded samples. We show results for spin milling on a mouse organotypicslice, where we exposed a large area (horizontal field width 638µm) of thesample surface and subsequentially imaged three different areas of interestrevealing structural details. In addition, we also demonstrate new results forcontextual imaging of cryo-samples, which we mill with different ion beamsoriginating from the plasma source. The cryo-samples were milled using eithernitrogen or argon ions and 3D data was acquired by collecting 20 nm slice datawith the secondary electron detector. By volume imaging of frozen mouse braintissue, Chlamydomonas and CHO cells, fine structural details such as synapses,subcellular compartments and organelles can be visualized without the need to treatthe sample with fixatives or stains. The PFIB technique offers new possibilities for theexploration of biological samples and enables both large volume milling ofcells and tissues and precise preparation of samples for electroncryo-microscopy.

FIB-SEM, a resolutive 3D large volume method to assess flagellar ultrastructural organization

E. Penard, S. Bonnefoy, M. Majrouh, N. Cayet, T. Blisnick, P. Bastin, A. Mallet; Institut Pasteur, Paris, France

Transmission Electron Microscopy (TEM) is the imaging method of choice to visualize intracellular structures but it is limited to the observation of 500 nm thick slice for electron tomography approaches. Many organelles such as cilia and flagella have a larger size which measure about 20 µm. To follow along

the whole flagellum, we need another 3D high-resolution approach to observe structural details like microtubules, involved in intracellular organization.The Focus Ion Beam-Scanning Electron Microscopy (FIB-SEM) is a 3D electron microscopy method allowing the obtention of a volume in x-y-z at isotropic resolution of 10 nm. This microscope is composed of an ionic beam which precisely mill our sample, and an electronic beam to observe the surface of our sample. Here, we study *Trypanosoma brucei,* and more particularly its flagellum with the axonemal microtubules and extra-axonemal structures. The *T.brucei* genome contains several TTLLs enzyme (Tubulin Tyrosine ligase like) involved in the tail addition of glutamate residues to tubulin α or β. We focalized on TTLL9 enzyme, involved in distinct glutamylation enzymatic activities and structural as well as functionality issues. Using next FIB-SEM, this provided a high-resolution isotropic 3D view of structural axonemal and flagellar defects along the whole flagellum of *ttll9-/-* knockout cells. Notably, it allows to visualize frequent disorganization of the axoneme or distribution of excessive Paraflagellar Rod structure (PFR) as well as mis-orientation of the central pair microtubules all along the flagellum. Our results clearly demonstrate and confirm the importance of FIB-SEM to address the topology of structural defects previously detected by TEM and prime importance to 3D image analysis. The FIB-SEM is a long technique requiring high expertise. In this poster, data acquired from isolated cells demonstrate that FIB-SEM can be used to answer important biological questions that can be addressed to various types of samples, microorganisms, infected cells or tissues.

B50/P1049

Autonomous Cell Feature Selection by Machine Learning

V. Tiryaki[1], **V. Ayres**[2], I. Ahmed[3], D. Shreiber[4]; [1]Siirt University, Siirt, Turkey, [2]Michigan State University, East Lansing, MI, [3]CUNY Medgar Evers, New York, NY, [4]Rutgers, The State University of New Jersey, Piscataway, NJ

Automated cell segmentation is key for rapid and accurate investigation of cell responses. As instrumentation resolving power increases, clear delineation of newly revealed cellular features at the submicron through nanoscale becomes important. Reliance on the manual investigation of myriad small features retards investigation; however, use of deep learning methods has great potential to reveal small cell features both at high accuracy and high speed, which may lead to new discoveries in the near term. Adaptation of deep learning methods for cellular investigations has received intense interest in the last decade because of the success of these methods in image classification, segmentation, and other problems involving recognition. Until recently, while cell segmentation could be completed with machine learning techniques, the performance was limited, and the selection of an optimum feature extraction method could be time-consuming. The main problem is determining the feature extraction method, which can vary depending on the classification problem. Deep learning methods can resolve this uncertainty because they allow automatic feature learning. In this study, semantic cell segmentation systems were investigated by implementing fully convolutional neural networks called U-nets for the segmentation of astrocytes cultured on poly-L-lysine-functionalized planar glass. As its first focus, the performances of major types of U-nets for automatic cell segmentation in AFM images were investigated. This is the first investigative study that we are aware of that uses U-net models for cell segmentation of AFM images. AFM height, deflection, and friction images were used as inputs separately and together, and the segmentation performances were investigated on five-fold cross-validation data. When transfer-learning methods were applied, statistically significant segmentation performance improvements were observed. Segmentation optimization for AFM versus electron

microscopy (EM) images was next investigated. The publicly-available dataset ISBI 2012 provided as an EM segmentation challenge was used and alternative current and classical methods were investigated. The best EM segmentation performance was obtained when Cellpose transfer learning [2] was applied while U-VGG19 outperformed for AFM images. The higher performance of U-VGG19 on the AFM data shows that transfer learning on the deep networks originally trained with big data can outperform transfer learning on the deep networks that are originally trained with a more similar but smaller datasets. Label-free imaging of adipocyte differentiation process and lipid-droplet analysis using low-coherent holotomography

H.-J. Kim; Tomocube, Inc., Daejeon, Korea, Republic of

Visualization and time-lapse tracking of adipocytes and their lipid droplets (LDs) in the process of differentiation are challenging due to the long-term differentiation period. The traditional fat staining method, such as oil red-O staining, had a disadvantage in that it was impossible to observe the state of living. Using fluorescence dye (BODIPY or Nile Red), living cells can be observed but it is difficult to track them for a long period due to the persistence problem of fluorescent dyes. Holotomography (HT) has emerged as a useful tool for imaging live specimens without additional pre-treatment such as fixation. Here, we applied a recently developed low-coherent holotomography imaging system (HT-X1) which provides label-free 3D visualization of live cells. Since LDs in HT images have a high refractive index (RI), they can be clearly distinguished from cells. We performed differentiation of 3T3-L1 fibroblast into adipocyte in the HT-X1 system and acquired a time-lapse movie of the differentiation process for 14 days. The high RI sphere structure was verified LD by fluorescent staining. We also observed the redifferentiation process from primary dedifferentiated adipocyte into mature adipocyte for 42 days. Images were acquired every 3 days in the same region, and the continuously increasing LD contents were quantitatively measured. The volume, projected area, and dry mass of LDs were increased according to the adipocyte maturation. Through the results, we suggest that low-coherent holotomography has an exclusive capability for phenotypic and quantitative studies of adipogenesis and LD accumulation in various cell types.

Quantitative phase imaging from brightfield: a new gold standard for cell confluence and counting

T. M. Joska, H. Fried, K. Chapman, A. Blanchard; Thrive Bioscience, Beverly, MA

Live cell imaging is a cornerstone in cell biology but manual evaluation of cell health by confluence, doubling rates, and cell counts remain labor intensive and subject to human error. Automated imaging approaches often only provide qualitative data, and frequently require toxic dyes that can confound results and harm or kill the cells in question. Thrive Bioscience, Inc. provides automated live-cell quantitative phase imaging from brightfield images (QPIB) across wells and plates within minutes offering greater reproducibility than manual techniques. The Thrive CellAssist system is a tightly integrated hardware and software solution for acquiring, analyzing, storing, and visualizing live cell images. Expandable from a single bench-top unit to a global network of automated, environmentally controlled imagers, it elevates imaging of live cells in culture from an occasional, manual process with

sporadic documentation, to a reproducible, routine, automated process that provides unparalleled insight into your cells' behavior. The Thrive CellEval software uses QPIB over every pixel to render stitched 3D images that outline cells as a means to count and derive confluence measures, track cell motility and growth rate, and much more. Confluence and cell counting measurements are validated over time with precise segmentation and optical volume measures. Further uses are automating scratch gap/migration assay by 1) automated identification of the scratch gap region, 2) the selection of regions devoid of the plowing effect, and 3) tracking of growth into the gap region over time. **At Thrive Bioscience**, *we image differently*. For more information on the CellAssist and CellEval software, visit our booth to explore the power of z-stacks and learn how brightfield images deliver superior laboratory workflows to improve experimental outcomes.

Pipeline development for correlative cryofluorescence microscopy and electron tomography of isolated plasma membranes.

W. Sun, D. Michalak, K. Sochacki, N. Mizuno, J. E. Hinshaw, J. Taraska; National Institutes of Health, Bethesda, MD

The proteins associated with the plasma membrane of mammalian cells control motility, adhesion, cargo import and export, and signaling. Visualizing their structures in the heterogenous molecular environment of the cell is key to understanding their cellular functions in health and disease. Cryo-electron tomography (cryoET) is a powerful tool for identifying and reconstructing *in situ* protein structures at sub-nanometer resolution. Despite its strengths, the efficacy of cryoET is limited by sample thickness (requires <200 nm) and has few tools for identifying proteins of interest. Thus, methods for sample thinning and protein labeling are necessary for a broad implementation of the technique. Specifically, the standard ion-milling techniques used for sample thinning are not well-suited for observing proteins at the plasma membrane. Here, we optimize a cryo-correlative light microscopy and electron tomography pipeline for the study of plasma membrane-associated organelles and protein complexes. This pipeline employs a method called “unroofing” to isolate plasma membranes immediately before freezing. By modifying the unroofing procedure we can produce ultra-thin samples of both the basal and apical plasma membrane from different types of cells. Protein probes designed for correlative microscopy are being developed and optimized to allow us to identify specific proteins of interest in cryoET images. This pipeline is being benchmarked with sub-tomogram averaging of previously solved structures. The goal of this work is to enable efficient high-resolution visual proteomics of the plasma membrane of eukaryotic cells.

Visualizing cytosolic and mitochondrial ATP changes upon metabolic inhibitions *in vitro* via a novel multi-organelle ATP biosensor

D. White, III, Q. Yang; Louisiana State University Health Sciences Center - New Orleans, New Orleans, LA

Adenosine 5’ triphosphate (ATP) is the main fuel resource utilized by all living cells. 90% of ATP is produced via mitochondrial oxidative phosphorylation (OXPHOS), with the remaining portions produced by glycolysis in the cytosol. Our lab designed a genetically-encoded fluorescent ATP indicator, called smacATPi (simultaneous mitochondrial and cytosolic ATP indicator), that allows for real-time visualization of cytosolic and mitochondrial ATP *in-vitro*. smacATPi combines previously described

individual cytosolic and mitochondrial ATP indicators, encoded for chimeric proteins of GFP- and mApple-F_0F_1-ATP synthase ϵ subunit (*B. subtilis*), with the latter containing a mitochondrial targeting sequence. Bioenergetics measured using a Seahorse bioanalyzer showed no metabolic interferences in cultured HEK293T cells transfected with smacATPi. To investigate the utility of smacATPi, mitochondrial and cytosolic ATP signals were investigated post-treatment of metabolic effectors. 2-deoxyglucose (2-DG) (25µM), a glycolysis inhibitor, triggered a 30% rapid decline in cytosolic ATP production and a 15% decrease in mitochondrial ATP. Oligomycin (5µM), a complex V inhibitor, induced a 10% decrease in mitochondrial ATP production and a 10% increase in cytosolic ATP. Within the inner mitochondrial membrane (IMM), the ADP/ATP carrier (AAC) protein plays a vital role in the appropriate movement of ADP and ATP between the cytosol and mitochondria. Although AAC has been extensively studied, its effects on ATP production have not yet been evaluated - especially in the setting of hypoxia. Atractyloside (ATR) is an AAC inhibitor, blocking ATP and ADP movement across the IMM. After ATR (100µM) treatment, both mitochondrial and cytoplasmic ATP signals were respectively decreased by 15% and 10%, indicating that inhibition of AAC-mediated ADP import would reduce both cytosolic and mitochondrial ATP content. In hypoxia, mitochondrial ATP was increased, and cytosolic ATP was decreased. ATR (100µM) treatment 2 hours post-initiation of hypoxia triggered an increase in cytosolic ATP compared to hypoxia alone, along with a downward trend of mitochondrial ATP. These results, for the first time, demonstrate real-time cytosolic and mitochondrial ATP changes upon metabolic inhibitions, suggesting complex and rapid ATP regulation between cytosolic and mitochondrial compartments under normoxic and hypoxic conditions.

Actin and Actin Associated Proteins 1

B56/P1054

Unraveling the role of the Arp2/3 complex in the NHEJ pathway of DNA repair

J. Salat, D. Mullins; University of California, San Francisco, San Francisco, CA

Actin has been extensively studied in the cytoplasm for its structural functions such as cell morphology, movement, and adhesion. On the other hand, research on the functions of actin in the nucleus has only begun to emerge. Previous work in our lab has shown nuclear actin filaments form in response to DNA damage in mammalian cells. The development of a nucleus-specific actin probe was crucial in visualizing actin filaments in the nucleus and determining that actin assembly is required for the DNA damage response. Actin regulators are involved in controlling when and where actin is assembled. The Actin Related Protein 2/3 (Arp2/3) complex is an actin regulator that nucleates an actin filament off an existing filament to form a branch. In the cytoplasm, the Arp2/3 complex nucleates actin branches that generate force to move membranes and is important for many cellular processes such as cell movement and phagocytosis. Recent research has found that the Arp2/3 complex is present in the nucleus where it is required for efficient DNA repair in the homology-directed repair pathway. Due to the Arp2/3 complex involvement in DNA repair, we tested whether it can bind to DNA and our fluorescence anisotropy data show the Arp2/3 complex binds to single-strand DNA with a K_d of 98 nM and double-strand DNA with a K_d of 382 nM. We also found that Arp2/3 nucleation activity is not disrupted by DNA binding and shown that in CH12 cells, a mouse B-cell model, the Arp2/3 complex is required for efficient cell proliferation and non-homologous end joining (NHEJ) during immunoglobulin class switch recombination.

Nuclear actin polymerization promotes DNA damage response

A. Varlet; Cornell University, Ithaca, NY

The DNA damage response (DDR) is a key process to maintain genetic stability and integrity. Recent findings support that nuclear actin assists DDR by serving as a scaffold for protein complexes or as an ATPase. However, it is not clear whether nuclear actin filaments (F-actin) are required for these processes. To identify the role of nuclear F-actin in DDR, we generated mouse and human cell lines stably expressing GFP tagged actin targeted to the nucleus using a nuclear localization sequence (GFP-NLS-actin), using either wild-type (WT) actin or a non-polymerizable actin R62D mutant. Double strand breaks were induced by treating cells with phleomycin for 3 hours and DDR was measured by staining for γH2Ax. Expression of NLS-actin R62D resulted in significantly reduced levels of γH2Ax in response to phleomycin treatment compared to NLS-actin WT and NLS-GFP controls. To exclude the possibility of a delay in γH2Ax phosphorylation in response to inhibition of nuclear actin polymerization, we treated cells with phleomycin for various durations up to 24 hours. Cells expressing mutant actin showed lower levels of γH2Ax that persisted for 24 hours, in comparison to both NLS-actin WT and NLS-GFP. Lastly, to assess whether nuclear F-actin regulates γH2Ax phosphorylation in response to various types of DNA lesions, we induced either replication stress with camptothecin and hydroxyurea, or single strand DNA breaks with 4-nitroqulinoline N-oxide. Expression of NLS-actin R62D caused a significant reduction of γH2AX in response to either drug treatments compared to NLS-actin WT control cells. Altogether, these results suggest that impairing nuclear actin polymerization inhibits γH2Ax phosphorylation in response to various types of DNA damage. Nonetheless, the molecular mechanism by which nuclear F-actin modulates DNA damage or DDR remains to be clarified. Insights into how nuclear F-actin regulates DDR will broaden our understanding of fundamental aspects of nuclear actin in cell and molecular biology and reveal new potential therapeutic avenues for the treatment of multiples defective DDR-associated diseases such as cancer.

B58/P1056

Shifts in Nucleocytoplasmic Compartmentalization of the Actin-Binding Protein CapG Analyzed With FRAP

M. Fernandez, M. Sinha, M. Renz; Stanford, Palo Alto, CA

The Gelsolin-related actin-binding protein CapG is the only member of its family that distributes diffusively in the entire cell, i.e., cytoplasm and cell nucleus. The function of CapG in the cell nucleus is unknown. In previous work, we showed a difference in CapG's nucleocytoplasmic shuttling in cancer and normal cells. Here, we set out to further characterize determinants of CapG's nucleocytoplasmic compartmentalization.

We are measuring changes in CapG-GFP nuclear import kinetics in one and the same cell by using Fluorescence Recovery after Photobleaching (FRAP) repeatedly in the same cell. Metabolic depletion using Na-azide and 2-de-oxyglucose decreases the CapG nuclear import indicating an energy-dependent nuclear transport process. The decrease, however, is not irreversible and can be rescued by washing the cells and replacing complete media. The addition of epidermal growth factor (EGF) increases nuclear CapG import in 40% of the measured cells. It is a fast, non-genomic effect, taking effect after only 8 min, further increasing after 30 min, and plateauing at about 50 min. At the same time, the addition of EGF does not shift the steady-state distribution of CapG as shown by a constant nucleocytoplasmic

fluorescence intensity ratio before and after the addition of EGF. In cells that have been serum-starved for 20-hrs and arrested in G0, the addition of EGF triggers an increase in CapG nucleocytoplasmic shuttling in up to 80% of the analyzed cells. Based on our preliminary data, mutating the potential phosphorylation site S337 does not abrogate the EGF-triggered increase in CapG transport. We continue to examine critical phosphorylation sites using repeated FRAP measurements in one and the same cell. We established repeat FRAP experiments in one and the same cell that does not result in apparent cell toxicity but can resolve increase and decrease in CapG nucleocytoplasmic shuttling with EGF and metabolic depletion, respectively. We will continue to use this assay to further describe determinants of CapG intracellular compartmentalization.

Cdc42ep3-bound septin filaments promote actin filament assembly.

M. Tomasso, S. Padrick, P. Mehetre, E. Brinckman, R. Ravi, J. Byrnett; Drexel University College of Medicine, Philadelphia, PA

Septins are filament-forming proteins that are involved in numerous cellular processes. Septins colocalize with actin, microtubule and membrane structures. The Cdc42 effector protein Cdc42EP3 (also known as BORG2) regulates septin localization to cellular actin structures, but it is unknown how Cdc42EP3 controls septin-actin association. Using biochemical analysis with purified components, we show that Cdc42EP3 binds to both septins and actin in a Cdc42-regulated fashion. Importantly, septin-bound Cdc42EP3 accelerates actin filament polymerization. Septin filaments composed of SEPT2, SEPT6 and SEPT7 directly interact with actin filaments, although this occurs less efficiently in pre-formed filaments. Thus, Cdc42EP3 is not needed to recruit actin filaments to septin filaments at equilibrium. Instead, Cdc42EP3 recruits actin monomers to septin filaments, promoting localized actin filament formation and septin-actin structure assembly.

Coordinated septin-actomyosin assembly in the stable bleb cortex

A. M. Paguntalan, P. W. Oakes, J. R. Beach, A. Caillier; Loyola University Chicago, Chicago, IL

The cell cortex is an active contractile network that provides the basis for many essential cellular processes, including morphogenesis, migration, communication, and mechanosensing. Cortical networks are comprised of two key cytoskeletal components: filamentous actin (F-actin) and non-muscle myosin IIA (NMIIA), while additional actin-binding proteins regulate filament turnover, stabilization, bundling, and crosslinking. Mechanical properties, especially contractility, of the cortex depend on both the organization of F-actin and NMIIA-dependent force production. Cortical mechanics are known to modulate cell-matrix adhesion, membrane dynamics, ion channel activity, and more. Thus, understanding the dynamic assembly of cortical networks is of fundamental importance. Septin-family GTP-binding proteins have been proposed as molecular scaffolds for cytoskeletal organization, such as the septin collar that mediates assembly of the contractile actomyosin ring during cytokinesis. At sites of mechanical strain, septins can assemble into higher order structures and bind actin filaments via NMIIA and other actin-binding proteins to reinforce structural stability. Yet, the precise mechanisms by which the mammalian septin cytoskeleton contributes to cortical architecture and stability remain unclear. Because examination of cortical networks is often obscured by high network density and internal cytoskeletal structures, a simplified model of the cortex, amenable to molecular imaging with high

spatiotemporal resolution, is required. Using a specialized micropillar confinement system, we mechanically compress mammalian fibroblasts and induce a transition from mesenchymal to stable bleb-based migration, characterized by the down regulation of stress fibers and focal adhesions and the formation of a single elongated leader bleb. By expressing fluorescently tagged cytoskeletal constructs (e.g. actin, NMIIA, septins, or Rho GTPases), we track the localization and coincidence kinetics of these proteins in our stable bleb system via high resolution live-cell microscopy. We confirm that, as previously described, NMIIA-driven contractility at the proximal base of the bleb generates a cortical density gradient via retrograde advection, which enables stable bleb-based migration. Due to the diversity of cortical architecture and lack of internal structures, this confinement-based inducible-bleb system provides a minimalist, yet relevant, model of the contractile cortex. Further studies will reciprocally investigate the necessity and sufficiency of septins and actomyosin during the assembly and remodeling of these contractile cortical networks, thereby providing insights into biophysical properties of cortices found in every cell in the body.

B61/P1059

Septin-actin crosstalk at the bud neck in*S. cerevisiae*

J. Magliozzi, S. D'Amaddio, B. Goode; Brandeis University, Waltham, MA

Septins and actin make up two separate cytoskeletal polymer systems in eukaryotic cells. However, mounting evidence from diverse species indicates that septins play important roles in regulating actin cytoskeleton spatial organization and dynamics. The goal of our work is to define the mechanistic basis for septin-actin crosstalk, using budding yeast as a model. In *S. cerevisiae*, septins polymerize into a higher order networks found at the bud neck, and recruit and scaffold > 50 other proteins to control polarized cell growth and cytokinesis. Using super-resolution microscopy, we recently discovered that yeast septins are organized into 8-10 evenly-spaced vertical bars, or 'pillars', which align with actin cables to facilitate transport of secretory vesicles to the bud tip (Garabedian et al., 2020). In addition, we showed that septin pillars are decorated by the formin Bnr1 and the F-BAR protein Hof1, which directly inhibits Bnr1, directly binds to F-actin, and links septins and F-actin in vitro. Here, we begin to investigate how three other septin-associated proteins located at the bud neck potentially influence actin cable organization and function: IQGAP (Iqg1), type-II myosin (Myo1), and the F-BAR protein Syp1 (homolog of FCHO1/2). Importantly, most of what is known about the functions of these three proteins is restricted to cytokinesis, whereas here we are investigating their potential roles much earlier in the cell cycle, during bud development. Using auxin inducible degron (AID) tags, we show that acutely depleting cells of either Iqg1 or Myo1 leads to severe defects in actin cable organization and secretory vesicle transport. Further, we show that Syp1, similar to Hof1, directly binds to and bundles F-actin, and physically links septins and actin in vitro. However, in contrast to Hof1, Syp1 enhances (rather than inhibits) Bnr1-mediated actin nucleation. Overall, these results demonstrate that yeast septin pillars recruit multiple proteins that directly bind F-actin and/or formins, each making genetically unique contributions to controlling actin cable organization and dynamics.

Mathematical modeling and biochemical analysis support partially ordered CaM-MLCK binding

M. J. S. MacEwen[1], D. Rusnac[1], H. Ermias[1], J. P. Dexter[2], Y. Sancak[1]; [1]Pharmacology, University of Washington, Seattle, WA, [2]Data Science Initiative and Department of Human Evolutionary Biology, Harvard University, Cambridge, MA.

Smooth muscle contraction depends on the activation of myosin light-chain kinase (MLCK) by calcium ions (Ca^{2+}) and calmodulin (CaM). Despite extensive biochemical analysis of this system, aspects of the mechanism of activation remain controversial, and competing theoretical models have been proposed for the binding of Ca^{2+} and CaM to MLCK. Though many of these models make assumptions about binding parameters, there is little literature that tests the models biochemically. Nevertheless, the proposed Ca^{2+}-CaM-MLCK binding models are analytically solvable for an equilibrium steady state and give rise to distinct predictions that hold regardless of the numerical values assigned to parameters. These predictions form the basis of a recently proposed, multi-part experimental strategy for model discrimination. Our team implemented this strategy by measuring Ca^{2+}-CaM-MLCK binding using an *in vitro*, plate reader-based FRET system. This system quantifies the binding of either wild-type or mutant CaM with defective EF-hand domains to a FRET reporter that uses a fragment of MLCK protein as a proxy for the full protein. We also performed Octet analysis (Bio-Layer Interferometry) as a second method to detect binding between FR and CaM and to corroborate the principal findings of our plate reader-based FRET assays. We observed binding between MLCK and either wild-type CaM or CaM with an N-terminus EF-hand mutation; we observed zero binding between MLCK and CaM with a C-terminus EF-hand mutation. Interpretation of our binding data in light of the mathematical models suggests a partially ordered mechanism for the binding of CaM to MLCK. In the literature of systems biology, it is rare for competing mathematical models to be assessed using biochemical experimentation, much less for such experimentation to decisively favor one model above the others. We believe that our unconventional and powerful strategy brings a valuable fresh perspective to the field. Our work may also prove useful in a translational or pharmaceutical context, as MLCK and its activation by CaM have been linked to the pathogenesis of human disease.

B63/P1061

ROCK activation contributes to Arp2/3 complex-deficient macrophage phenotypes

R. Manickam, **J. Rotty**; Uniformed Services University, Bethesda, MD.

In recent years there has been significant interest in understanding the interplay between different populations of actin filaments, and the factors that organize them. One prominent example is the mutually antagonistic relationship between non-muscle myosin II and Arp2/3 complex. One aspect of this relationship is likely due to the well-established antagonism between Rho (which activates myosin II) and Rac (which activates Arp2/3 complex). However, there is likely still more mechanism to uncover regarding the interplay between these important cytoskeletal regulators. Previous findings revealed that genetic deletion of the Arp2/3 complex (*Arpc2-/-*) in macrophages generates phenotypes consistent with hyperactive myosin II. *Arpc2-/-* macrophages are significantly smaller than wildtype (WT), protrude in part via blebbistatin-sensitive surface blebs, and use myosin II to migrate faster than their WT counterparts. New data suggests that ROCK activation drives these *Arpc2-/-* phenotypes. ROCK-dependent phosphorylation of cofilin and myosin light chain are enhanced in KO macrophages. Furthermore, inhibition of ROCK or myosin II causes *Arpc2-/-* macrophages to spread and become less

elongated, thereby returning to a size and shape similar to WT cells. These data together suggest that significant elements of the *Arpc2-/-* macrophage phenotype may actually be due to ROCK/myosin II hyperactivation. Phenotypes consistent with enhanced cortical contractility led to the hypothesis that Piezo mechanosensitive ion channels may be activated in the *Arpc2-/-* macrophages. Several groups have demonstrated that Piezo activation induces ROCK activity. Treatment of WT macrophages with the Piezo agonist Yoda1 was sufficient to rapidly disrupt lamellipodia and contract cells, replicating features of the *Arpc2-/-* phenotype. This suggests that enhanced Piezo-ROCK positive feedback overwhelms the Arp2/3 complex's antagonism toward ROCK. Future experiments will be focused on determining whether acute Arp2/3 complex regulation influences Piezo activity and myosin II's ability to access the actin cortex. These experiments have the potential to reveal a mechanism whereby a precise Arp2/3 and ROCK balance dynamically alters cell morphology and behavior.

B64/P1062

An unconventional myosin-based mechanism of vesicle transport in *Toxoplasma gondii*

J. A. Kellermeier, T. E. Sladewski, Jr, **A. T. Heaslip**; Molecular and Cell Biology, University of Connecticut, Storrs, CT.

In many eukaryotes, vesicle transport is driven by molecular motor proteins that bind and transport cargo along F-actin or microtubule tracks. In the apicomplexan parasite *Toxoplasma gondii (T. gondii)*, F-actin (Act1) and Myosin F (MyoF) transport numerous vesicular cargos, including secretory vesicles. However, it is unclear how MyoF and Act1 facilitate vesicle transport because their cellular organization and biochemical properties are poorly understood. To gain mechanistic insight into how Act1 and MyoF function to transport cargo, we recombinantly purified tag-free Act1 from SF9 cells, and used a real-time microscopy-based actin growth assay to show that Act1 can form long (>60 μm) F-actin filaments *in vitro* with a 10-fold higher critical concentration than mammalian actin. We then characterized the motile properties of MyoF on its native track. Using single-molecule imaging approaches, we find that MyoF is not processive as a single motor. However, teams of MyoF can move continuously towards the plus-end of F-actin, where they become retained. Surprisingly, the tail domain of MyoF also binds directly to F-actin bundles, raising the intriguing possibility that MyoF does not associate directly with vesicular cargo but instead functions as an actin organizer in the cell. To explore this hypothesis, the localization of MyoF-EmGFP was assessed using live cell microscopy. This revealed no vesicle enrichment; instead, MyoF had a dynamic filamentous organization throughout the cytosol. To determine if MyoF plays a role in actin organization, actin was visualized in live parasites using an Actin Chromobody (ActinCB) tagged with EmGFP upon MyoF knockdown. In control parasites, we observed highly dynamic actin filaments or bundles that underwent continual rearrangement. In contrast, MyoF knockdown resulted in the formation of large actin bundles adjacent to the Golgi which had drastically reduced dynamics. Collectively, these results demonstrate that MyoF influences vesicle transport by controlling the dynamics and organization of the actin cytoskeleton in *T. gondii*.

B65/P1063

Using MVID-Causing Mutations to Investigate MYO5B Motor Function

D. M. Bowman[1,2], M. J. Tyska[1,2], J. R. Goldenring[1,2,3]; [1]Department of Cell and Developmental Biology, Vanderbilt University School of Medicine, Nashville, TN, [2]Epithelial Biology Center, Vanderbilt University Medical Center, Nashville, TN, [3]Section of Surgical Sciences, Vanderbilt University Medical Center, Nashville, TN.

Myosin Vb (MYO5B) is a non-conventional myosin motor that has been implicated in plasma-membrane recycling and apicobasal polarity, primarily in the intestinal epithelium and liver. Mutations in MYO5B lead to the autosomal recessive disorder microvillus inclusion disease (MVID) that causes life-threatening diarrhea in neonates due to the mis-trafficking of apical transporters and proteins. MVID-causing MYO5B mutations are truncations or frameshifts that can lead to loss of MYO5B and point mutations in specific domains of the myosin motor. It is unknown how individual point mutations impact the function of the MYO5B motor. Understanding how different MVID-causing mutations in MYO5B disrupt the function of the motor functionality is critical to learning how MYO5B operates within the apical recycling and delivery pathways. I hypothesized that point mutations in the MYO5B motor head lead to defects in motor functionality by impacting the ability to bind actin, translocate, or hydrolyze ATP. To address my hypothesis, I used a live-cell assay to examine the functionality of the MYO5B motor and mutants independently of the cargo domain. I created a truncated MYO5B (amino acids 1-1015) motor construct with a C-terminal triple citrine tag and constructs containing select patient MYO5B motor mutations. The MYO5B motor domain constructs were co-expressed with mCherry-espin in the protrusion forming cell line, LLC-PK-CL4. The localization of the MYO5B-motor at the tips of microvilli indicated a functional motor, while a lack of MYO5B-motor at the tips of microvilli indicated a dysfunctional motor. A tip to cytoplasm ratio was used to quantify this change in distribution. In accordance with previous literature, the wild-type MYO5B motor localized to the tips of microvilli with a ratio of 4.087, while the P660L mutation localized to the bases of microvilli and had a tip ratio of 0.1000, providing more evidence that this mutation is a rigor mutation. Patient mutations I408F and R824C did not accumulate at the tips of microvilli with a tip ratio of 0.1380 and 0.4963, respectively. Surprisingly some MVID-causing MYO5B mutations did not fully impair MYO5B motor function. G519R had a tip ratio of 1.870, and D492G had a tip ratio of 1.660. Further investigation needs to be done to determine the effect these mutations have on the overall protein function. Studying the subtle differences in the phenotype of patient mutations could lead to a better understanding of the disease pathology and MYO5B function.

B66/P1064

Bending forces and nucleotide state jointly regulate F-actin structure

M. J. Reynolds, C. Hachicho, A. G. Carl, R. Gong, G. M. Alushin; Laboratory of Structural Biophysics and Mechanobiology, The Rockefeller University, New York, NY.

ATP hydrolysis-coupled actin polymerization is a fundamental mechanism of cellular force generation. In turn, force and actin filament (F-actin) nucleotide state regulate actin dynamics by tuning F-actin's engagement of actin binding proteins (ABPs) through unknown mechanisms. Here, we show that actin nucleotide state modulates F-actin structural transitions evoked by bending forces. Cryo-electron microscopy structures of ADP- and ADP-P_i-F-actin with sufficient resolution to visualize bound solvent reveal inter-subunit interfaces bridged by water molecules that could mediate lattice flexibility. Despite

extensive ordered solvent differences in the nucleotide cleft, these structures feature nearly identical lattices and essentially indistinguishable protein backbone conformations unlikely to be discriminable by ABPs. We next introduce a machine-learning enabled pipeline for reconstructing bent filaments, allowing us to visualize both continuous structural variability and side-chain level detail. Bent F-actin structures reveal major rearrangements at inter-subunit interfaces characterized by striking alterations of helical twist and deformations of individual protomers, transitions which are distinct in ADP- and ADP-P_i-F-actin. This suggests phosphate rigidifies actin subunits to alter F-actin's bending structural landscape. We therefore propose actin nucleotide state can serve as a co-regulator of F-actin mechanical regulation, as bending forces evoke nucleotide-state dependent conformational transitions that are likely detectable by ABPs.

Phactr4 Coordinates with Arp2/3 Complex to Drive Membrane Protrusion in Multiple Macrophage Contexts

R. Manickam, J. D. Rotty; Biochemistry, USUHS, Bethesda, MD.

There are several human diseases, termed "actinopathies" which result from genetic variants of actin cytoskeleton proteins, leading to clinical immunodeficiencies. Of these, several actinopathies are linked, directly or indirectly, to dysregulated Arp2/3 complex function. While the function of Arp2/3 in the structural actin cytoskeleton has been well characterized, the potential mechanisms underlying heightened inflammatory phenotypes and immune dysfunction related to Arp2/3 deficiency remain less well understood. Unpublished data from our lab uncovered a novel potential Arp2/3 interacting protein called Phactr4, a relatively understudied protein which binds protein phosphatase 1 (PP1) as well as monomeric actin. Previous findings have shown that genetic deletion of the Arp2/3 complex (*Arpc2-/-)* in macrophages leads to phenotypic changes including increased serine/threonine phosphorylation of several proteins, including: phospho-cofilin, phospho-myosin light chain, p-ERK, p-P38, p-P65 and others. This points to a link between phosphoregulation and the Arp2/3 complex. We hypothesize that Phactr4 provides specificity to PP1 in certain dynamic contexts by coordinating with the Arp2/3 complex. Subpopulations of Phactr4 co-localize with Arp2/3 at the leading edge, and this population increases after induced cell spreading. Interestingly, *Arpc2-/-* macrophages display differential phagocytic ability, where the CR3 pathway is much less capable at internalizing iC3b-opsonized beads, while the defect in internalization of IgG-opsonized beads is less severe. Our preliminary work suggests that Phactr4 is preferentially localized to CR3-driven phagocytic cups, and is largely absent from FcR-driven phagocytic cups. These data together suggest that Phactr4 and Arp2/3 may be coordinating to drive membrane protrusion during certain dynamic cellular events, such as cell spreading, directed migration, and complement mediated phagocytosis. Future experiments will focus on characterizing Phactr4 deficient macrophages and whether Arp2/3 complex activity recruits Phactr4 to the leading edge. Understanding the Arp2/3-dependent interactions involved with the less well characterized Phactr4-PP1 complex will help us better understand the mechanisms underlying migration and phagocytosis in an immunological context.

Determining the role of Plastin-3 in osteoblast mineralization and mechanosensation

S. M. Chin, S. Jansen; Washington University in St. Louis, Saint Louis, MO.

Plastin-3 (PLS3) is a calcium-sensitive actin-bundling protein that has recently been linked to the development of childhood-onset osteoporosis. The physiological role of PLS3 in bone health is unclear and, by extension, it also remains an open question how disruption of PLS3 affects cellular functions and ultimately contributes to early-onset osteoporosis. Here, we investigated the role of PLS3 in focal adhesions, which are large molecular complexes that link the actin cytoskeleton to the ECM and contribute to cellular processes such as mechanosensation and cell adhesion. Our results demonstrate that endogenous PLS3 shows a distinct localization in nascent vs. mature focal adhesions. In nascent focal adhesions, PLS3 shows a diffuse localization, however, in mature focal adhesions, PLS3 closely colocalizes with the actin stress fiber in the tail end of the focal adhesion. Interestingly, characterization of PLS3 pathogenic mutations defective in calcium-sensitivity and/or bundling activity reveals altered localizations within focal adhesions, suggesting that both calcium-regulation and bundling contribute to the function of PLS3 in focal adhesions. To gain more insight into the role of PLS3 in focal adhesions, we tested how control and PLS3 knockdown osteoblast cells sense/respond to changes in substrate stiffness using polyacrylamide hydrogels coated in Matrigel. While control cells plated on substrates of different stiffnesses exhibit increases in cell size in response to increasing substrate stiffness, PLS3 knockdown cells exhibit similar sizes regardless of substrate stiffness. Characterization of the actin cytoskeleton in control cells demonstrates changes to the actin cytoskeleton on stiffer substrates consistent with increased cell tension, including formation of actin stress fibers and larger focal adhesions, while PLS3 knockdown cells display similar cytoskeletal morphologies regardless of substrate stiffness. Taken together, these findings suggest that PLS3 knockdown osteoblasts are impaired in either sensing changes to the stiffness of their environment or transducing those cues to the actin cytoskeleton, which may contribute to the development of osteoporosis in patients carrying mutations in the PLS3 gene.

An interphase actin wave promotes mitochondrial content mixing to maintain cellular homeostasis

S. M. Coscia[1], A. S. Moore[2], E. L. F. Holzbaur[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]Howard Hughes Medical Institute, Ashburn, VA.

Cellular health is dependent on mitochondrial homeostasis and the proper regulation of mitochondrial dynamics. We discovered a mechanism regulating mitochondrial dynamics via a cycling wave of actin polymerization/depolymerization. In metaphase the force of actin polymerization propels mitochondria in a comet-tail mechanism, resulting in equivalent partitioning of mother cell mitochondria between daughters. Actin cycling persists in interphase, however during this cell cycle stage F-actin assembly leads to mitochondrial fission, as we observed fragmentation dependent on the essential fission mediator DRP1. We hypothesized that cycling produces force which is resisted by tethering of mitochondria to microtubules, leading to mitochondrial tubulation and thus fission. In support, upon chemical microtubule depolymerization, actin wave-associated mitochondria ceased to fragment and instead displayed enhanced motility as revealed by tracking and displacement index analysis. Next, we focused on the machinery driving cycling, which is blocked by inhibitors of the kinase CDK1. We probed for the involvement of putative CDK1-regulated F-actin nucleators, including the formin FMNL1. Depletion of FMNL1 blocked actin cycling and expression of a non-phosphorylatable mutant at the CDK1

site had a dominant negative effect. We next probed the interphase function of this wave. We noted a loss of mitochondrial membrane potential, as measured by TMRE uptake, in cells depleted of FMNL1. Moreover, Seahorse analysis indicated that FMNL1-depleted cells consumed oxygen at a slower rate, leading to lower ATP levels. While these data indicate that interphase cycling is required to maintain mitochondrial health, we found that the actin wave continues to propagate following CCCP-induced mitochondrial depolarization, indicative that altered mitochondrial health does not feed-back to inhibit cycling. Finally, we asked if the interphase wave promotes mitochondrial content mixing, required to maintain mitochondrial function. In support, inhibition of cycling blunted the spread of mitochondrially-targeted photoactivatable GFP and mitochondrial tracking revealed that mitochondria fragmented by the wave often re-fused with distinct neighbors. Thus, we propose that interphase actin cycling maintains mitochondrial health by enhancing content mixing to promote inter-organelle complementation.

Delphilin FH2 Linker Subdomain Prolines affect Profilin-Actin Polymerization

B. Christian, M. Quinlan; Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, CA.

Formins make up a large family of actin-binding protein that nucleate actin filaments and promote filament elongation. The formin, Delphilin, is uniquely expressed in Purkinje cells, a highly branched neuron important for learning. Its interaction with Glutamate Receptor Delta 2 (GluRδ2) at the post-synaptic density has been documented, but otherwise Delphilin's biological role remains unknown. We previously biochemically characterized Delphilin as an actin nucleator which preferentially polymerizes non-muscle actin over muscle actin isoforms. Close examination of Delphilin's actin-binding FH2 domain shows that the Linker subdomain has a high proline-content compared to other formin family Linker subdomains: 5 prolines of 19 total amino acids in human Delphilin. Most Linkers are on average 20 residues long and thought to be disordered. The proline residues in the Delphilin-Linker are proximally placed such that there is a high probability of a polyproline II helix in this Linker, making it more rigid than most Linkers. I am investigating the contribution of this Linker subdomain to Delphilin's actin nucleating activity. I purified a construct of the C-terminal half of human Delphilin (hDelFF), including the FH1 and FH2 domains (Delphilin has no tail). I also created a version in which the prolines in the Linker are mutated to glycines (hDelFF-LM). With these, I performed bulk elongation assays with pyrene-actin. Both the hDelFF and hDelFF-LM constructs completely inhibit actin filament elongation at saturating concentrations, with a K_d of about 10 nM. Interestingly, I observe a difference when profilin is added. With profilin, hDelFF-mediated elongation is not fully inhibited at saturation. In contrast, the hDelFF-LM slows elongation more effectively than the wild-type hDelFF construct. Thus, the Linker subdomain is important for actin polymerization when using profilin-actin. We are working to determine the mechanism and whether the observed property is specific to Delphilin or present among formins. We are also looking into how the FH1 or profilin-actin may change a formin's FH2 gating properties. Gating is thought to be a characteristic solely attributed to the FH2 domain, but literature suggests that the addition of profilin may alter the gating limit in several formins. I am investigating this phenomenon in Delphilin and other highly characterized formins.

B71/P1069

β-actin protein is essential for retinal physiology

P. Vedula[1], M. E. Fina[2], B. A. Bell[3], S. S. Nikonov[2], A. S. Kashina[1], D. W. Dong[1]; [1]Biomedical Sciences, University of Pennsylvania, Philadelphia, PA, [2]Department of Neuroscience, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, [3]F.M. Kirby Center for Molecular Ophthalmology, Scheie Eye Institute, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Actins are abundant and ubiquitously expressed proteins that are essential components of the cytoskeleton in both muscle and non-muscle cells. Higher vertebrates express two non-muscle actins - β- and γ- cytoplasmic actins. These two proteins differ by only 4 conservative substitutions in their N-terminus, that have been completely preserved over 320 million years of evolution. The functional differences between these nearly identical, and highly conserved proteins have been a mystery. Here, we addressed the role of these N-terminal substitutions using a gene-edited mouse model expressing γ-actin both natively and from the nearly intact β-actin gene. These mice completely lack β-actin protein but retain the nucleotide-level elements of both cytoplasmic actin genes. Thus, any phenotypes in these mice are caused by the replacement of β-actin-specific N-terminal amino acids with those of γ-actin, making this model uniquely suited to address the biological role of these amino acid differences *in vivo*. Strikingly, while these mice undergo normal embryogenesis, the absence of β-actin leads to physiological defects in the retina, including reduced light sensitivity in photoreceptors and progressive retinal degeneration, accompanied by disorganization of actin structures in the retina layers. Importantly, the phototransduction G-protein is mislocalized in the photoreceptors. Furthermore, these mice show prominent defects in the microvilli, actin-rich cytoplasmic protrusions, of the retinal pigment epithelium and the Müller glial cells . Our results demonstrate a crucial function for the highly conserved amino acid differences between β- and γ-actin in the proper structural organization and physiology of the mammalian retina.

Vinculin organizes actomyosin and maintains epithelial cell-cell junctions at tricellular tight and adherens junctions

J. N. Iseler, L. van den Goor, A. L. Miller; Department of Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI.

Epithelial cells form barriers that coat and protect organs and organisms from their environments. Epithelial tissue function requires both adherens junctions to adhere cells together and tight junctions to create a selectively permeable barrier between neighboring cells. Junctional integrity must be maintained when epithelia are challenged by mechanical stress, such as food passing through the intestines or the bladder expanding. Vinculin, a mechanosensitive protein, strengthens adherens junctions in response to mechanical stress through strengthening connections to an actomyosin (F-actin and Myosin II) array. We hypothesize that Vinculin reinforces tricellular tight and adherens junctions in response to increased tension by maintaining proper actomyosin organization. To test this idea, we challenged the junctions of the gastrula stage *Xenopus laevis* epithelium using two different techniques: addition of extracellular ATP and a tissue stretcher. First, we aimed to characterize how Vinculin and F-actin are reorganized at adherens junctions after either tension-increasing treatment by quantifying changes in fluorescence intensity of mNeon-Vinculin and LifeAct-RFP (an F-actin probe). After ATP treatment, we found that Vinculin intensity is enriched at tricellular junctions and reorganizes from

distinct “spots” into elongated “spokes” along the junction. Our preliminary data shows similar trends for Vinculin localization after using the tissue stretch device. In both stretched and ATP-treated tissues, medial apical and junctional F-actin intensity is increased under high tension. Next, we aimed to investigate whether Vinculin supports tricellular junction integrity. To test this, we performed immunofluorescence imaging of the tricellular tight junction protein Angulin-1 and actomyosin after Vinculin knockdown. Preliminary experiments show that Vinculin knockdown decreases Angulin-1 intensity at tricellular junctions and disrupts actomyosin organization at cell vertices, suggesting that Vinculin plays a role in maintaining tricellular tight junctions. Taken together, these data suggest that mechanosensitive recruitment of Vinculin to tricellular adherens junctions under increased tension is essential for maintaining junctional integrity and proper actomyosin organization.

B73/P1071

Fast actin disassembly and mechanosensitivity of the actin crosslinking protein fimbrin during clathrin-mediated endocytosis

S. Mousavi[1,2], X. Li[1,2], M. Lacy[3,2], J. Berro[1,2,4]; [1]Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, [2]Nanobiology Institute, Yale University, West Haven, CT, [3]Yale School of Medicine, New Haven, CT, [4]Department of Cell Biology, Yale University School of Medicine, New Haven, CT.

The actin cytoskeleton is central to force production in numerous cellular processes in eukaryotic cells. During clathrin-mediated endocytosis (CME), actin dynamic is required when membrane tension or turgor pressure is large. Previous experimental work from our lab showed that several endocytic proteins, including actin and actin interacting proteins, turn over several times during the formation of a vesicle during CME in yeast. Their dwell-time distributions, which indicate how long individual molecules stay at endocytic structures, have a peak of around 1 s, and the distribution for the filament crosslinking protein fimbrin contains a second peak of around 0.5 s. To better understand the nature of these dwell-time distributions, we developed a stochastic model for the dynamics of actin and its binding partners. Our model demonstrates that very fast actin filament disassembly is necessary to reproduce experimental dwell-time distributions. Our model also predicts that actin-binding proteins rapidly decorate growing filaments and filaments are fully decorated. Last, our model predicts that fimbrin detachment from actin endocytic structures is mechanosensitive to explain the extra peak observed in the dwell-time distribution for the actin crosslinker fimbrin.

B74/P1072

Adaptive Role for Actin Cross-linkers in Force Generation at Sites of Clathrin-mediated Endocytosis in Yeast

J. Hill, D. Drubin; University of California, Berkeley, Berkeley, CA.

In budding yeast, clathrin-mediated endocytosis (CME) requires the synergistic activities of actin polymerization and actin-binding proteins such as crosslinkers to generate the forces required for invagination of the plasma membrane against high turgor pressure. Despite their essential role in actin force generation, few studies have addressed actin crosslinker function and mechanism in live cells. Endocytic internalization is impeded when the main yeast actin filament crosslinker, the fimbrin-related protein Sac6, is absent, or when membrane tension is raised by elevating turgor pressure. Here we combine live cell imaging studies of Sac6 and mathematical modeling to gain new insights into the role

of actin crosslinkers in actin force generation. By quantitatively measuring the maximum number of Sac6 molecules at sites of CME in cells with elevated turgor pressure, we show that sites with more crosslinkers are more effective at internalization under high load. Additionally, we used an experimentally constrained, agent-based mathematical model to recapitulate the result that endocytic networks with more double-bound crosslinkers internalize the plasma membrane against increased turgor pressure more effectively. In simulations, endocytic networks with more double-bound crosslinkers have less actin on average than in networks with fewer double-bound crosslinkers, consistent with more filaments experiencing a stall force as they grow against the membrane. These networks also have a higher fraction of growing plus ends oriented towards the plasma membrane where addition of new actin monomers contributes to force generation and internalization of the vesicle. Our results provide a richer understanding of the crucial role played by actin filament crosslinkers during actin network force generation, highlighting the contribution of these proteins to the adaptive response of the actin cytoskeleton to increased load in the context of clathrin-mediated endocytosis.

Higher-Order Actin-Based Structures

Cdc42-Dependent Perinuclear Stress Fibers are a Functionally Distinct Network With Septins, Myo18Aalpha and MRCK

M. Utgaard, S. Chandrasekar, P. Oakes, J. Beach; Cell and Molecular Physiology, Loyola University, Chicago, IL.

Stress fibers are actomyosin bundles that form throughout many cell types. Numerous types of stress fibers have been reported with distinct compositions, assembly mechanisms, and functions. Ventral stress fibers are located on the ventral cortex and are anchored to the substrate on both ends by focal adhesions. A distinct sub-population of ventral stress fibers are the perinuclear stress fibers (PSF). Relative to other stress fibers throughout the cell, these PSFs have been less explored and their function remains ambiguous. Consistent with published studies, in addition to actin and myosin 2, we find that the perinuclear network contains the Cdc42 effector kinase MRCKα, the motor-dead myosin 18Aα, and septins, a fourth component of the cytoskeleton involved in numerous cellular processes. Interestingly, our super-resolution imaging reveals that while septins often align with the actomyosin stress fibers, they also appear to form distinct, adjacent structures. In contrast, septins are near perfectly coincident with myosin 18Aα and MRCKα, which were previously known to complex with one another. Considering Cdc42 is a known upstream modulator of both MRCK and septins, we explored Cdc42 contributions to PSFs. We observe that wild-type EGFP-tagged Cdc42 localizes to PSFs, but this localization is dramatically enhanced in a constitutively-active Cdc42 mutant. Constitutively-active Cdc42 expression also enhanced septin recruitment to PSFs, and inhibition of Cdc42 with a small molecule (ZCL278) caused septins to dissociate from PSFs and relocalize to the peripheral cortex. Fluorescent recovery after photobleaching (FRAP) of fibroblasts expressing EGFP-sept2 demonstrated that septin on PSFs has a slower turnover than septin that is localized at the cortex, consistent with these being two distinct septin structures. Finally, we find that PSFs that are decorated with septins/MRCKα/myosin18Aα do not exert significant traction stresses relative to other stress fibers in the cell. Our testable working model is that this septin/MRCKα/myosin18Aα network is inhibiting actomyosin force generation to support nuclear mechanics.

B76/P1074

Tunable autoinhibition of plastins/fimbrins defines their unique role in the actin cytoskeleton organization

C. Schwebach[1], E. Kudryashova[1], R. Agrawal[2], W. Zheng[3], E. Egelman[3], **D. Kudryashov**[1]; [1]Ohio State University, Columbus, OH, [2]Cornell University, Ithaca, NY, [3]University of Virginia, Charlottesville, VA.

Plastins (a.k.a. fimbrins) are conserved actin-bundling proteins contributing to the organization of lamellipodia, microvilli, and the contractile ring. Accordingly, plastins participate in various cellular events such as motility, endocytosis, and cytokinesis by organizing actin in both aligned bundles (parallel or antiparallel) and branched networks. We hypothesized that this unique versatility of plastins stems from a tunable inhibitory association between their actin-binding domains (ABD1/2). We demonstrate here that while ABD2 in isolation can bind actin with a low nanomolar Kd, it is potently inhibited by an equally strong interaction with ABD1, resulting in a rather weak bundling. Uncoupling the ABDs via phosphorylation of a Serine residue at their interface (or a mutation mimicking thereof) strongly potentiates actin cross-linking and dramatically affects the actin cytoskeleton in transfected cells. We suggest that the strong and tunable allosteric inhibition between the domains allows plastins to modulate the cross-linking strength, contributing to the remodeling of actin assemblies of different morphologies and defining the unique place of plastins in actin organization.

B77/P1075

Human Epithelial Cell Polarity is Dependent on ARHGAP18, an ERM Specific RhoA GAP, to Regulate Microvilli and Apical Actomyosin Networks.

A. T. Lombardo, C. A. R. Mitchell, R. Zaman, D. J. McDermitt, A. Bretscher; Molecular Biology and Genetics, Cornell University, Ithaca, NY.

Vertebrate tissue assembly relies on the mechanical and biochemical polarity of cells, with each cell having regions of distinct morphologies and protein concentrations. Creation of polarized cellular regions is defined in part by the broad gradients of small GTP-binding proteins which regulate actomyosin cytoskeletal networks. These networks link to the plasma membrane to establish the cell structures that define each differentiated cell. Here, we show ARHGAP18 binds to, and is activated by, the actin-membrane-linker ezrin, to regulate RhoA specifically at the apical membrane of epithelial cells. We utilize human cells totally lacking the expression of all three ERMs (Ezrin Radixin Moesin) their activating kinases LOK and SLK or ARHGAP18 to define a RhoA negative feedback loop regulating polarity determination through actomyosin organization. Using spinning disc confocal imaging, scanning electron microscopy and Super-Resolution Stochastic Optical Reconstruction Microscopy (STORM) we track individual microvilli and visualize changes in single actin filaments to define a local regulation of RhoA on a microdomain scale. Additionally, we utilize fluorescent biosensors to visualize the localized activation of RhoA and downstream reorganization non-muscle myosin-II from within the terminal web to aberrant activation inside microvilli when ARHGAP18 is lost. Collectively this work seeks to address a decades old question of how the ERM family of proteins negatively regulate the RhoA signaling pathway in humans. Our findings offer insight into how cells simultaneously regulate both whole cell scale polarity signals and the maintenance of specific cytoskeletal structures.

B78/P1076

An adhesion-based mechanism stabilizes apical microvilli at the margins of transporting epithelial cells

C. S. Cencer[1], J. B. Silverman[1], S. Mao[1], L. M. Meenderink[2], E. S. Krystofiak[1], B. A. Millis[1], M. J. Tyska[1]; [1]Vanderbilt University, Nashville, TN, [2]Vanderbilt University Medical Center, Nashville, TN.

Transporting epithelia of the kidney and small intestine utilize actin-supported cell surface protrusions, known as microvilli, to expand surface area available for solute transport. Microvilli found on the surface of these epithelia constitute a well-organized “brush border” made up of thousands of protrusions connected via a tip-localized intermicrovillar adhesion complex (IMAC) composed of cadherins CDHR2 and CDHR5. Previous work in our laboratory showed that microvilli of early, differentiating cells are unstable and exhibit a cycle of growth and collapse, while mature cells contain robust and stable clusters of microvilli. Whether the IMAC contributes to nascent microvilli accumulation and stabilization during cell differentiation remains unclear. Here we show that, at time points early in differentiation, epithelial cells present two general populations of microvilli: (1) a marginal population at the edges of cells, characterized by high protrusion density, and (2) a medial population characterized by much lower protrusion density. Strikingly, marginal microvilli extend across cell-cell junctions to physically contact microvilli on neighboring cells, using transjunctional CDHR2 and CDHR5 adhesion complexes. Additionally, Fluorescence recovery after photobleaching and microvilli tracking experiments revealed that transjunctional adhesion complexes between marginal microvilli are more stable than those bridging medial clusters of microvilli. Tracking analysis on live kidney proximal tubule CL4 cells showed that marginal microvilli are not motile, suggesting that transjunctional adhesion serves as an anchoring point for nascent microvilli. Given the stabilizing nature of transjunctional adhesion complexes, we predicted that cell-cell junctions may be influenced by apical CDHR2/CDHR5 transjunctional contacts. Indeed, in a CDHR2 KO mouse model and in CDHR2 KO CL4 cells, endogenous signal of tight junction protein ZO-1 is abnormal. As a result, KO cells exhibit increased dynamics within a monolayer, leading to stretched and disorganized cell phenotype. Overall, these findings suggest a new, adhesion-based mechanism for the stabilization of microvilli and support of cell-cell junctions, changing our understanding of how transporting epithelial cells utilize cell-cell contacts to create optimal tissue structure.

B79/P1077

Defining mechanisms of microvilli biogenesis using direct visualization

I. Gaeta[1], L. Meenderink[2], M. Postema[1], C. Cencer[1], M. Tyska[1]; [1]Vanderbilt University, Nashville, TN, [2]Veterans Affairs Tennessee Valley Health Care System, Nashville, TN.

Microvilli are actin-bundle-supported surface protrusions that play essential roles in diverse epithelial functions, from nutrient absorption to mechanosensation. Despite the importance of microvilli for proper epithelial cell function, the mechanism by which cells build microvilli and the proteins involved in this process are not well understood. Classic electron micrographs indicate the presence of an electron dense protein complex at the distal tips of microvilli, which has been long hypothesized to coordinate protrusion growth due to its proximity to the fast-growing ends of actin filaments. Indeed, time-lapse data revealed that specific factors, including epidermal growth factor pathway substrate 8 (EPS8) and insulin-receptor tyrosine kinase substrate (IRTKS) (also known as BAIAP2L1), appear in diffraction-limited puncta at the cell surface and mark future sites of microvillus growth. New core actin bundles elongate from these puncta in parallel with the arrival of ezrin and subsequent plasma membrane encapsulation.

In addition to de novo growth, we also observed that new microvilli emerge from pre-existing protrusions. Moreover, we found that nascent microvilli can also undergo collapse, resulting in disassembly of the core actin bundle itself. To further develop our understanding of microvilli biogenesis, we used a biotin proximity labeling approach to probe for new molecules involved in microvillus growth, using EPS8 as bait. Mass spectrometry of biotinylated hits identified a previously uncharacterized proximal protein, KIAA1671. In silico domain analysis indicates this protein is a large (~200 kDa), primarily disordered protein that contains few recognized domains. We find that KIAA1671 localizes to the base of the brush border in native intestinal tissue and polarized epithelial cell culture models, and to actin positive structures in non-polarized cell types. Furthermore, we find that KIAA1671 co-accumulates with EPS8 at sites of microvillus growth, suggesting that KIAA1671 is involved in the growth of microvilli. Thus, using biotin proximity labeling in conjunction with live cell imaging, we have identified a novel factor that targets to the apical surface of epithelial cells and may be involved in microvilli morphogenesis. These studies are the first to offer a temporally resolved microvillus growth mechanism and highlight factors that participate in this process; they also provide important insights on the growth of apical specializations that will likely apply to diverse epithelial contexts.

B80/P1078

A novel population of short actin filaments at stereocilia tips contribute to a tip-down widening mechanism

X. Liao[1], **B. Perrin**[1], C. Tung[1], J. F. Krey[2], P. G. Barr-Gillespie[3]; [1]Indiana University - Purdue University Indianapolis, Indianapolis, IN, [2]Oregon Hearing Research Center, Oregon Health and Science University, Portland, OR, [3]Oregon Health and Science University, Portland, OR.

Stereocilia are actin-based protrusions on auditory sensory cells that convert mechanical energy into ion influx upon deflection by sound waves. Stereocilia size is crucial for this mechanotransduction function. The length and width of a stereocilium is dictated by its core of bundled, parallel actin filaments (F-actin). The core filaments are oriented with their fast-growing barbed ends towards stereocilia tips and their slower-growing pointed ends oriented towards bases. F-actin in the stereocilia core is highly stable, but actin at stereocilia tips turns over more rapidly. Here, we provide evidence that the dynamic actin at tips includes short actin filaments (tip filaments) that are separate from the core filaments and suggest that these tip filaments contribute to stereocilia growth. We identified tip filaments by probing permeabilized postnatal mouse cochlear tissue with purified, exogenous His-tropomodulin1 (His-TMOD1). Tropomodulins are well-characterized proteins that bind pointed ends of actin filaments, but not barbed ends. His-TMOD1 labeled the tips of stereocilia in all rows before postnatal day 6 (P6), with labeling declining until P9. Since actin in the stereocilia core have only their barbed ends at stereocilia tips, we propose that the pointed ends detected by the His-TMOD1 probe are short actin filaments that are not part of the core. Tip filament levels are highest when stereocilia are widening, suggesting they may contribute to this aspect of stereocilia growth. Correspondingly, transient overexpression of EGFP-actin changed the distribution of pointed ends so they were more evident in the stereocilia shaft, which is consistent with actin filaments adding to the core in a tip-down fashion. In addition, live-cell imaging revealed that overexpressed EGFP-actin initially localized to stereocilia tips, but then extended down the stereocilia shaft over time. Super-resolution imaging of fixed samples showed that the newly expressed EGFP-actin signal surrounded the stable, preexisting F-actin core. Together, these data suggest a tip-down widening mechanism where tip filaments may initiate actin polymerization and create new parallel F-actin at the periphery of the stereocilia core.

B81/P1079

Comparative analysis of bacterial actin-based motility mechanisms

M. Bacher, D. Serwas, M. D. Welch; MCB, University of California, Berkeley, Berkeley, CA.

Bacteria in the genus *Rickettsia* are arthropod-associated obligate intracellular organisms that have evolved to utilize host cell components for their survival. After invading host cells and gaining access to the cytoplasm, many *Rickettsia* species polymerize host actin filaments on their surface and undergo actin-based motility. *Rickettsia* express two different bacterial proteins that drive motility. RickA is well conserved between species and promotes actin polymerization by activating the host Arp2/3 complex. Sca2 is more divergent between species, suggesting species-specific differences in its biochemical mechanisms of action. For the disease-causing spotted fever group species *R. parkeri*, actin-based motility occurs in temporally distinct phases, with "early" (<1h post infection) motility driven by RickA, and "late" (>8h post infection) motility driven by Sca2. The ancestral and non-pathogenic species *R. bellii* expresses orthologs of RickA and Sca2, but it remains unclear how these two factors contribute to the mechanism and timing of actin-based motility in this species. To examine the biochemical activities of *R. bellii* RickA and Sca2, we purified glutathione S-transferase (GST) fusion proteins. We found that GST-RickA and GST-Sca2 conjugated to fluorescent beads promote actin polymerization in *X. laevis* egg extract, suggesting a direct role in bacterial-induced actin assembly. We next examined the timing of *R. bellii* actin-based motility in infected A549 human lung epithelial cells. *R. bellii* only initiated actin-based motility at times >4h post infection, while *R. parkeri* initiated motility within 1h post infection. Moreover, actin tails formed by *R. bellii* were thinner in width and more curved in shape. To further compare the ultrastructure of *Rickettsia* actin tails, we have initiated cryo-electron tomography studies. Our initial observation of actin tails formed by *R. parkeri* revealed that individual actin filaments emanate from the bacterial pole and are organized into parallel unbranched arrays. Together, these data suggest that RickA and Sca2 orthologs from diverse *Rickettsia* species function to polymerize actin, yet there are species-specific differences that result in variations in the timing and mechanism of actin-based motility. Further comparative analyses will shed light on the evolution of motility mechanisms and their role in pathogenicity.

B82/P1080

Arp2/3 complex-nucleated, light-dependent filopodia in amoeboid algae perform bidirectional cyclosis

P. Avasthi, **C. D. MacQuarrie**; Arcadia Science, Berkeley, CA.

Chlorarachniophytes are a unique class of marine algae. Many species in this group perform amoeboid motility and can form long extensions reaching up to 1 mm in length and 2 µm in diameter. These extensions appear to serve multiple functions including predation, motility, and possibly photosynthesis. Through live-cell DIC imaging, we observed rapid, bidirectional cytoplasmic transport occurring in these extensions, reminiscent of cytoplasmic streaming in fungi and plant cells. Here we explore the contributions of the actin cytoskeleton to this unique structure. *Amorphochlora amoebiformis* and *Bigelowiella longifila* cells were treated with cytoskeletal drugs or fluorescent dyes and observed using confocal microscopy. We observed multiple components being trafficked through these extensions including mitochondria, chloroplasts, DNA, and tubulin. Furthermore, the formation of these extensions appears to be actin dependent. Treatment with actin polymerization inhibitors Latrunculin B or

Cytochalasin D resulted in stubby extensions, while treatment with CK-666, which inhibits the branched-actin nucleating Arp2/3 complex, prevented the formation of these extensions entirely. Surprisingly, these extensions are light-dependent, suggesting a novel link between chloroplast activity and actin nucleation in algae.

Liquid-like assembly of VASP catalyzes actin polymerization and bundling

K. Graham[1], A. Chandrasekaran[2], L. Wang[3], A. Ladak[1], E. Lafer[3], P. Rangamani[2], J. Stachowiak[1]; [1]The University of Texas At Austin, Austin, TX, [2]University of California San Diego, La Jolla, CA, [3]University of Texas Health Science Center at San Antonio, San Antonio, TX.

The actin cytoskeleton underlies many critical cellular processes including morphogenesis, trafficking, and motility. The organization of actin filaments into higher order networks or bundles is often required to sustain the forces involved in many of the mechanical functions of the cytoskeleton. Actin filament bundling is regulated by a family of actin-binding proteins. Recent work has revealed that several proteins comprising this cytoskeletal network have been found to undergo liquid-liquid phase separation. How might liquid-like phases contribute to filament organization and bundling? Here, we show that the processive actin polymerase and bundling protein, VASP, forms liquid-like droplets under physiological conditions. These VASP droplets catalyze actin polymerization and bundling through a mechanism that depends on the relative material properties of the filaments and the droplets. Specifically, as actin polymerizes within VASP droplets, elongating filaments partition to the perimeter of the droplet to minimize filament curvature, forming an actin-rich ring within the droplet. The rigidity of this ring is balanced by the droplet's surface tension, as predicted by a continuum-scale computational model. However, as actin polymerizes and the ring grows thicker, its rigidity increases and eventually overcomes the surface tension of the droplet, deforming into a linear bundle. The resulting bundles contain long, parallel actin filaments that grow from their tips, reminiscent of filopodia. Once the parallel arrangement of filaments is created within a VASP droplet, it propagates through the addition of new actin monomers to achieve a length that is many times greater than the initial droplet. Significantly, the fluid nature of the droplets is critical for bundling, as more solid droplets resist deformation by preventing the rearrangement of filaments that is necessary to form bundles. These results reveal a novel mechanism of filament bundling that may be relevant to the assembly of cellular architectures such as filopodia, stress fibers, and focal adhesions.

B84/P1082

Physical and kinetic determinants of shape changes in liquid droplets of processive actin polymerase, VASP containing actin filaments

A. Chandrasekaran[1], K. Graham[2], L. Wang[3], A. Ladak[2], E. Lafer[3], J. Stachowiak[2], P. Rangamani[1]; [1]Mechanical and Aerospace Engineering, University of California, San Diego, San Diego, CA, [2]Department of Biomedical Engineering, University of Texas at Austin, Austin, TX, [3]Department of Biochemistry and Structural Biology, University of Texas Health Science Center at San Antonio, San Atonio, TX.

Actin, one of the most abundant cytoskeleton proteins in cells, aided by accessory proteins, forms elaborate networks of a wide array of shapes tailored specifically for cellular functions such as cell growth, adhesion, and locomotion. Growing evidence suggests that phase separation of essential proteins, including the actin-binding proteins, promotes spatial and dynamic control of cell chemical

responses. However, the role of phase separation in mechanochemical responses of actin networks is poorly understood. Here, we use computational modeling to study liquid droplets of the processive actin polymerase Vasodilator stimulated phosphoprotein (VASP). Actin selectively partitions inside the VASP droplets to form actin filaments resulting in an actin shell confined in VASP droplets. Using a continuum modeling, we show that as actin accumulates, VASP droplets deform from circular to elliptical droplets. Additionally, we predict that the droplet deformation happens above a critical actin ring thickness. These modeling predictions are consistent with experimental observations. The shape changes of the droplets are driven by the competition between the actin bending energy and the droplet surface energy. Finally, we explore the kinetic aspects of such transitions using agent-based modeling in CytoSim and find the conditions that favor the formation of an actin shell and ring inside a droplet with high surface energy. We identify filament elongation rate and crosslinker unbinding rate as crucial parameters that dictate the final shape of the actin network. In summary, we have developed a framework to understand how the chemical evolution of actin filaments affects the mechanical properties of a liquid droplet-actin system.

Molecular condensation regulates actin nucleation during immune signalings

Y. Miao; Nanyang Technological University, Singapore, SINGAPORE.

Rapid actin cytoskeleton remodeling on demand is essential to coordinate cellular processes during eukaryotic cell immune signaling. Host cells respond acutely by increasing actin polymerization and stabilization during host-pathogen communication. For example, upon recognizing pathogenic microbe, plants trigger rapid actin polymerization via condensing, thereby activating the actin nucleation factor via diverse mechanisms on the cell surface. Here, I will present a central mechanism by which membrane-associated formin condensation remodels actin cytoskeleton dynamically, in time and space, during early plant immune signaling. In addition, plant type I-formin is plasma membrane-integrated nucleator behavior like a mammalian integrin protein, which senses extracellular biophysical and chemical cues. We will also present the mechano-regulation of formin condensation and activity during cell immune signaling by modulating plant surface scaffolding structures, cell wall (CW)-plasma membrane (PM)- and actin cytoskeleton (AC) continuum.

B86/P1084

Ribonucleoprotein condensates regulate actin network polarization in the filamentous fungus Ashbya gossypii

Z. Geisterfer, A. Gladfelter; Biology Department, University of North Carolina At Chapel Hill, Chapel Hill, NC.

The dynamic restructuring and the precise positioning of polarized cytoskeletal networks, such as the actin cytoskeleton, is essential for the development of diverse cell morphologies, cell motility, cell signaling, and a host of other processes. Despite nearly 100 years of active research and a deep inventory of actin-regulatory proteins, how a cell positions these molecules at the right place and time remains poorly understood. Recent insights have implicated a role for biomolecular condensates in the spatial organization of the actin cytoskeleton in neurons, T-cells, and yeast. Though the mechanisms by which biomolecular condensates contribute to the regulation of the actin cytoskeleton are poorly understood, biomolecular condensation represents a potentially powerful mechanism by which cellular

material may concentrated or focused. Early studies in the Gladfelter lab have shown a necessary role for the RNA-binding protein, Whi3, in promoting lateral branching events in the genetically tractable model system, A. gossypii. Notably, Whi3 phase-separates at existing and incipient branch sites with mRNA transcripts coding for the formin, Bni1, and master-scaffolder, Spa2. Importantly, preliminary studies also show Whi3-coated beads are sufficient to generate and maintain polarized actin networks in A. gossypii cell-free extracts, showing Whi3 ribonucleoprotein (RNP) granules are sufficient to trigger actin assembly without other spatial landmarks. In addition, Whi3-bound mRNA transcripts are subject to translational repression in bulk cell-free extract studies, suggesting that Whi3 RNP granules regulate actin network polarization through focused protein synthesis of actin machinery and scaffolders. It remains unknown if and how Whi3 condensates control translation, and how the activity of these compartments are then coordinated. Similar membrane-less regulatory "hubs" are likely conserved in higher eukaryotes and may act in signal transduction in the post-synapse in neurons, or in homeostasis in large syncytia such as muscle cells or the placenta.

Substrate stiffness regulates tunneling nanotube formation and function

S. Lin[1], A. P. Liu[1,2,3,4]; [1]Department of Mechanical Engineering, University of Michigan, Ann Arbor, MI, [2]Department of Biomedical Engineering, University of Michigan, Ann Arbor, MI, [3]Cellular and Molecular Biology Program, University of Michigan, Ann Arbor, MI, [4]Department of Biophysics, University of Michigan, Ann Arbor, MI.

Cells constantly sense and respond to mechanical stimuli from their microenvironment. One of the most studied mechanical factors in the complex microenvironment is substrate stiffness. Although substrate stiffness is known to be a critical physical factor mediating cell dynamics and function, how it regulates actin-based protrusions is incompletely understood. As long-distance cell-cell communication conduits, tunneling nanotubes (TNTs) are actin-based membranous protrusions that hover over the substrate and extend over tens of micrometers. Although the molecular mechanisms of TNT formation have been intensively studied, it remains an open question concerning the mechanical d mechanisms underlying TNT formation. Here, by generating a series of silicon substrates covering the range of matrix stiffness in physiological tissues, we demonstrate that substrate stiffness plays a critical role in TNT formation and function. Cells grown on softer substrates formed not only more TNTs but also longer TNTs with faster growth speed. Since traction force and cell mechanical properties such as membrane tension are known to be modulated by substrate stiffness, it is plausible that substrate stiffness regulates TNT via these biomechanical factors. Interestingly, we found that increase in TNT formation on softer substrate does not lead to increase in vesicle transfer, a functional criterion of TNT. We found that while efficiency of vesicle transfer is positively correlated with cell-cell connection by TNT, it is negatively correlated with TNT length, suggesting that the length of TNT may be a critical factor when considering TNT functionality. Altogether, our findings reveal that substrate stiffness not only regulates the biogenesis and dynamics of TNT, but also impact the functionality of these structures. As tissue stiffness changes in numerous disease conditions, our study sheds light on how substrate stiffness could be linked to direct cell-cell communication during disease progression.

B88/P1086

Anillin and myosin synergistically contract actin networks

A. Beber, R. Podhájecký, P. Šliková, Z. Lánský, M. Braun; Institute of Biotechnology CAS, Prague, CZECH REPUBLIC.

Actin-based contractility underlies the dynamics of the cell cortex and cytokinesis. Myosin is the canonical molecular motor propelling this contractility. Additionally, anillin, an actin filament crosslinker, present at the cortex and the cytokinetic contractile ring, likewise generates contractile forces. While anillin binds both actin and myosin, it is unclear if the proteins cooperate. Here we show in a minimal reconstituted system that anillin and myosin synergistically control the contraction of actin filament bundles, two-dimensional networks and rings. This can be explained by our observation that only in the presence of both proteins single actin filaments robustly contract, while myosin or anillin alone, did not alter the geometry of single actin filaments. Based on our simulations we hypothesize that this process depends on the direct interaction between these two proteins. Our results suggest anillin promotes myosin-dependent rearrangements within actin networks

B89/P1087

Cortical tension drug screen links mitotic spindle integrity to RhoA pathway

D. Wang[1], **P. Gunning**[2], Y. Wang[3], X. Di[1], F. Wang[4], A. Wanninayaka[2], D. Jin[1], E. Hardeman[2]; [1]University of Technology Sydney, Sydney, AUSTRALIA, [2]University New South Wales, Sydney, AUSTRALIA, [3]University of Sydney, Sydney, AUSTRALIA, [4]Beihang University, Beijing, CHINA.

Mechanical force generation plays an essential role in many cellular functions including mitosis. Actomyosin contractile forces mediate the separation of daughter cells in mitosis and are implicated in mitotic spindle integrity via cortical tension. To identify potential novel regulators of mitotic cortical tension we conducted a small molecule screen of compounds previously identified from a high chemical diversity library of compounds that impact the organization of the actin cytoskeleton. In addition to screening 150 compounds that produce diverse reorganization of the actin cytoskeleton we also tested 32 compounds that are known to impact progression through mitosis. We initially measured the levels of actin and myosin in the mitotic cortex as a first pass followed by direct measurement of cortical tension to identify proteins implicated in this process. We show inhibitors of Rho kinase and compounds that target the actin-associated protein tropomyosin 3.1 (Tpm3.1) are the most potent inhibitors of cortical actomyosin enrichment and tension. Tpm3.1 is essential for non-muscle myosin 2A (NM2A)-mediated cortical tension independent of the cortical levels of actin and NM2A. The dependence of cortical tension on Tpm3.1 is isoform specific since knockdown of Tpm4.2 has no impact on cortical tension. We further demonstrate a critical role for cortical tension in Tpm3.1-driven rescue of mitotic spindle integrity induced by anti-cancer microtubule depolymerizing agents. Induction of microtubule depolymerization acts via GEF-H1 release and downstream RhoA activation to increase cortical actomyosin and Tpm3.1. Inhibition of GEF-H1 and other steps in the RhoA pathway synergize with microtubule depolymerizers to produce multipolar mitotic spindles. Overall, this suggests that microtubule dynamics regulate actomyosin cortical function via RhoA to ensure integrity of the mitotic spindle. Central to this mechanism is the dependence of NM2A on Tpm3.1 to produce the functional engagement of actin filaments responsible for cortical tension.

B90/P1088

Determining the role of the mammalian formin, formin homology 2 domain-containing 3 (FHOD3), in cardiomyocytes

D. Valencia[1], M. Quinlan[1], A. Nakano[2]; [1]Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, CA, [2]Molecular, Cell, and Developmental Biology, University of California, Los Angeles, Los Angeles, CA.

The highly organized structure in striated muscle cells, known as the sarcomere, is responsible for contraction. A mammalian formin known as Formin HOmology Domain containing 3 (FHOD3) has been shown to be important for sarcomere development and maintenance in cardiomyocytes. However, the specific mechanisms of sarcomere formation and maintenance remain unclear. The objective of this research is to better understand which biochemical activities of FHOD3 are necessary or sufficient for sarcomere formation and maintenance in cardiomyocytes. Here, using bulk actin assembly assays and seeded elongation assays, we found that FHOD3 is a moderately strong nucleator and weak elongator *in vitro*. Further, we successfully performed a proof-of-principle rescue experiment of wild-type FHOD3 in cardiomyocytes through an siRNA knockdown, followed by adenoviral infection to allow for exogenous expression of wild-type FHOD3. This rescue experiment paves the way for future experiments using function-separating mutants of FHOD3 to understand whether nucleation strength or elongation ability are more important for proper sarcomere formation in cardiomyocytes. This work will help us better understand the mechanisms by which many formins build specific structures *in vivo*.

B91/P1089

Control of actin cable length by decelerated growth and network geometry

S. G. McInally, J. Kondev, B. L. Goode; Brandeis University, Waltham, MA

The sizes of many subcellular structures are coordinated with cell size to ensure that these structures meet the functional demands of the cell. In eukaryotic cells, these subcellular structures are often membrane-bound organelles, whose volume is the physiologically important aspect of their size. Scaling organelle volume with cell volume can be explained by limiting pool mechanisms, wherein a constant concentration of molecular building blocks enables subcellular structures to increase in size proportionally with cell volume. However, limiting pool mechanisms cannot explain how the size of linear subcellular structures, such as cytoskeletal filaments, scale with the linear dimensions of the cell. Recently, we discovered that the length of actin cables in budding yeast (used for intracellular transport) precisely match the length of the cell in which they are assembled. Using mathematical modeling and quantitative imaging of actin cable growth dynamics, we found that as the actin cables grow longer, their extension rates slow (or decelerate), enabling cable length to match cell length. Importantly, this deceleration behavior is cell-length dependent, allowing cables in longer cells to grow faster, and therefore reach a longer length before growth stops at the back of the cell. In addition, we have unexpectedly found that cable length is specified by cable shape. Our imaging analysis reveals that cables progressively taper as they extend from the bud neck into the mother cell, and further, this tapering scales with cell length. Integrating observations made for tapering actin networks in other systems, we have developed a novel mathematical model for cable length control that recapitulates our quantitative experimental observations. Unlike other models of size control, this model does not require length-dependent rates of assembly or disassembly. Instead, feedback control over the length of the cable is an emergent property due to the cross-linked and bundled architecture of the actin filaments

within the cable. This work reveals a new strategy that cells use to coordinate the size of their internal parts with their linear dimensions. Similar design principles may control the size and scaling of other subcellular structures whose physiologically important dimension is their length.

B92/P1090

Actin wave mediates cell shape-dependent actin accumulation for protrusive activity

K. Yagami, K. Baba, S. Misu, H. Katsuno-Kambe, K. Okano, Y. Sakumura, Y. Hosokawa, N. Inagaki; Nara Institute of Science and Technology, Ikoma, Nara 630-0192, Japan

Actin filaments (F-actins) accumulate at cell protrusions, for example, leading edge in migrating cells, microvilli in epithelial cells, invadopodia in cancer cells, and dendritic spine in neurons. However, how F-actins accumulate at cell protrusion is unclear. Previously, our group reported the mechanism of actin wave propagation along neuronal axons. Actin waves propagate by polymerization of F-actins which are anchored to the extracellular adhesive substrate through the clutch molecule Shootin1 and the cell adhesion molecule L1-CAM. G-actins dissociating from the rear of the filaments move toward the polymerizing ends by diffusion, because G-actin concentration is locally higher at the rear due to disassembly and is lower at the front due to polymerization. Through this mechanism, actin waves transport actin and actin-associated proteins along axons. The purpose of this study is to examine a possibility that F-actins accumulate at cell protrusions via actin waves.First, we prepared a glass substrate with triangle cell adhesion area. U-251 glioma cells cultured on the substrate formed triangular shape. In the triangular cells, F-actins accumulated at the three corners. Higher accumulation was observed when the corner angle is smaller. This result suggests that F-actins sense the cell shape and spontaneously accumulate at cell protrusions. Second, we observed F-actins that migrate in the direction of polymerization as actin waves at ventral and lateral sides of glioma cells using total internal reflection fluorescence microscopy. The ventrally-generated actin waves reached the cell edge and moved laterally. Shootin1b co-migrated with the actin waves. Shootin1b-KO delayed the speed of ventral and lateral actin waves and disturbed F-actin accumulation at the corners of the triangle. In addition, mathematical models demonstrated that the mechanism of actin waves can explain the F-actin accumulation at cell protrusions. Furthermore, Shootin1b-KO delayed cell polarity formation and migration of glioma cells. These data suggest that the cell shape-dependent actin accumulation via actin waves plays a key role in cellular protrusive activity.

B93/P1091

3D architecture of phagocytic podosomes examined using iPALM

J. C. Herron[1], **S. Hu**[1], T. Watanabe[1], A. T. Nogueira[1], B. Liu[1], M. E. Kern[1], J. Aaron[2], A. Taylor[2], M. Pablo[1], T.-L. Chew[2], T. C. Elston[2], K. M. Hahn[1]; [1]University of North Carolina At Chapel Hill, Chapel Hill, NC, [2]Howard Hughes Medical Institute Janelia Research Campus, Ashburn, VA

Actin-based structures known as podosomes play important roles in migration, phagocytosis, and other cellular processes. Using interferometric photoactivated localization microscopy (iPALM), we were able to examine the actin structure of phagocytic podosomes with 15-20 nm resolution. These studies were supplemented by structured illumination microscopy (SIM) used to examine the distribution of actin-associated molecules, including paxillin, talin, myosin II, alpha-actinin, and cortactin. We used a frustrated phagocytosis model, in which macrophages attempt to engulf circular patterns of IgG antibodies attached to coverslips. They form a phagocytic apparatus, but are ‘frustrated’ because they

are unable to fully engulf the IgG. This generates arrays of podosomes with regular, well-defined geometry, enabling us to apply a semi-automatic pipeline based on persistent homology to identify and measure features across podosome populations. This revealed that podosomes have an hourglass shape, with an actin knob protruding into the plasma membrane, and two actin networks extending from the hourglass. Associated proteins were concentrated at the base and in some cases along the sides of the podosomes. The morphology of phagocytic podosomes will be important as further studies reveal how the arrangement of signaling molecules controls function, and how podosomes sense and respond to mechanical forces.

B94/P1092

Reconstitution of the transition from a lamellipodia- to filopodia-like actin network with purified proteins

C. Suarez, J. D. Winkelman, A. J. Harker, P. M. McCall, A. N. Morganthaler, M. L. Gardel, D. R. Kovar; University of Chicago, Chicago, IL

How cells simultaneously assemble and maintain functionally diverse actin filament networks with distinct architectures and dynamics within a common cytoplasm is an outstanding question. Filopodia are finger-like membrane protrusions composed of long, parallel actin filaments bundled by fascin, which sense extracellular chemical and mechanical signals to help steer motile cells. Two processive actin filament barbed end elongation factors, formin and Ena/VASP, localize to filopodia tips and drive their elongation. One hypothesis is that filopodia are generated from the lamellipodia, which consists of densely packed, branched actin filaments that are nucleated by Arp2/3 complex and kept short by capping protein. Are different actin filament elongation factors necessary and sufficient to facilitate the emergence of filopodia with diverse characteristics from a highly dense network of short-branched capped filaments?We combined bead motility and micropatterning biomimetic assays, with multi-color Total Internal Reflection Fluorescence microscopy imaging, to successfully reconstitute the formation of filopodia-like networks (FLN) from densely-branched lamelipodia-like networks (LLN) with eight purified proteins (actin, profilin, Arp2/3 complex, Wasp pWA, fascin, capping protein, VASP and formin mDia2). Although saturating capping protein concentrations inhibit FLN assembly, the inclusion of mDia2 or VASP differentially rescues the transition of LLNs to FLNs. Formin mDia2-generated FLNs are relatively long and lack capping protein, whereas VASP-generated FLNs are comparatively short and contain capping protein. Our biomimetic reconstitution systems reveal that formin or VASP are necessary and sufficient to induce the transition from a LLN to a FLN, and establish robust in vitro platforms to investigate FLN assembly mechanisms.

Motors: Dyneins

B96/P1093

Using cryo-EM to visualize snapshots of dynein's activation pathway

A. A. Kendrick, A. E. Leschziner, S. L. Reck-Peterson; Cellular and Molecular Medicine, University of California, San Diego, San Diego, CA.

Regulation of cytoplasmic dynein-1 (dynein) is critical for diverse functions of eukaryotic cells, including cell division and long-range intracellular transport. Both dynein and Lis1, an essential dynein regulator, are mutated in patients with neurodevelopmental diseases and are conserved from fungi to mammals.

Dynein activity is controlled by an autoinhibited state called “Phi”, in which its two motor domains interact in a way that prevents motility. Lis1 is important for promoting the formation of active dynein complexes and it has been proposed to do so by stabilizing a dynein conformation that is not autoinhibited. Recently, we solved a structure of dynein bound to Lis1 in which two Lis1 dimers are inserted between two dynein motor domains; this “Chi” conformation appears to capture an early step in the dynein activation pathway. What other steps are involved in the full activation of dynein remains unknown. Here, our goal was to use Cryo-EM to visualize as many of these steps as possible to determine the structural changes underlying dynein activation by Lis1. We did so by purposely introducing heterogeneity during our Cryo-EM sample preparation; including ATP in our samples allowed dynein to go through its mechanochemical cycle. Using this approach, we captured eight distinct dynein and dynein-Lis1 structures from the same sample. These snapshots reveal novel conformations of dynein-Lis1 that we propose represent additional intermediate states in the dynein activation pathway. We will present a new model for how Lis1 relieves dynein autoinhibition and promotes conformations that are compatible with motility.

B97/P1094

Microtubule binding-induced allostery promotes Pac1/LIS1 dissociation from dynein prior to cargo transport

C. Beauchamp-Perez[1], N. Flint[1], L. G. Lammers[1], Y. Wang[2], P. Chai[2], K. Zhang[2], **S. M. Markus**[1]; [1]Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, [2]Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT.

The lissencephaly-1 gene (Lis1, or Pac1 in budding yeast) is a highly conserved regulator of the retrograde microtubule motor dynein. Lis1 functions in part by stabilizing an open/partially active conformational state of dynein, and by enabling dynein localization to the plus ends of dynamic microtubules. Although dynein-Lis1 binding is required for dynein cargo transport functions, dissociation of this complex prior to initiation of motility appears to be equally important, as preventing as much leads to defects in dynein function. We sought to understand whether and how dynein-Lis1 binding affinity is modulated. To this end, we engineered dynein mutants that lock the motor in a constitutively microtubule-bound (MT-B) or microtubule-unbound (MT-U) conformational state. Whereas the MT-B mutant exhibits low affinity for Pac1 in cells, we find that the MT-U mutant binds with high affinity to Pac1, and as a consequence remains almost irreversibly bound to microtubule plus ends in cells. Using a combination of in vivo and in vitro approaches, we find that a monomeric motor domain fragment is sufficient to exhibit these opposing affinities for Lis1, and that this phenomenon is conserved with human proteins. A cryoEM structure of the human MT-B mutant reveals changes at the Lis1-binding surface that may account for the differential binding affinity of dynein for Lis1 when it is either bound or unbound to microtubules. Our data reveal that microtubule binding-induced conformational changes in dynein coordinate its dissociation from Lis1/Pac1, which is required for dynein activity.

B98/P1095

Lis1 bridges dynein to dynactin’s p150 arm to regulate complex assembly and motility

C. Lau, K. Singh, A. Carter; MRC-LMB, Cambridge, UNITED KINGDOM.

The dynein/dynactin/adaptor motor complex is a tightly regulated molecular machine that transports cargo along microtubules. One of its main regulators is Lis1, mutations of which cause the

neurodevelopmental disease lissencephaly. Lis1 is known to bind to the dynein motor domain and is important for the initiation of transport. Key questions are how Lis1 stimulates dynein's interaction with dynactin and whether it remains attached to the resulting complex during transport. Here we determine the cryo-EM structure of Lis1 bound to a dynein/dynactin/adaptor complex on microtubules. We use JIP3, the cargo adaptor for lysosomes, showing for the first time that this family of adaptors activates dynein. Unexpectedly we find Lis1 bridges dynein's motor to dynactin's p150 arm, a critical domain for processive dynein/dynactin movement. Our structure is the first observation of the p150 arm in its fully open and active conformation, showing its interaction with dynein's intermediate chain as well as Lis1. Our work explains how Lis1 directly aids dynein/dynactin complex formation and provides a mechanism for it to remain attached during cargo transport.

B99/P1096

A dynein-Lis1 structure captures an intermediate state in dynein's activation pathway

E. P. Karasmanis[1], J. M. Reimer[1], A. A. Kendrick[1], J. A. Rodriguez[1], J. B. Truong[1], A. E. Leschziner[1], S. L. Reck-Peterson[1,2]; [1]University of California San Diego, San Diego, CA, [2]Howard Hughes Medical Institute, Chevy Chase, MD.

Cytoplasmic dynein-1 is the major motor responsible for intracellular transport of cargo towards microtubule minus ends. Dynein motors are autoinhibited in a "Phi" conformation and undergo a series of conformational changes to form active complexes, which consist of two dynein dimers, the dynactin complex and activating adaptor(s). We and others have recently shown that Lis1 is required to form these active dynein complexes. Here, using cryo-electron microscopy, we solve a high-resolution structure of two Lis1 dimers inserted in-between a dynein motor dimer. Our structure reveals two new contact sites between dynein and Lis1 and is suggestive of the mechanism by which Lis1 promotes the relief of dynein autoinhibition. Using structure-guided mutagenesis, we disrupted each of these sites and showed that they are required for Lis1's regulation of dynein in vivo in *S. cerevisiae*. In vitro reconstitution of human dynein complexes in the presence of wild type or mutated Lis1, suggests that these contact sites are also important for Lis1's role in forming activated human dynein-dynactin-activating adaptor complexes. We propose that our structure represents an intermediate in dynein's activation pathway.

B100/P1097

Structure of dynein-dynactin on microtubules shows tandem adaptor binding

S. Chaaban, A. P. Carter; MRC Laboratory of Molecular Biology, Cambridge, UNITED KINGDOM.

Cytoplasmic dynein is a microtubule motor that is activated by its cofactor dynactin and a coiled-coil cargo adaptor. Up to two dynein dimers can be recruited per dynactin, and interactions between them affect their combined motile behaviour. Different coiled-coil adaptors are linked to different cargos, and some share motifs known to contact sites on dynein and dynactin. There is currently limited structural information on how the resulting complex interacts with microtubules and how adaptors are recruited. Here, we develop a cryo-EM processing pipeline to solve the high-resolution structure of dynein-dynactin and the adaptor BICDR1 bound to microtubules. This reveals the asymmetric interactions between neighbouring dynein motor domains and how they relate to motile behaviour. We find unexpectedly that two adaptors occupy the complex. Both adaptors make similar interactions with the

dyneins but diverge in their contacts with each other and dynactin. Our structure has implications for the stability and stoichiometry of motor recruitment by cargos.

B101/P1098

Evolutionarily conserved roles of the dynein intermediate chain and Ndel1 in assembly and activation of dynein

K. Okada[1], **B. R. Iyer**[2], L. G. Lammers[2], P. Gutierrez[1], W. Li[1], S. M. Markus[2], R. J. McKenney[1]; [1]Biochemistry and Molecular Biology, University of California Davis, Davis, CA, [2]Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO.

In the absence of cargo, cytoplasmic dynein assumes an autoinhibited conformation and must be activated for its transport function through the regulated assembly of a dynein-dynactin-adapter (DDA) protein super complex. The interaction between dynein and dynactin was first ascribed to a small portion of the N-terminus of the dynein intermediate chain (IC) and a fragment of the coiled-coil domain of the dynactin subunit p150^{Glued}. This intrinsically disordered N-terminal segment of the IC (ICN) also directly interacts with the dynein regulators Nde1 and Ndel1, which compete with p150^{Glued} for binding to ICN. However, high-resolution cryo-EM structures of DDA complexes did not reveal the relevant domains of ICN and p150^{Glued}, raising questions about the importance of this interaction. Using a combination of *in vitro* and *in vivo* analyses we assessed the importance and evolutionary conservation of the ICN-p150, ICN-Ndel1, and Ndel1-Lis1 interactions in the assembly of DDA complexes. Deletion of ICN abolishes dynein's interaction with dynactin at plus ends in budding yeast, and abrogates the assembly of active DDA complexes *in vivo* and *in vitro*. In both yeast and mammalian systems, we find that the ICN plays an evolutionarily conserved role in binding Ndel1 (Ndl1 in yeast), which recruits LIS1 (Pac1 in yeast) to the dynein complex. Interestingly, we find that Lis1/Pac1 cannot simultaneously bind to Ndel1/Ndl1 and the dynein motor domain, indicating that Lis1 must dissociate from Ndel1 prior to binding dynein. Whereas addition of either Ndel1 or p150^{Glued} disrupt DDA complex assembly *in vitro*, neither affected preassembled DDA complexes, nor bound to processively moving motor complexes, indicating that the ICN may preferentially bind p150^{Glued} in the context of an active DDA complex. With the help of AlphaFold2 structure predictions, we delineate residue level interaction surfaces between the human and yeast ICN-Lis1-Ndel1 tripartite complex. Our study reveals previously unknown regulatory steps in the dynein activation pathway and provides a more complete model for how both Lis1/Ndel1 and dynactin/cargo-adapters integrate to regulate dynein motor activity.

B102/P1099

Using multi-scale computational approach to investigate Dynein's motility

L. Li; University of Texas El Paso, El Paso, TX.

Dynein is a molecular motor for cargo transportation and force generation in cells. Dysfunction of dynein is associated with many diseases, such as ciliopathies, lissencephaly and other neurodegeneration disorders. Understanding the functions of dynein is crucial for developing new treatments of such diseases. Electrostatic interactions play important roles in proteins including dyneins. A lot of efforts have been made to study the electrostatic interactions in biological systems. However, it is extremely challenging to accurately calculate the electrostatic interactions in large biological systems such as dynein. I will introduce a novel multi-scale simulation approach which is used to study dynein's motion along microtubules. The electrostatic binding funnel around microtubule is observed, which

drags the dynein to the binding pocket. The electrostatic forces on dynein residues form a torsion which reorients the dynein when it is in an un-native orientation. Furthermore, the electrostatic component of the binding energy of dynein and microtubule strongly affects the velocity and run length of the dynein. These results reveal the mechanisms of dynein's motility and functions along microtubule, which shed light on treatments of molecular motor related diseases.

The Kash5 protein involved in meiotic chromosomal movements is a novel dynein activating adaptor

R. Agrawal[1], J. P. Gillies[1], J. L. Zang[1], J. Zhang[2], S. R. Garott[3], H. Shibuya*[2], J. Nandakumar*[1], M. DeSantis*[1]; [1]MCDB, University of Michigan, Ann Arbor, MI, [2]University of Gothenburg, Gothenburg, SWEDEN, [3]Biological Chemistry, University of Michigan, Ann Arbor, MI.

Dynein is the primary retrograde molecular motor that harnesses ATP hydrolysis to move cargo on microtubules in multiple biological contexts. Dynein meets a unique challenge in meiosis by moving chromosomes tethered to the nuclear envelope to facilitate homolog pairing essential for gametogenesis. The nuclear envelope (NE) is intact during prophase I, implying that dynein is separated from its cargo by two lipid bilayers (the inner nuclear membrane [INM] and outer nuclear membrane [ONM]) and the perinuclear space between them. Despite being a process essential to meiosis progression and fertility, how dynein is activated to drive these movements across the NE remains unknown. Dynein tethers to chromosomes via the highly conserved linker of nucleoskeleton and cytoskeleton (LINC) complex at the NE. The LINC complex consists of a SUN protein (SUN1) and a KASH protein (KASH5) that span the INM and ONM, respectively and bind each other in the perinuclear space. While SUN1 tethers the chromosomes to INM, KASH5 binds dynein completing the attachment between dynein and the chromosomal cargo. Binding of an activating adaptor is required to make dynein processive, however, the identity of the activating adaptor required for dynein to move meiotic chromosomes is unknown. We show that meiosis-specific nuclear envelope protein KASH5 is a dynein activating adaptor. Using GST-pull downs, co-immunoprecipitation, isothermal calorimetry, and SEC-MALS we show that KASH5 directly binds dynein using a mechanism conserved among activating adaptors. Using single-molecule total internal reflection fluorescence (TIRF) microscopy, we demonstrate that purified KASH5 converts dynein into a processive motor that walks processively on microtubule tracks. We generated a homology model to map the dynein-binding surface of KASH5, identifying mutations that abrogate dynein binding in vitro and disrupt recruitment of the dynein machinery to the nuclear envelope in cultured cells and mouse spermatocytes in vivo. Together, this work identifies the first transmembrane activating adaptor of dynein and provides detailed molecular insights into how dynein is activated to power chromosome movements in meiosis to pair homologs.

Ninein expression and involvement in phagocytosis in macrophages

S. Omer, N. Gandhi, R. Harrison; University of Toronto, Scarborough, ON, CANADA.

Phagocytosis of pathogens and foreign particles is a central process of the innate immune system. After target internalization by macrophages, the resultant phagosomes undergo an intricate maturation process that overlaps with its movement toward the cell center, ultimately resulting in degradation of the engulfed particle. Our work and others have shown that the minus-end-directed dynein microtubule motor is recruited to late phagosomes and is critical for phagosome maturation. It remains unclear

whether dynein activity and dynein adaptors are involved in earlier steps of particle internalization. Here we show that the microtubule-nucleator ninein that is known to localize primarily to the centrosome, is recruited to phagocytic cups co-localizes with F-actin and EEA1, early endosomal markers in the macrophage-like RAW 264.7 cell line. Similar accumulations at the phagocytic cups were also observed for dynein motor and its cofactor, dynein intermediate chain as early as 5 min after encountering IgG-opsonized particles. Ninein knockdown experiments showed defective macrophage spreading and reduced internalization of IgG- opsonized particles. We examined the potential mechanism of defective phagocytosis and found that ninein depletion impaired microtubules nucleation, reduced the radial microtubule array and resulted in defective dynein localization. These findings suggest that ninein participates in the early events of Fcγ-mediated phagocytosis, potentially by regulating MT organization and/or facilitating dynein-mediated early phagocytic force generation. We also discovered that macrophages express three ninein isoforms. Interestingly, western blotting of isolated latex-bead phagosomes revealed the presence of dynein and dynactin together with an additional smaller ninein isoform, suggesting distinctive regulation of ninein and dynein cellular functions within macrophages.

Phagosomal pH regulates motor protein kinetics in macrophages

S. Patel, H. S. Shamroukh, K. C. Kondapalli, **S. K. Tripathy**; Department of Natural Sciences, University of Michigan - Dearborn, Dearborn, MI.

Macrophages are professional phagocytes involved in elimination of microbial pathogens and antigen presentation to T-cells of the immune system. Macrophages internalize microbes trapping them within a vacuole known as the phagosome. Directed transport of the phagosome on the microtubules, towards the minus ends, for fusion with lysosomes is crucial for pathogen degradation. Motion of the phagosome on the microtubules is bidirectional, with a tug-of-war between dynein and kinesin motor proteins, directing the phagosome towards and away from the lysosome respectively. The factors regulating this phagosome transport are, however, not completely clear. In a recently published study, we showed that the sodium proton exchanger, NHE9, regulates luminal pH of the phagosome to impact phagosome transport. Specifically, we demonstrated that an increase in luminal pH leads to significant decrease in the processive movements and run length without effecting the velocity. Our objective here, was to expand on these observations and characterize the impact of luminal pH on the kinetics of the motor proteins under load. To this end, we engineered stable overexpression of NHE9 in the well-established macrophage cell line, RAW264.7. We determined that phagosomes in control cells were consistently more acidic at all the evaluated time points post-ingestion of gram-negative bacteria (Escherichia coli) or gram-positive bacteria (Staphylococcus aureus), relative to phagosomes in NHE9 overexpressing macrophages. Next, we conducted optical trapping experiments at single-molecule resolution on 800nm carboxylate-coated polystyrene beads, phagocytosed by RAW 264.7 cells. We observed that under load, the average binding time of dynein was significantly higher than kinesin for the acidic phagosomes of control cells. Interestingly, the binding times of these motor proteins were similar for the relatively alkaline phagosomes in NHE9 overexpressing cells. Based on these observations, we hypothesize that the reduction in run length is a direct consequence of the decreased dynein binding time. It is plausible that the increase in diffusive motion of the relatively alkaline phagosomes, we noted previously, is due to an unresolved tug-of-war between the opposite motors. These findings have significant implications for our understanding of macrophage mediated immune response.

Elucidating mitochondrial transport regulation using synthetic cargo in living cells

C. Gladkova, R. D. Vale; HHMI Janelia Research Campus, Ashburn, VA.

Mitochondrial microtubule-based transport shapes the cellular mitochondrial network alongside cycles of fusion, fission and mitochondrial turnover. Defects in these processes that collectively govern mitochondrial dynamics contribute to neurodegeneration. Anterograde transport supports energetically demanding peripheral processes such as cell motility and synaptic activity, while retrograde transport favours mitochondrial turnover in the cell body. Anterograde kinesin-1 and retrograde dynein/dynactin motor complexes both interact with mitochondria via a conserved two-component Miro/TRAK adaptor complex to facilitate bidirectional mitochondrial motility. Because of the close coupling of mitochondrial transport with other facets of mitochondrial dynamics, it has been challenging to isolate specific cues that regulate mitochondrial transport directly. To probe the direct molecular determinants of mitochondrial transport and directionality in cells, we have developed an orthogonal protein scaffold-based cargo assay. We recapitulate the Miro/TRAK mitochondrial adaptor complex by displaying the mitochondrial transport adaptor Miro on the surface of a self-assembled 60-subunit icosahedral particle in cells [1], and co-expressing a cytosolic form of TRAK. Through detailed molecular dissection, live-cell imaging and biochemistry we define elements that regulate the balance between the two opposing motors. We also reveal how these regulators may tune mitochondrial transport in response to environmental changes. Our tool enables us to bridge molecular-level understanding of mitochondrial transport from *in vitro* work and the complex regulation of mitochondrial transport in cells.

Structural and mechanistic insights into dynein-based mRNA sorting during *Drosophila* development

M. A. McClintock[1], K. Singh[2], S. Chilaeva[1], A. P. Carter[2], S. L. Bullock[1]; [1]Cell Biology, MRC Laboratory of Molecular Biology, Cambridge, UNITED KINGDOM, [2]Structural Studies, MRC Laboratory of Molecular Biology, Cambridge, UNITED KINGDOM.

Subcellular targeting of mRNA by microtubule-based motors is a widespread mechanism for spatial control of protein function. Much of our understanding of this process comes from studies of *Drosophila* oogenesis and embryogenesis, which rely on asymmetric protein expression for axis determination and polarized cell functions. In these systems, sequence-divergent RNA localization signals are detected by the non-canonical RNA-binding protein Egalitarian (Egl) and direct the activation of cytoplasmic dynein via association with the coiled-coil adaptor Bicaudal-D (BicD). How divergent localization signals are recognized by Egl is unclear. Furthermore, it is not understood how dynein motor activity is adapted by localizing mRNAs during oogenesis to produce different localization patterns of axis determinants. Using cryo-electron microscopy, we have determined the structures of Egl-BicD complexes bound to RNA localization signals from transcripts that adopt different subcellular localizations. We describe the modular architecture of the RNA-binding pocket of Egl, which is formed by novel double-stranded RNA-binding motifs and a previously annotated exonuclease domain. This modularity confers flexibility to the complex and enables accommodation of RNA localization signals that are structurally related yet not identical. Additionally, by combining single-molecule reconstitutions with *Drosophila* genetics, we show that engagement of Egl with the localizing transcript *gurken* (*grk*) promotes the adaptation of dynein behavior by the hnRNP Squid (Sqd). Our data suggest that Sqd promotes the multimerization of both *grk*

mRNA and active dynein motor complexes, leading to specific targeting of the mRNA to the dorso-anterior region of the oocyte. Collectively, our data provide the first structural insights into recognition of RNA localization signals by a microtubule-bound motor and reveal control of mRNA copy number as an effective strategy for modulating the localization of RNA-motor complexes.

B108/P1105

New adaptor proteins of dynein-dynactin motor complex

T.-Y. Yeh[1], A. Vemu[1,2], B. Clarkson[1], J. Bennett[1], K. Meurer[1], S. A. Ketcham[1], T. A. Schroer[1]; [1]Johns Hopkins University, Baltimore, MD, [2]National Institute of Neurological Disorders and Stroke, Bethesda, MD

Cytoplasmic dynein is well known for transporting intracellular cargoes along microtubules. However, how it is targeted to its many cargoes is not fully defined and other roles have not been completely explored. Here we show the diversity of cytoplasmic dynein functions in endomembrane organization using the small molecule dynein inhibitor, dynarrestin. We find that dynein stabilizes endocytic recycling tubules on microtubules, and that it serves as a "brake" to slow kinesin-mediated movement of post-Golgi carriers.Dynactin is an essential component of the dynein motor complex. The complex is stabilized by "activating adaptor" proteins, which tether dynein to dynactin and various cargoes. High-resolution cryo-EM studies have shown that many adaptors directly contact the dynactin DCTN5 (p25) component at distinct sites. Using DCTN5 knockdown followed by mutant rescue we identified two functional motifs: a basic loop and the C-terminal alpha helix. Lysine residues K74 or K78 in the basic loop are required for binding to adaptors (BICD1/2 and Hook1/FIP3, respectively) that mediate dynein-based membrane transport. The C-terminal alpha-helix, which is essential for viability in mice, is required for normal regulation of actin dynamics and primary ciliogenesis. This motif is required for association with a different set of adaptors (Hook2, Hook3, girdin, daple). Furthermore, we used a bioinformatics approach to identify three novel adaptor candidates. These proteins can bind to dynein and dynactin directly, and their binding relies on DCTN5. DCTN5 loop K74 and K78 residues and C-terminus differently contribute to these adaptor candidates interaction with dynein/dynactin.

B109/P1106

Investigating the mechanism of the dynein regulatory protein, Ndel1

S. R. Garrott, A. Siva, J. P. Gillies, R. C. El Jbeily, M. E. DeSantis; University of Michigan, Ann Arbor, MI

Dynein is a microtubule minus-end directed motor protein that functions in cell division, intracellular cargo trafficking, and neuronal migration. The paralogs Ndel1 and Nde1 are involved in all of dynein's processes and are implicated in numerous neurodevelopmental diseases, but the mechanisms and direct effects of Ndel1/Nde1 in dynein regulation are unclear. The discovery of dynein's conformational equilibrium, whereby dynein shifts from an autoinhibited conformation to an active conformation, has been instrumental to uncovering the mechanisms of other dynein regulatory proteins, but Ndel1/Nde1 have not been studied in this context. In this study, we investigated Ndel1's mechanisms of dynein regulation, using dynein's conformational equilibrium as a new framework to understand Ndel1. We confirmed Ndel1-dynein binding sites and determined affinities of these sites using quantitative pull-down assays; we also used this method to determine how Ndel1 influences dynein binding to other key regulatory proteins. We next used single molecule TIRF microscopy to determine how Ndel1 affects motility of the active dynein-dynactin-cargo adaptor complex. We also used TIRF microscopy to probe

how Ndel1 and Lis1 function together in regulating dynein motility. Finally, we used negative stain electron microscopy to examine Ndel1's effects on dynein conformation. The major finding of this study is that, in contrast to dynactin, cargo adaptors, and Lis1, which promote dynein activity, Ndel1 acts as a scaffold that inhibits activation of dynein motility and modulates other regulatory proteins' ability to bind dynein. The results of this study provide a comprehensive view of Ndel1's function in dynein regulation, placing its function into the larger dynein regulatory network.

B110/P1107

Spatial Regulation of Dynein Forces on Microtubule Asters in Frog Eggs

T. Mitchison, C. Field; Harvard Medical School, Boston, MA

Centrosomes are positioned by dynein pulling on astral microtubules. In small cells, where microtubules reach the cortex, this force is exerted mainly by cortical dynein. In large Xenopus eggs, where microtubules do not reach the cortex for much of the cell cycle, dynein is thought to pull on astral microtubules from sites scattered throughout the cytoplasm, but spatial regulation of dynein in large cells is poorly understood. After anaphase of 1st mitosis, centrosomes move away from the midplane of the egg, which is defined by microtubule bundles coated with Chromosome Passenger Complex (CPC). Previous models hypothesized that dynein forces on centrosomes are directed outwards from the midplane by differences in aster radius or surface area between the sides facing the midplane vs. the outside. We hypothesized that the AURKB activity of the CPC might locally inactivate dynein at the midplane, causing a force asymmetry that directs centrosome movement. We are testing this hypothesis in egg extracts using polarized sperm asters, which recruit CPC to a crescent on the chromatin-proximal side. Using an improved method for freezing egg extract, we analyzed aster growth and movement with high reproducibility. Polarized asters moved in response to dynein-dependent forces with the CPC-positive side usually trailing, consistent with negative regulation of dynein by the CPC. Beads coated with the dynein adapter HOOK2 recruit dynein and model organelles. Co-recruitment of CPC to HOOK2 beads inhibited their transport by dynein. This inhibition required AURKB activity, consistent with inhibition of dynein by AURKB. Preliminary biochemistry suggested that AURKB did not inhibit binding of dynein or dynactin subunits to HOOK2. Instead, active CPC recruited KIF20A, a plus end-directed motor that may oppose dynein motility. This finding suggests a role for KIF20A in regulating the balance of motor-dependent forces on centrosomes, in addition to its known role in recruiting CPC to midplane microtubules.

Exploring dynein regulation in directed cell migration

J. L. Zang, A.-M. Zheng, D. Gibson, M. DeSantis; University of Michigan, Ann Arbor, MI

Directional cell migration requires the dramatic reorganization and coordination of all cytoskeletal networks in the cell. Although cell migration is largely an actin driven process, the microtubule network also plays a vital role in mesenchymal migration. A polarized microtubule network provides necessary tracks for the continuous traffic of polarization proteins towards the leading edge, which is important for directional persistence during migration. This microtubule orientation is established by cytoplasmic dynein-1 (dynein), the main minus-end directed microtubule motor in the cell. Upon a migratory stimulus, dynein produces traction forces on the microtubule network to move the centrosome and golgi apparatus to be anterior to the nucleus in the direction of migration. While it is known that dynein

enriches at the cortex of a migrating cell to induce the centrosome repositioning, the molecular mechanisms of how dynein localizes to the leading edge cortex or is activated during migration are currently unknown. Using proximity-dependent biotinylation coupled with mass spectroscopy on two known dynein regulators (Lis1 and Ndel1), biochemistry, and cell biology, I have identified novel machinery governing dynein regulation at the cell cortex. Here I show the necessity of this machinery for the dynein dependent reorientation of the centrosome and the maintenance of direction during cell migration. I hypothesize that upon migration, specific proteins localized to the cortical leading edge recruit Lis1 and Ndel1, which then locally activate a small pool of dynein for the proper polarization of the microtubule network. This work provides mechanistic insight into the regulation of dynein's activity in mesenchymal cell migration.

Impact of a Dynactin p62 (DCTN4) Variant on Lung Epithelial Functions

E. Mattson, S. Ma, T. Schroer; Johns Hopkins University, Baltimore, MD

A variant of the dynactin component p62(DCTN4 rs35772018; hereafter DCTN4-Y270C) has been correlated with earlier onset of chronic Pseudomonas infection in CF patients, and worsened outcomes in ARDS, two conditions which lead to chronic inflammation and wounding of the lung epithelium. Response of the lung epithelium to infection and damage involves its role as an innate immune tissue, its barrier function, and its ability to migrate and undergo wound healing. I will describe what we have found with regards to the role of DCTN4-Y270C in all three of these functions. Our lab has shown that cells expressing DCTN4-Y270C migrate more slowly than WT in scratch-wound assays. We also see altered focal adhesions, defective integrin cycling, and aberrant actin dynamics. This suggests that DCTN4-Y270C impacts dynein-dependent transport of integrin and possibly other cargoes. To gain insight into the molecular basis of the subcellular trafficking and cell migration defects, we used an unbiased proximity-dependent biotinylation (BioID) screen. Several promising differentially interacting candidates were identified in the BioID datasets, including RUFY1, a Rab4/14 binding protein that has been shown to regulate integrin trafficking, and Ephexin-4, which has been implicated in actin dynamics and microtubule mediated focal adhesion disassembly. The bronchial epithelium is an innate immune tissue, and RNA sequencing of human bronchial epithelial (HBE) cells expressing Y270C revealed an altered immune profile with downregulation of several pathways involved in innate immune response. Alteration of these pathways and downregulation of critical anti-microbial peptides likely play a role in impaired antimicrobial function of DCTN4-Y270C.Finally, although we have observed normal tight junction formation in polarized DCTN4-Y270C HBEs, we observe alterations in adherens junction proteins with downregulation of E-cadherin and upregulation of N-cadherin. This, along with upregulation of several other EMT related genes suggests a partial EMT phenotype in the Y270C HBE. The functional consequences of this still need to be explored. In the context of the DCTN4-Y270C mutation, cystic fibrosis and ARDS can be viewed as a sensitizing background that enhances this mutation's negative impact on lung disease. Knowledge of the mechanisms by which DCTN4-Y270C exerts its effects will not only open up the opportunity for development of therapies to combat its detrimental effects, but will also allow us to predict if those with DCTN4-Y270C will be more susceptible to certain environmental insults that they should be advised to avoid such as smoking and exposure to infection (SARS-CoV2).

B113/P1110

Investigating the Molecular Evolution of Dynein and the Dynactin Complex

S. Bohling, H. Goodson; University of Notre Dame, Notre Dame, IN

The last eukaryotic common ancestor, LECA, is the progenitor of all eukaryotic organisms. We can learn about LECA through the study of early diverging organisms, and understanding the cell biology of LECA can provide insight into the cell biology of all eukaryotes. Red algae diverged from the lineage leading to green plants over 1 billion years ago. The cytoskeleton is essential for key cellular processes including cell division, intracellular transport, and cell motility. Therefore, learning more about the cytoskeleton of red algae could provide insight into the biology of LECA and thus into the function of cytoskeletal proteins in all eukaryotic cells. My work uses bioinformatic and computational biology approaches to identify the molecular motor cytoplasmic dynein and its accessory dynactin complex in both red algae and their phagotrophic sister phylum *Rhodelphis*. This work is interesting because until recently, plants (including red algae) were thought to completely lack cytoplasmic dynein/dynactin, and it was often assumed that these proteins were limited to the clade containing animals and fungi. Our work shows that dynein is found in *Rhodelphis* and several clades of red algae; consistent with this observation, several components of dynactin complex are found in these organisms as well. This observation shows that cytoplasmic dynein existed in at least the common ancestor of plants and animals/fungi. Interestingly, some red algae (Atlantic *Porphyra umbilicalis* and its Pacific relatives) seem to be in the process of losing their dynein proteins, as the dynein motor is present, but divergent, and dynactin complex proteins are either difficult to recognize or absent. Future studies will look at the relationship between dynein and dynactin complex proteins in red algae and other divergent organisms to gain a better understanding of the cell biology of LECA.

Motors: Kinesins in Mitosis and Spindle Regulation

B114/P1111

MKLP1 mediates RNA granule assembly and protein translation in the midbody

S. Park, R. Dahn, A. R. Skop; University of Wisconsin-Madison, Madison, WI.

MKLP1 is a spindle-midzone kinesin motor protein that functions in midzone/midbody microtubule assembly, and is necessary for the completion of cytokinesis. Abscission results in two daughter cells, and one midbody remnant (MBR)--a RNA-enriched extracellular vesicle suspected to play a role in mediating cell fate. Recent work from the Prekeris and Simpson labs have shown that midbody remnants (MBRs) can increase cell proliferation indexes when placed on naïve HeLa cells (Peterman, 2019; Rai, 2021), suggesting that information being transferred to cells. To determine how the midbody/MBR assembly might be mediated by MKLP1 and known midbody RBPs, we sought to take a cell biological and genetic approach. Using RNAScope™ Poly A mRNA probes, we discovered that RNAs are abundant in the midbody matrix, a region devoid of tubulin antibody. This accumulated mRNAs mass at the midbody is wrapped by MKLP1, and is lost in MKLP1 siRNA-treated cells. The RBPs, Arc and ESCRTIII, are not necessary for RNA accumulation at the midbody matrix, as Poly A probes reveals a normal accumulation of RNA. Next, using Click-It chemistry, we utilized homopropargylglycine (HPG), a Methionine analogue, to visualize active protein synthesis in the central matrix of midbody, which was co-incident with the Poly A RNAscope pattern, and also sensitive to MKLP1 knockdown, suggesting that either MKLP1 directly plays a role in translation event, or that decreased translation is due to lack of the

assembly of midbody-enriched RNA. Lastly, we discovered that Arc and ESCRTIII are necessary for mediating the levels of protein translation in the midbody. Active protein synthesis does not require the following midbody RBPs: Annexin A11, ATXN2L, Stau1, and TIS11b. In sum, we suggest that MKLP1 mediates the assembly and translation of RNAs in the midbody/MBRs, and that both Arc and ESCRT-III appear to modulate the levels of translation in the midbody. How the midbody RNP assembles and behaves as a novel translationally active extracellular vesicle (MBR stage) in cell communication is a focus of our lab.

Using a Comprehensive Approach to Study the Mechanisms of Eg5 and Microtubule

W. Guo[1], J. E. Sanchez[2], L. Li[1]; [1]The University of Texas at El Paso, EL PASO, TX, [2]The University of Texas at El Paso, El Paso, TX.

Kinesins are microtubule-based motor proteins that play important roles ranging from intracellular transport to cell division. Human Kinesin-5 (Eg5) is essential for mitotic spindle assembly during cell division. By combining molecular dynamics (MD) simulations with other multi-scale computational approaches, we systematically studied the interaction between Eg5 and the microtubule. We find the electrostatic feature on the motor domains of Eg5 provides attractive interactions with the microtubule. Additionally, the folding and binding energy analysis reveals that the Eg5 motor domain performs its functions best when in a weak acidic environment. Molecular dynamics analyses of hydrogen bonds and salt bridges demonstrate that, on the binding interfaces of Eg5 and the tubulin heterodimer, salt bridges play the most significant role in holding the complex. The salt bridge residues on the binding interface of Eg5 are mostly positive, while salt bridge residues on the binding interface of tubulin heterodimer are mostly negative. In contrast, the interface between α and β-tubulins is dominated by hydrogen bonds rather than salt bridges. Compared to the Eg5/α-tubulin interface, the Eg5/β-tubulin interface has a greater number of salt bridges and higher occupancy for salt bridges. This asymmetric salt bridge distribution may play a significant role in Eg5's directionality. The residues involved in hydrogen bonds and salt bridges are identified in this work and may be helpful for anticancer drug design.

B116/P1113

Charge Changes in the Neck-linker of KIF18A Alter its Microtubule Preference, Cause Spindle Positioning Defects, and Impact Mitotic Function

K. A. Queen[1], A. Cario[1], S. E. Vandal[2], A. F. Thompson[1], C. L. Berger[1], J. Stumpff[1]; [1]University of Vermont, Burlington, VT, [2]Dartmouth Geisel School of Medicine, Hanover, NH.

Eukaryotic cells express many kinesins (45 in mammals) to support diverse cellular processes. Despite the unique functions these motors serve, kinesins share a conserved enzymatic region consisting of a motor domain and neck linker. The neck linker of kinesins undergoes conformational changes to ensure productive unidirectional stepping along microtubules. Our work focuses on the kinesin-8 KIF18A, which has an extended neck linker that not only serves to promote unidirectional stepping but also allows for obstacle navigation and subsequent accumulation to the plus-ends of kinetochore microtubules. Given the critical functions of the neck linker, we were interested in understanding how modifications within this structural region affect the canonical mitotic functions of KIF18A. KIF18A is a mammalian mitotic kinesin that plays important roles in chromosome alignment, kinetochore-microtubule attachment, and mitotic progression. These functions are mediated by the accumulation of KIF18A at the plus-ends of

kinetochore microtubules where it suppresses microtubule dynamics. KIF18A has three identified sites of modification within its neck linker, which occur at K356, S357, and K360, suggesting this may be an important regulatory region. Using an inducible cell line approach, we found that a phospho-mimetic S357D mutation alters the localization of KIF18A within the spindle, moving the motor off stable kinetochore microtubules and onto dynamic peripheral microtubules. The S357D mutant also exhibits altered localization in monopolar and interphase cells. Changes in localization are accompanied by defects in the ability of KIF18A S357D to promote mitotic progression, support chromosome alignment, and maintain spindle position. We investigated if this altered localization and mitotic defects are due to changes in single molecule motility or tubulin density but found no changes compared to wild-type KIF18A. However, removing the kinetochore microtubule specific microtubule associated protein HURP, allowed for re-localization of KIF18A S357D to k-fiber plus ends. This re-localization resembles the effects of removing obstacles from kinetochore microtubules in the presence of a shortened neck-linker KIF18A mutant. Taken together, this work indicates that KIF18A S357D may mimic a shortened neck-linker state, essentially excluding KIF18A S357D from kinetochore microtubules, resulting in alterations in the localization and the function of the motor.

The β-tubulin tail differentially regulates kinesin-5 motors

E. C. Thomas, J. K. Moore; University of Colorado - Anschutz Medical Campus, Aurora, CO.

The tubulin code hypothesis predicts that tubulin proteins create programs for regulating the activities of kinesin motors, but we still lack an understanding of how molecular differences in microtubule networks can regulate kinesin function. The carboxy-terminal tails of tubulins are highly divergent and could provide an adjustable platform to control kinesin function. In this work, we identify through a genetic screen two budding yeast kinesin-5 motors, Cin8 and Kip1, that differentially interact with the β-tubulin tail. In wild-type cells, interactions with the β-tubulin tail recruit Cin8 to the spindle and establish a sequential recruitment of Kip1, which is otherwise insensitive to the β-tubulin tail. We determined that a negatively charged patch of acidic amino acids in the β-tubulin tail mediates the interaction with Cin8 and promotes its motility toward the plus-end of microtubules. Two positively charged regions within the Cin8 motor domain coordinate these charge-charge interactions with the negative β-tubulin tail. These regions are divergent in Kip1, providing a basis for its differential interaction with the β-tubulin tail. Finally, we demonstrate that interactions between Cin8 and the β-tubulin tail are necessary to promote stable, controlled spindle elongation during anaphase. The β-tubulin tail is highly divergent across species and is targeted for a variety of posttranslational modifications; it may therefore represent a mechanism for tuning spindle elongation across species and cell types. Interestingly, the positively charged regions of Cin8 are present in mammalian kinesin-5, suggesting that the mechanism may be conserved. Altogether this work proposes a molecular mechanism for how interactions between tubulin tails and kinesin motors can increase kinesin motility to promote spindle function.

Microtubules in Disease

Tau Phosphorylation Impedes Cohesive Envelope Formation

V. Siahaan[1], E. Žatecká[2], A. Karhanová[1], M. Braun[1], Z. Lansky[1]; [1]Czech Academy of Sciences, Institute of Biotechnology, Prague, CZECH REPUBLIC, [2]Department of Cell Biology, Faculty of Sciences, Charles University, Prague, CZECH REPUBLIC.

In neurodegenerative diseases, collectively termed tauopathies, malfunction of the protein tau and its detachment from axonal microtubules are correlated with axonal degeneration and often are associated with abnormal phosphorylation of tau. Tau proteins, being intrinsically disordered, individually diffuse on microtubules and upon cooperative formation of cohesive envelopes, alter the spacing of the tubulin dimers constituting the microtubules[1]. Thereby, tau envelopes differentially regulate the accessibility of the microtubule lattice for other proteins, including molecular motors and microtubule severing enzymes[2]. Phosphorylation of tau reduces the affinity of tau for microtubules, however, the impact on envelope formation is not known. Pin1 is a peptidyl-prolyl cis-trans isomerase that catalyzes the isomerization of phosphorylated Serine/Threonine-Proline motifs in tau, restoring the affinity of phosphorylated tau for microtubules. Here, using in vitro reconstitution, we show that (a) phosphorylation impedes the formation of tau envelopes, while de-phosphorylation of tau enhances envelope formation and (b) Pin1 promotes envelope formation of phosphorylated tau. Our results demonstrate a mechanism by which Pin1 promotes the functioning of tau after phosphorylation, suggesting how Pin1 may decrease deleterious consequences of tau phosphorylation and hyperphosphorylation in neurodegenerative disease.

Trisomy 21 increases microtubules and disrupts centriolar satellite distribution

B. L. McCurdy, C. E. Jewett, A. J. Stemm-Wolf, C. G. Pearson; University of Colorado Anschutz Medical Campus, Aurora, CO.

Trisomy 21, the source of Down syndrome, causes a 0.5-fold protein increase of the chromosome 21-resident gene Pericentrin (PCNT) and reduces primary cilia formation and signaling. Here, we investigate how PCNT and chromosome 21 genetic imbalances disrupt primary cilia. Using isogenic RPE-1 cells engineered with increased chromosome 21 dosage, we find PCNT protein accumulates around the centrosome as a cluster of enlarged cytoplasmic puncta that localize along microtubules (MTs) and at MT ends. These cytoplasmic PCNT puncta impact the density, stability, and localization of the MT trafficking network required for primary cilia formation. The PCNT puncta appear to sequester cargo peripheral to centrosomes in what we call ‘pericentrosomal crowding’. The centriolar satellite proteins PCM1, CEP131, and CEP290, important for ciliogenesis and signaling, accumulate at enlarged PCNT puncta in trisomy 21 cells. Reducing PCNT when chromosome 21 ploidy is elevated is sufficient to decrease PCNT puncta and pericentrosomal crowding, reestablish a normal density of MTs around the centrosome, and restore ciliogenesis to wild-type levels. A transient reduction in MTs also decreases

pericentrosomal crowding and partially rescues ciliogenesis in trisomy 21 cells, indicating that increased PCNT leads to defects in the MT network deleterious to normal centriolar satellite distribution. Trisomy 21 cilia frequencies eventually increase to wild-type levels after sustained duration in starvation media. This suggests that MT-dependent trafficking events required for ciliogenesis are initially waylaid but resolved with time. Importantly, initial steps of ciliogenesis require removal of the centriolar capping protein CP110 from the mother centriole. We find that depletion of CP110 protein levels in elevated chromosome 21 ploidy rescues primary ciliogenesis to normal levels. This suggests that bypassing MT-based trafficking events when chromosome 21 dosage is elevated rescues primary ciliogenesis and reinforces our conclusion that chromosome 21 aneuploidy disrupts MT-dependent intracellular trafficking required for primary cilia formation.

Dystrophin and Ensconsin Cooperate to Maintain Nuclear Spacing in Myofibers by Regulating Distinct Aspects of Microtubule Organization

J. R. Padilla, A. Burgess, G. Aleck, L. Ferreira, E. S. Folker; Biology, Boston College, Chestnut Hill, MA.

Nuclei are evenly spaced in myofibers and disruptions in this spacing are a hallmark of poorly functioning muscles. Whereas some muscle disorders such as Emery-Dreifuss muscular dystrophy, which is linked to mutations in genes encoding nuclear envelope proteins, can be tied directly to the spacing of nuclei, Duchenne Muscular Dystrophy (DMD), caused by a mutation in *dystrophin* is more difficult to connect to nuclear spacing. Nevertheless, mispositioned nuclei are evident in DMD patients. To determine whether *dystrophin* regulates nuclear spacing independent of myofiber regeneration, we depleted Dystrophin from *Drosophila* muscles at specific developmental stages. Depletion of Dystrophin during active nuclear movement did not affect the nuclear spacing, however, depletion of Dystrophin after the completion of nuclear movement resulted in a loss of nuclear spacing indicating that Dystrophin is necessary to maintain nuclear spacing in differentiated myofibers. Intriguingly, nuclear spacing was not affected by the depletion of any other component of the dystroglycan complex indicating that Dystrophin regulates nuclear spacing by a novel mechanism. Because Dystrophin can bind microtubules, we screened microtubule associated proteins for functional interactions with *dystrophin* that regulate nuclear spacing*. Ensconsin/MAP7* was the only gene identified to functionally interact with *dystrophin.* Animals carrying a mutation in both genes had significantly more disrupted nuclear spacing than animals with a mutation in either gene alone. To identify the underlying mechanism of this functional interaction, we examined microtubule organization. Disruption of Ensconsin or Dystrophin expression reduced the number of nucleus-associated microtubules. Additionally, the disruption of Ensconsin expression reduced the length of microtubules whereas the disruption of Dystrophin increased the looping of microtubules and resulted in microtubules that grew back toward the nucleus. Simultaneous disruption of both Ensconsin expression and Dystrophin expression caused muscles to have shorter microtubules with more dramatic looping and a reduced number of nucleus-associated microtubules. Taken together, these data suggest that *dystrophin* and *ensconsin* cooperate to maintain nuclear spacing in myofibers via their regulation of distinct aspects of microtubule organization.

A Specific Isoform of the Nesprin Msp300 Organizes the Perinuclear Microtubule Organizing Center in Fat Body Cells

G. M. Morton[1], Y. Zheng[2], C. Zheng[1], T. L. Megraw[1]; [1]Biomedical Sciences, Florida State University, Tallahassee, FL, [2]Xiamen University, Xiamen, CHINA.

The goal of this project was to determine how the Nesprin Msp300 controls assembly of the microtubule-organizing center (MTOC) on the nuclear surface in Drosophila fat body cells. Msp300 appears to form the foundation for this MTOC on the nuclear surface and is required to recruit the microtubule minus-end stabilizer Patronin and the microtubule polymerase Msps to form a functional MTOC. Remarkably, the microtubule nucleator γ-tubulin is not required at the fat body perinuclear MTOC. Msp300 is a component of the linker of nucleoskeleton and cytoskeleton (LINC) complex, which spans the nuclear envelope and provides a physical connection between the cytoplasm and the interior of the nucleus. Comprising the LINC complex are the KASH-domain and SUN-domain proteins, which are present on the outer and inner nuclear membrane, respectively. Surprisingly, while Msp300 is required for MTOC formation, the sole SUN protein in Drosophila is not required, indicating that Msp300 associates with the nuclear surface in a non-conventional manner in fat body cells. The Msp300 gene is complex, encoding at least eleven isoforms. Using a combination of mutant and RNAi isoform depletion approaches, we have identified a set of three similar isoforms that are specifically necessary for MTOC formation. The consequences of disrupting the fat body non-centrosomal MTOC is microtubule disruption, nuclear mispositioning, and impaired retrograde endocytic trafficking, and we show that the Msp300 isoforms we identified are necessary for some and perhaps all of these functions. In contrast, the loss of other Msp300 isoforms does not significantly impair ncMTOC function. Overall, our results reveal a novel function of a unique set of Msp300 isoforms in the fat body to organize the perinuclear MTOC.

The tail anchored membrane protein SLMAP3 orchestrates muscle development by rearrangement of the microtubule organizing center (MTOC)

A. P. Dias, T. Rehmani, M. Salih, B. Tuana; Cellular and Molecular Medicine, University of Ottawa - Faculty of Medicine, Ottawa, ON, CANADA.

We have previously shown that SLMAP3 is a component of the centrosomal MTOC, to where it is directed by its N-terminal sequences including the FHA domain (J Cell Sci (2004) 117 (11): 2271-2281). SLMAP3 also localizes in the nuclear envelope (NE), where it is anchored by its C-terminal transmembrane domain. Muscle development is regulated by cytoskeleton remodelling, which includes the reorganization of MTOC components from the centrosome to the NE. Such a switch is important for myoblast fusion and proper nuclear positioning for normal myotube and muscle formation. Defects in these processes are associated with muscle dysfunction. To investigate the role of SLMAP3 in vivo, we generated SLMAP3 knockout (KO) mice using the Cre-Lox system, which exhibit late embryonic/perinatal lethality. RNA-seq analysis of SLMAP3 KO embryos indicated enrichment of biological processes involved in muscle development. Histological analysis of quadriceps indicated ~40% reduction of fiber length in SLMAP3 KO embryos compared to wild type (WT). Deletion of SLMAP3 in C2C12 mouse myoblast by CRISPR/Cas9 impacted myotube formation with ~98% reduction in fusion index and 7.6-fold less myosin heavy chain protein expression after 4 days in differentiation medium. Analysis of SLMAP3 interactors

by Immunoprecipitation-Mass Spectrometry (IP-MS) indicated its association with MTOC proteins, including akap9, pde4dip, pcm1 and pericentrin. Pericentrin staining indicated defects in the MTOC rearrangement in both SLMAP3 KO C2C12 cells and SLMAP3 null embryonic skeletal muscle. During differentiation, approximately 50% of the myogenin+ SLMAP3 KO C2C12 cells displayed NE-MTOC compared to 97% of myogenin+ WT cells. Still, the majority of the NE-MTOC in the KO cells exhibited weak and less defined pericentrin distribution, similar to that observed in skeletal muscle of SLMAP3 null embryos. Also, the mean distance between the nuclei in SLMAP3 null embryonic skeletal fibers was about half of the distance observed in WT myofibers, indicating impairment of nuclei positioning and defective NE-MTOC distribution. Our results indicate a novel role for SLMAP3 in myogenesis, via mechanisms involving MTOC dynamics orchestrated through its unique structural elements. (Supported by CIHR).

Regulation of microtubule acetylation during the DNA damage response promotes efficient repair

S. S. Wallis, S. A. Godinho; Cancer Cell and Molecular Biology, Barts Cancer Institute, London, UNITED KINGDOM.

The microtubule cytoskeleton forms an integral part of eukaryotic cells. Over the past decade, there has been growing evidence that microtubules also play an important role in the repair of double strand breaks (DSBs) during the DNA damage response (DDR) by increasing DSB mobility. Recent work suggested that microtubule post-translational modifications (PTMs) are involved in the DDR, with acetylated tubulin levels increasing in response to DNA damage. This is particularly interesting as microtubule acetylation has been associated with increased kinesin-1 activity, which is known to affect DSB repair efficiency. However, how microtubule PTMs regulate the DDR and whether this can be exploited to enhance cancer treatment remains largely unknown. In this work, we show that microtubule acetylation, but not other PTMs tested, increases in a biphasic manner during the DNA damage response: an early peak in response to DNA damage and late peak correlated with DNA damage repair. Cells with defective DDR display a significantly lower late peak of microtubule acetylation, suggesting that efficient repair is important for increased tubulin acetylation at later time points. Furthermore, we show that depletion of alpha-tubulin acetyltransferase 1 (αTAT1), the enzyme responsible for microtubule acetylation, dramatically impairs the DDR, while overexpression of αTAT1 increases repair speed. Furthermore, using live-cell tracking of DNA damage foci, we observe a significant decrease in DSB mobility in cells depleted of αTAT1. Taken together, these results suggest that DSB mobility is regulated by tubulin acetylation and important for DNA repair. We propose a model by which the DDR is fine-tuned by microtubule acetylation to promote enhanced kinesin-1 activity to ensure efficient and timely repair. Finally, we demonstrate how changing levels of microtubule acetylation can be exploited to enhance the response to a commonly used chemotherapeutic, opening new avenues to treat cancer.

The ubiquitous Microtubule Associated Protein 4 (MAP4) controls organelle distribution by regulating the activity of the kinesin motor

I. Nabti[1], B. J. N. Reddy[2], R. Rezgui[1], W. Wang[2], S. P. Gross[2], **G. T. Shubeita**[1]; [1]New York University Abu Dhabi, Abu Dhabi, UNITED ARAB EMIRATES, [2]University of California Irvine, Irvine, CA.

Regulation of organelle transport by molecular motors along the cytoskeletal microtubules is central to maintaining cellular functions. We show that the ubiquitously-expressed tau-related protein, MAP4, can bias the bidirectional transport of organelles towards the microtubule minus-ends. This is concurrent with MAP4 phosphorylation, mediated by the kinase GSK3β. We demonstrate that MAP4 achieves this by tethering the cargo to the microtubules, allowing it to impair the force generation of the plus-end motor kinesin-1. Consistent with this, MAP4 physically interacts with the motor complex via dynein and dynactin, and associates with cargoes through its projection domain when phosphorylated. Its phosphorylation coincides with perinuclear accumulation of organelles, a phenotype that is rescued by abolishing the cargo-microtubule MAP4 tether, or by pharmacological inhibition of dynein, confirming the ability of kinesin to inch along, albeit inefficiently, in the presence of phosphorylated MAP4. These findings have broad biological significance because of the ubiquity of MAP4 and the involvement of GSK3β in multiple diseases, more specifically in cancer, where MAP4-dependent redistribution of organelles may be prevalent in cancer cells, as we demonstrate here for mitochondria in the lung carcinoma epithelial cells.

Tubulin Posttranslational Modification by Taurine is Tissue Selective, is increased in some Tumors, and Occurs in Single Molecule Patterns

A. White, **D. Sackett**; National Institute of Child Health and Human Development, NIH, Bethesda, MD.

Posttranslational modification (PTM) of tubulin encompasses a number of chemical changes to alpha and beta tubulin. These occur mostly on the disordered, acidic C-terminal tails (CTT) of 10-20 residues of alpha and beta that extend out from the surface of the microtubule (MT). An interesting PTM series entails the removal of the C-terminal tyrosine from alphas that have been incorporated into the MT, and its replacement when the tubulin is released as free dimer. We recently reported that taurine occurs as a C-terminal adduct to the de-Tyr CTT, blocking re-Tyr. Taurine is the most abundant free amino acid in the body and has long been thought to never be incorporated into any proteins. We used mass spectrometry to demonstrate taurine adducts to the C-terminus of de-Tyr alpha tubulin in chicken red blood cell tubulin, but now know that it is more widespread. We developed an antibody to alpha-CTT-taurine which shows that taurine-tubulin is abundant in rodent brain, skeletal muscle, and heart but absent or nearly so in some other tissues. Similarly, some but not all cell lines derived from these tissues of rodents and humans show abundant taurine-tubulin. Tissue microarrays of normal and tumor samples shows increased taurine-tubulin in some tumors (such as some sarcomas) but not in others (such as breast cancers). Examination of the distribution of taurine-tubulin in cultured cells by super-resolution STED microscopy shows a remarkable pattern of taurine modification on the MT. Taurine adducts occur as single molecules of alpha tubulin-taurine separated by regular spacings with no taurine modification. Thus, taurine incorporation at the C-terminus of de-Tyr alpha tubulin is the only known incorporation of taurine into any protein, and a possible modulator of the evolutionarily conserved

cyclic Tyr / de-Tyr modifications of tubulin. It shows a unique tissue selectivity and pattern of MT labeling, and is increased in some tumors.

Non-Centrosomal Microtubule Organising Centres Controlled by Light in Pluripotent Cells

J. Greaney[1], H. Janovjak[2], J. Zenker[1]; [1]Australian Regenerative Medicine Institute, Monash University, Melbourne, AUSTRALIA, [2]Flinders Health and Medical Research Institute, Flinders University, Adelaide, AUSTRALIA.

The arrangement of microtubule organising centres (MTOCs) in a cell is a key mediator of cellular identity by controlling the architecture of the microtubule network and its associated organelles and biomolecules. Commitment of stem cells to a particular cell lineage is characterised, in part, by the transition from non-centrosomal MTOCs (ncMTOCs) to centrosomes. However, the real-time regulation of MTOC switching during pluripotency exit remains elusive.
We set out with the objective to design an optogenetically-controlled version of calmodulin-regulated spectrin-associated protein 3 (CAMSAP3), which drives the formation of the interphase bridge, the characteristic ncMTOC in the preimplantation mouse embryo. Opto-CAMSAP3 localised and functioned as normal in dark conditions and, upon light-illumination, dissociated from microtubules, rendering it non-functional with sub-cellular and sub-second spatiotemporal precision in the preimplantation mouse embryo and in human induced pluripotent stem cells (hiPSCs).
Unexpectedly, this led to the discovery of an array of perinuclear CAMSAP3 deposition in the preimplantation mouse embryo responsible for mediating the interphase perinuclear microtubule architecture. Known from mammalian muscle cells and *Drosophila melanogaster* embryos, perinuclear ncMTOC activity determines nuclear organisation and signalling. Thus, lacking centrosomes, the cells of the preimplantation embryo present an extraordinary plasticity in the usage of various ncMTOCs.
Our novel Opto-CAMSAP3 tool enables targeted disruption of CAMSAP3-dependent ncMTOC activity, while leaving other avenues of MTOC activity unaffected. The identification of the real-time changes in microtubule organisation underlying pluripotency and cell lineage specification *in vivo* and *in vitro* may open the door for new ways to regulate microtubule organisation and cell behavior non-invasively for applications in regenerative and reproductive research.

Mediation of cisplatin resistance through cis and trans effects on microtubule dynamics

K. Mahalingan[1], S. Horibata[2], R. Patel[3], Y. Fan[3], J. Hotz[3], K. MacRenaris[2], D. Meerzaman[4], M. Gottesman[3], A. Roll-mecak[1]; [1]NINDS, Bethesda, MD, [2]MSU, East Lansing, MI, [3]NCI, Bethesda, MD, [4]NINDSNCI, Bethesda, MD

More than half a century after its discovery, cisplatin remains one of the most widely used anti-cancer drugs in the world. Despite this, cisplatin resistance is a major problem in cancer therapy. In ovarian cancer, cisplatin resistance accounts for more than 60% of all mortality. Thus, there is an urgent need to understand the mechanisms of cisplatin action. Although cisplatin cytotoxicity has long been associated with DNA damage, our RNA seq analysis of cisplatin-resistant ovarian cancer cells show many changes in microtubule cytoskeleton genes that correlate with drug resistance. Using *in-vitro* assays we show that clinical concentrations of cisplatin directly affect microtubule dynamics by increasing the frequency of microtubule depolymerization events. Cisplatin resistant cells counteract this destabilization through

changes in expressed tubulin isotypes and by over-expressing tubulin polymerization promoting protein (TPPP3). By reconstituting for the first-time microtubule dynamics with tubulin purified from cisplatin sensitive, resistance and re-sensitized cells we find that changes in tubulin isotypes in resistant cells directly stabilize microtubules, and that TPPP3 synergizes with the tubulin isotype repertoire for maximal microtubule stabilization to counteract the destabilization effects of cisplatin. TPPP3 depletion restores partial cisplatin sensitivity. Consistent with this, we find that patients with low TPPP3 expression have markedly improved therapeutic outcome. The demonstration of the direct effects of cisplatin on microtubule dynamics and that microtubule dynamics changes contribute to cisplatin resistance have direct bearing on cisplatin associated neuropathies and ototoxicity as well as cisplatin and paclitaxel combination chemotherapy, as the two drugs have opposing effects on microtubule dynamics. Our study also demonstrates that tubulin isotype repertoire changes, long associated with drug-resistance in tumors, have direct effects on microtubule dynamics and that they evolve synergistically with changes in the proteome associated with microtubules.

B129/P1125

Microtubule Acetylation Promotes Eribulin-induced Cell Death by Accelerating ER-Mitochondria Ca^{2+} Transfer

S. Song, J. Jeong, S. Keum, Y. Hwang, M. Ji, M. Lee, Y. Hwang, J.-H. Choi, S. Rhee; Chung-ang University, Seoul, Korea, Republic of

Eribulin is a newly developed anticancer drug that has been developed for patients who have not responded to first- or second-line anticancer therapy. However, after a series of treatments, most breast cancer cells developed resistance to eribulin. The goal of this study is to identify the signaling pathway induced by eribulin to provide clues for overcoming eribulin resistance. In breast cancer cells, eribulin treatment reduced microtubule (MT) dynamics while increasing its acetylation around the nucleus, but not in eribulin-resistant cells. The eribulin sensitivity to the breast cancer cells was reduced by silencing of α-tubulin N-acetyltransferase 1 (*ATAT*1), a major MT acetyltransferase. In addition, combining eribulin with tubacin, a MT acetylation restored MT dynamics and increased the cell death in eribulin-resistant cells. Mechanistically, eribulin-induced microtubule acetylation around the nucleus confers cells with the ability to promote mitochondrial-endoplasmic reticulum (ER) clustering, which accelerates Ca^{2+} transfer from ER to mitochondria, eventually leading to cell death. Taken together, our findings suggest that MT acetylation is a potential target for treatment of eribulin-resistance breast cancer cells.

B130/P1126

Determining the Role of Acetylated Microtubules in Double-Strand Break Repair and Mobility

J. F. Cátala Torres, A. Deb Roy, T. Inoue; Johns Hopkins University Sch Med, Baltimore, MD

The DNA damage response (DDR) protects us against constant genotoxic insults by coordinating the detection and repair of DNA damage. DNA double-strand breaks (DSBs) are one of the most dangerous forms of DNA damage, due to their propensity to cause mutations that may lead to disease. Although the molecular mechanisms behind DSB repair have been extensively studied, only recently has chromatin mobility come into focus. Upon the onset of DNA damage, microtubules (MTs) interact with nuclear envelope proteins to promote the mobility of DSBs and aid in their repair. Despite the central role of MTs in damaged chromatin mobility, it is not known how they are regulated in response to DNA damage. MT post-translational modifications (PTMs) present a quick and reversible way through which

the DDR can regulate DSB mobility. We and others have observed that MT acetylation increases following the induction of DNA damage. This PTM is evolutionarily conserved across eukaryotes and is exclusively mediated by alpha-tubulin N-acetyltransferase 1 (αTAT1). We have observed that mouse embryonic fibroblasts (MEFs) with an αTAT1 knock-out (KO) contain high basal levels of DSBs. These observations led us to hypothesize that the DDR drives MT acetylation to promote the movement and repair of DSBs. We utilized MEF cells from αTAT1 KO mice to study defects in the DDR in an MT acetylation-free background. We expressed fluorescently labeled 53BP1—a DDR protein—in these cells and observed the repair and mobility of DSBs using live cell microscopy. Our data show that upon treatment with a radiomimetic drug to induce DNA damage, cells lacking αTAT1 are more prone to accumulate DSBs. Wild-type cells repaired most DSBs by 3h, while αTAT1 KO cells did not fix the damage in that timeframe. In addition, we observed that DSBs in cells lacking αTAT1 move less, as determined by their displacement within a 10 min period. These results suggest an important role for microtubule acetylation in the DDR. Given that cells lacking αTAT1 showed defects in both DSB repair and mobility, it is possible that microtubule acetylation promotes DSB mobility to assist in repair. We will use synthetic biology tools developed in our lab to elucidate the mechanism behind this new role of acetylated microtubules in DNA damage repair and gain insight into the development of mutation-driven diseases such as cancer.

B131/P1127

Do microtubule depolymerizers induce inflammation in quiescent and non-quiescent cells?

L. J. Horin, T. J. Mitchison; Harvard University, Boston, MA

Microtubule (MT) destabilizing drugs are used in the clinic as chemotherapeutics for both liquid and solid tumors such as leukemia, melanoma, and non-small cell lung cancer. Although they are widely thought to act by targeting rapidly dividing cells, these therapies can also cause toxicity in tissues composed of quiescent and post-mitotic cells such as neuronal and vascular cells, suggesting that disruption of MT integrity can induce a cell stress response in non-dividing cells. In the literature there are conflicting reports of whether MT drugs causing inflammatory responses, and, as such, further work to clarify the link between MTs and cellular stress response is warranted, especially in different cellular contexts. To examine whether treatment with MT destabilizers causes inflammatory responses, we used several methods to detect markers of inflammation in non-quiescent and quiescent cells. First, we used pathway analysis of multiple published transcriptomics datasets and found that in cardiac tissue and quiescent RPE1s, several genes were upregulated that correlate with NFkB activation in response to short-term treatment with CA4 and other MT depolymerizers. Next, we measured relative NFkB activation in non-quiescent A549 Dual reporter cells in response to a 16 hr treatment with combretastatin A4 (CA4) and TNFα. There was a slight 1.4-fold increase in NFkB, though this was less than the 4.5-fold and 2.0-fold induction by treatment with 1 ng/ml and 0.1 ng/ml TNFα. This suggests there is not a significant effect of CA4 on inflammation in non-quiescent cells. Furthermore, co-treatment of CA4 and TNFα did not amplify NFkB expression, suggesting there is no synergistic effect between the two pathways. Finally, we used immunofluorescent labeling of p65 and phospho-NFkB to measure activation and translocation of NFkB in quiescent RPE1s and serum-starved human pulmonary microvascular endothelial cells (HPMECs). In both groups, treatment with 1 uM CA4 for 2 hours slightly decreased the intensity of these labels compared to DMSO, but there was no difference in nuclear translocation of NFkB into the nucleus. Overall, these data suggest that CA4 does not upregulate inflammatory pathways to a significant degree in quiescent and non-quiescent cell culture models.

Future work will use live cell fluorescence assays to sensitively clarify the relationship between MT depolymerization and inflammation.

Microtubule Networks in Mitosis

B132/P1128

Investigating the role of γ-TuRC minus-end capping in microtubule regulation *in vitro* and in cell division

A. Y. Berman, M. Wieczorek, T. M. Kapoor; The Rockefeller University, New York, NY.

The γ-Tubulin Ring Complex (γ-TuRC) plays an important role in centrosomal and non-centrosomal microtubule formation and organization during mitosis. The γ-TuRC is an ~2.3 MD assembly consisting of γ-tubulin, GCP2-6, MZT1 and 2, and actin that together form a cone-shaped structure. Fourteen γ-tubulins are arranged in a ring at the top of the complex, poised to interact with α,β-tubulins. Microtubule regulation by the γ-TuRC is central to mitosis when microtubule dynamics are increased and microtubule formation and organization are regulated to assemble a bipolar spindle. The γ-TuRC performs at least two functions: it can serve as a template for microtubule nucleation, and it can bind to either nucleated or pre-formed microtubules as a minus-end cap. While recent advances in the structural and biochemical analysis of the γ-TuRC have increased our understanding of γ-TuRC-dependent microtubule nucleation, its microtubule capping activity remains poorly characterized. Furthermore, the role of the γ-TuRC's capping activity in a cellular context remains unclear. To address this, we utilized biochemical reconstitutions and cellular assays to characterize the γ-TuRC's capping activity. Single filament assays showed that γ-TuRC capping of dynamic microtubules, which suppressed growth and shrinkage at minus-ends, had lifetimes of ~1 minute. In contrast, γ-TuRCs remained associated with the minus-ends of newly nucleated microtubules for several minutes. γ-TuRCs reconstituted with nucleotide-binding deficient γ-tubulin (γ-tubulin$^{\Delta GTP}$) formed ring-shaped complexes that did not nucleate microtubules, but capped dynamic microtubule minus-ends at lifetimes similar to wild-type complexes. In dividing cells, knockdown of γ-tubulin and add-back of γ-tubulin$^{\Delta GTP}$ resulted in mitotic spindle defects. However, microtubule regrowth assays revealed that while knockdown of γ-tubulin suppressed non-centrosomal microtubule formation, add-back of γ-tubulin$^{\Delta GTP}$ rescued this process. Our results suggest that γ-TuRC minus-end capping, a nucleotide-binding-independent activity, is required for non-centrosomal microtubule formation during cell division.

B133/P1129

The mitotic spindle protein CKAP2 regulates microtubule dynamics and ensures faithful chromosome segregation.

L. Paim, T. S. McAlear, A. Lopez-Jauregui, S. Bechstedt; Anatomy and Cell Biology, McGill University, Montreal, QC, CANADA.

During mitosis, cells rely on the concerted action of microtubule-associated proteins (MAPs) and motor proteins to assemble the mitotic spindle that orchestrates chromosome segregation. Cytoskeleton-Associated Protein 2 (CKAP2) is predominantly expressed during mitosis and previous work from our lab has shown that it potently increases microtubule nucleation and stability *in vitro*; however, its roles during mitosis in cells are poorly understood. Therefore, to study the function of CKAP2 in cells, we performed CRISPR-Cas9 genome editing to generate knock-out (KO) clones using human fibrosarcoma

cell line HT-1080. Immunofluorescence experiments of wild-type (WT) cells demonstrated that CKAP2 is barely detectable during interphase, however, with the onset of mitosis, CKAP2 localises primarily at the centrosomes and spindle microtubules, subsequently shifting its localisation to the chromatin during telophase. As expected, CKAP2 expression was lost in all three KO clones and significant spindle abnormalities, such as multipolar spindles, chromosome misalignments and lagging chromosomes at anaphase were more frequently observed in KO cells as compared to WT cells. In addition, multiple nuclear abnormalities were detected in KO cells more frequently than in WT cells, with cells displaying multinucleated/fragmented nuclei and abnormal donut-shaped nuclei. Consistent with a role of CKAP2 on chromosomal stability, chromosome spreads and FACS analyses revealed that CKAP2 KO cells were highly aneuploid, and two out of three KO clones displayed a near-tetraploid genome. To investigate the mechanism whereby the loss of CKAP2 impacts chromosomal stability, we performed live cell imaging experiments of cells expressing a fluorescent EB3 marker to directly assess microtubule dynamics, and found that microtubule growth rates were significantly reduced in KO cells, both during mitosis and interphase, as compared to WT cells. Our findings demonstrate the powerful role of CKAP2 as a microtubule nucleation factor in cells and provide a mechanistic explanation for the severe spindle phenotypes and oncogenic potential of CKAP2 misregulation.

B134/P1130

Midzone Microtubule Dynamics in Anaphase cells

C. Fermino Do Rosario[1], Y. Zhang[1], A. Shorey[1], J. Stadnicki[1], J. Ross[2], P. Wadsworth[1]; [1]UMass Amherst, Amherst, MA, [2]Syracuse University, Syracuse, NY.

During anaphase, antiparallel overlapping midzone microtubules elongate, contributing to chromosome segregation and specification of the location of contractile ring formation. Midzone microtubules are dynamics in early but not in late anaphase; however, the kinetics and mechanism of stabilization are incompletely understood.Quantification of midzone microtubules dynamics following photoactivation of LLCPk1 cells expressing PA-GFP tubulin shows that immediately after anaphase onset, a single highly dynamic population of microtubules is present (avg t ½ fast 17 sec). As anaphase progresses, both dynamic and more stable population of microtubules coexist, with a gradual increase in the dissipation half-time for the slower population (avg t ½ slow 85 - 183 sec early to later anaphase). By midcytokinesis, however, only static microtubules (no dissipation of fluorescence) are detected. We tested the contributions of furrowing and of midzone associated proteins to midzone microtubule dynamic behavior. Blocking furrow ingression using either C3 or latrunculin treatment resulted in two spatially distinct microtubule populations in telophase cells: peripheral microtubules that were highly dynamic (avg t ½ 25 sec) and central microtubules with fast and slow populations (avg t ½ fast 9 sec and t ½ slow 127 sec) which did not transition to a static array. Depletion of either PRC1 or Kif4a, which did not block furrow ingression in most cells, also prevented formation of a static array in telophase cells, although microtubules were partially stabilized with turnover similar to mid anaphase cells. In Kif4a depleted or C3 treated telophase cells, the length of PRC1 decorated microtubule overlaps were nearly 5X longer than the short highly compacted zones in control telophase cells. In summary, these results demonstrate that dynamic turnover and sliding midzone microtubules is gradually reduced as anaphase progresses and microtubules are further stabilized during cytokinesis. These data reveal the importance of the PRC1/Kif4a module and midzone microtubule compaction in generating a static midzone.

Augmin prevents merotelic attachments by promoting proper arrangement of kinetochore and bridging fibers

V. Štimac, I. Koprivec, I. Tolić; Rudjer Boskovic Institute, Zagreb, CROATIA.

The mitotic spindle functions as a molecular micromachine that evenly distributes chromosomes into two daughter cells during cell division. Spindle microtubules in human cells are nucleated at centrosomes, at kinetochores, and on the lateral surface of pre-existing microtubules by the augmin complex. However, it is unknown how the augmin-mediated nucleation affects distinct microtubule bundles and thereby mitotic fidelity. Here we show, by using superresolution microscopy of human spindles along with depletion of the augmin complex subunits HAUS6 or HAUS8, that midplane-crossing microtubules are no longer organized into a bridging fiber that connects sister k-fibers when augmin is depleted, suggesting that augmin is responsible for the highly organized architecture of the mitotic spindle. Augmin depletion leads to a three-fold increase in segregation errors when the checkpoint is weakened. A significant number of lagging chromosomes appeared in the inner part of the mitotic spindle close to the main spindle axis, where the midplane-crossing microtubule disorganization is most prominent and proper bridging fibers are often absent. In augmin depleted cells, backtracking of lagging kinetochores until metaphase revealed their larger tilt and shorter interkinetochore distance, suggesting that lack of augmin leads to compromised microtubule arrangement facilitating the formation of merotelic attachments. Merotely was both visible in metaphase cells as well as persistent in anaphase following augmin depletion, indicating that augmin is necessary to both prevent and resolve the segregation errors through an interplay of bridging and k-fibers. The impairment of microtubule arrangement following augmin depletion is reflected in the 25% reduction of k-fibers and 65% reduction of bridging fibers, which are often completely missing. The absence of bridging fibers is characterized by a reduction of the interkinetochore distance. Altogether, our results demonstrate a critical role of augmin in the formation of a properly structured mitotic spindle, suggesting a model where augmin promotes mitotic fidelity and tension on kinetochores by generating highly organized mechanical entities consisting of two sister kinetochore fibers connected by a bridging fiber.

Model mitotic spindle and chromosome as coupled oscillators

J. Zhu, C. Edelmaier, B. Heck, E. Bartle, P. Maddox, E. Nazockdast; University of North Carolina, Chapel Hill, NC.

Mitotic chromosomes of cells throughout phylogeny oscillate during prometaphase and metaphase. Chromosome oscillation can be used as a mechanical read-out of the location, direction, and magnitude of the forces within the spindle. Understanding these force generation mechanisms will further provide insights into how the same forces result in chromosome alignment during metaphase and segregation during anaphase. Several factors are believed to contribute to the oscillation of chromosomes: microtubule poleward flux, centromere stretch, the dynamic instability of microtubules, polar ejection force, and motor proteins. However, the relative contributions of these factors remain poorly understood. **We tested how mechanical couplings at three interfaces: the microtubule and the kinetochore, the kinetochore and the chromosome, and between chromosomes in tandem, contribute to chromosome oscillations.** To investigate the detailed structure of these interfaces, we developed a single molecule live imaging technique - Halo-FSM - founded on the principle of conventional

fluorescent speckle microscopy. Using this technique, we quantified the dynamics of individual microtubules at the kinetochore, with adequate resolution to discern evidence of the asynchrony of dynamics instability between microtubules at a given kinetochore. We also pinpointed the position of the microtubule tip with ~20 nm accuracy in living mitotic cells. Our preliminary data not only invoke the possibility that more than one population of kinetochore-microtubule exists within a given k-fiber but also suggests that microtubule ends penetrate deeper into the kinetochore than previously appreciated. Further, while classic laser ablation experiments in grasshopper spermatocytes assured that kinetochore pairs are mechanically independent, our results with mammalian Ptk1 cells suggest that this is not true in all organisms. In summary, we present evidence for a novel structural principle of the mitotic spindle as a coupled oscillator system.

B137/P1133

Kinetochore centering and oscillations are regulated by overlap-length dependent forces

P. Risteski, J. Martinčić, M. Jagrić, I. M. Tolić; Ruder Boskovic Institute, Zagreb, CROATIA.

Pre-anaphase kinetochore oscillations at the spindle midplane occur in the majority of the cell types and result from a tug-of-war between sister kinetochore fibers (k-fibers). Recently, we have shown that k-fibers are mechanically coupled to overlap bundles, i.e. bridging fibers, which slide apart and drive microtubule poleward flux of sister k-fibers. However, how overlap bundles are involved in the regulation of kinetochore centering and de-centering events that result in kinetochore oscillatory motions at the spindle equator has not been explored. By developing a new speckle microscopy assay we found that longer k-fiber fluxes at a higher rate than the shorter one, moving the kinetochores towards the center. This differential k-fiber flux arises due to asymmetry in the size of overlap regions between k-fibers and bridging fibers. Kinetochore centering efficiency is better when overlaps are shorter and thus k-fiber flux is slower than the bridging fiber flux. In addition to k-fiber flux being length-dependent in metaphase, we found that kinetochore congression velocity in prometaphase is reversely proportional to the flux of the k-fiber associated with proximal pole, which directly supports the idea that microtubule poleward flux drives kinetochore centering in both phases. Interestingly, k-fiber flux rates correlate with the kinetochore oscillation velocities and overlap lengths across a panel of siRNA treatments, implying that the velocity of kinetochore movements is a result of forces transmitted from the overlaps. We measured polymerization at the plus ends and depolymerization at the minus ends of both growing and shrinking sister k-fibers and found these events to be correlated. This correlation was also observed when polymerization and depolymerization events were increased in spindles with increased overlaps due to Kif18A depletion. Moreover, we found that plus ends of growing k-fibers largely polymerize whilst those of shrinking k-fibers exhibit pausing or slowly polymerizing events, thereby suggesting that shrinking k-fibers de-center kinetochores via depolymerization at their minus ends. Thus, we propose that overlaps promote kinetochore centering via length-dependent sliding forces and de-centering via flux-driven regulation of microtubule polymerization and depolymerization events on growing and shrinking k-fibers.

B138/P1134

Three-dimensional reconstruction of mitotic spindles in the late *C. elegans* embryo

C. Okafornta, M. Köckert, G. Fabig, T. Müller-Reichert; Experimental Center, Faculty of Medicine Carl Gustav Carus, Technische Universität Dresden, 01307 Dresden, GERMANY.

The hallmark of mitosis in eukaryotic cells is the efficiency of the bipolar spindle apparatus to align and segregate the chromosomes. While there are many microtubules (MTs) that make up the spindle network, they can be classified by the interaction of their plus ends with target sites. For instance, kinetochore MTs (KMTs) associate with the chromosomes to connect them with the centrosomes. In the one-cell *C. elegans* embryo, KMTs make up about 2.8% of all MTs and achieve an indirect kinetochore-to-centrosome connection by anchoring into the spindle network (Redemann et al., 2017, *Nat. Commun*. 8: doi.org/10.1038/ncomms15288). Here, we use three-dimensional (3D) electron tomography to analyze the length distribution of KMTs in the spindles of late *C. elegans* embryos (Lindow et al., 2021, *J. Microsc.* 284: 25-44). We analyzed mitotic spindles in 16- and 32-cell embryos with the identity of each of the embryonic cells since the development in *C. elegans* is well annotated (Sulston et al., 1983, *Dev. Biol.* 100: 64-119). We show that the connection of KMTs to the centrosomes in spindles of later embryonic cells, especially from the 16-cell to the later stages of the *C. elegans* embryo, favors a switch to a direct connection. We discovered further that, although the total number of the MTs in a relatively small cell decreased by an order of magnitude, the total number of the KMTs remained approximately constant and was thus similar to the number of KMTs as previously observed in the one-cell embryo. Our aim is to analyze this switch in the kinetochore-to-centrosome connection in spindles of different *C. elegans* cell lineages.

B139/P1135

Differential regulation of astral microtubules in a shared cytoplasm

A. Bera, M. L. Gupta; Iowa State University, Ames, IA.

Microtubules (MTs) are essential, intrinsically dynamic cytoskeletal filaments, polymerized from heterodimeric tubulin. Thousands of MTs can work collaboratively to accomplish complex functions like cell division/migration and intracellular cargo transport, with a high degree of fidelity to ensure cell viability and genome stability. Failure in spatiotemporal coordination of MTs can penalize processes like mitosis/meiosis, oogenesis/oocyte maturation and embryo/neurodevelopment. But the mechanisms coordinating the actions of many dynamic MTs to engineer complex cellular machines, or how subsets of MTs faithfully cooperate within the overall network, remain largely unknown. Such mechanisms are difficult to discern in complex cells, containing thousands of MTs. Using *Saccharomyces cerevisiae*, a simple eukaryotic model with easily trackable astral MTs, we uncovered a novel phenomenon controlling MT number inside the daughter cell, or bud, during mitosis. In anaphase cells with mispositioned spindles, the entry/exit of MTs into the bud is regulated by the net MT occupancy status of the bud. This phenomenon is independent of bud neck size, MT length, spindle's distance from the bud neck or even total number of spindles inside the cell. Utilizing live-cell epifluorescence imaging, we have uncovered that highly conserved bud neck components and the plus-end directed, MT-depolymerizing motor, kinesin-8/Kip3, potentially regulate MT entry/exit into the bud. Therefore, we propose a preliminary model wherein controlling MT number inside the bud maximizes the efficiency of cell's spindle positioning mechanism. Elucidating these mechanisms represents a significant advance in

understanding how the actions of many dynamic MTs is coordinated to achieve diverse and complex cellular processes.

B140/P1136

Regulation of spindle pole architecture by the microtubule focusing machineries

G. Guilloux, R. Gibeaux; CNRS - Institut of Genetics and Development of Rennes, Rennes, FRANCE.

The spindle is a bipolar structure, composed of microtubules (MTs), which can adapt its size and architecture among cell types and organisms to ensure mitosis faithfulness. However, how specific spindle morphologies are established is poorly understood. To address this question, we use *X. laevis* and *X. tropicalis* egg extracts. Indeed, *X. tropicalis* spindles are not only shorter than their *X. laevis* counterparts, but they are also architecturally different, notably at their poles. Using these two systems, we aim to understand the mechanisms that control the variability of spindle pole architecture. To overcome the fact that motors involved in pole formation, such as XCTK2 and Eg5, are also involved in organizing the spindle mid-zone, we reduced the complexity of the spindle by studying MT focusing in asters that mimic spindle pole organization. We first compared different types of MT asters (triggered by centrosomes, DMSO or Ran mutant) between species. While the three aster types exhibited size difference between the two species, only those triggered by DMSO presented an increased MT density at the aster center for *X. tropicalis* as observed at spindle poles. By mixing *X. tropicalis* and *X. laevis* extracts and assembling such asters, we found that common focusing mechanisms act in these two species. Measurements of MT growth speed showed no difference between species, which is thus an unlikely mechanism to explain the observed differences. Adapting expansion microscopy to analyze asters, we found aster centers not to be a simple focal point as expected from low-resolution observations, but rather a meshwork. This suggested crosslinking of MTs and a likely important role of Eg5 and/or XCTK2 for pole organization. Surprisingly, while inhibition of Dynein only mildly defocused asters, inhibition of Eg5 and XCTK2 led to MT focusing around a spherical structure and to asters focusing as spirals, respectively. This suggests a complementary action of these three motors, to allow for MT minus-end clustering and MT arrangement stabilization through anti-parallel and parallel interactions.

B141/P1137

Asymmetric requirement for α-tubulin over β-tubulin

L. C. Wethekam, J. K. Moore; Department of Cell and Developmental Biology, University of Colorado Anschutz Medical Campus, Aurora, CO.

Most eukaryotes express families of genes for the α- and β-tubulin monomers that comprise the tubulin heterodimer. How cells regulate the balance of α- and β-tubulin to maintain stoichiometry for heterodimers, and the consequences of monomer imbalance, are not understood. In this study, we use the budding yeast *S. cerevisiae* to investigate the role of gene copy number in maintaining levels of α- and β-tubulin proteins and how shifting the expression of α- or β-tubulin genes impacts the supply of tubulin proteins and microtubule function. We find that α-tubulin gene copy number is uniquely important for maintaining an excess α-tubulin protein compared to β-tubulin protein and prevents the accumulation of toxic levels of β-tubulin. Decreasing β-tubulin gene copy number or increasing α-tubulin expression has minor effects on microtubule function and cell proliferation. In contrast, increased expression of β-tubulin relative to α-tubulin is toxic to cells, leading to the formation of noncanonical

tubulin-containing polymers, unstable mitotic spindles, and disrupted cell proliferation. We use a structure-guided mutagenesis approach to show that β-tubulin toxicity arises from the catalytically inactive GTP-binding pocket that is normally sandwiched between α- and β-tubulin in the heterodimer, and the recruitment of XMAP215/Stu2 to noncanonical polymers formed by super-stoichiometric β-tubulin. The latter suggests a previously unappreciated binding mode between β-tubulin and XMAP215/Stu2. Based on these results, we propose a novel model for the relationship between α- and β-tubulin in which α-tubulin must be maintained in excess to promote GTP hydrolysis and to prevent the accumulation of non-catalytic assemblies of β-tubulin.

B142/P1138

Rotation of microtubule asters under confinement

A. Sami[1], D. B. Stein[2], G. Kabacaoglu[3], J. S. Oakey[4], T. Sulerud[1], M. J. Shelley[2], J. C. Gatlin[1]; [1]Molecular Biology, University of Wyoming, Laramie, WY, [2]Center for Computational Biology, Flatiron Institute, New York, NY, [3]Mechanical Engineering, Bilkent University, Ankara, TURKEY, [4]Chemical Engineering, University of Wyoming, Laramie, WY.

During interphase of the cell cycle, the microtubule (MT) cytoskeleton forms a radial array referred to as the MT aster. The MTs that compose this structure (astral MTs) serve a broad range of functions within the cell including structural mechanics, cell motility, cell division, intracellular transport, and spatial organization. Several of these critical functions require that the aster position itself in the cell such that its center is close to that of the cell's. However, the mechanisms by which this positioning occurs, and that of the nucleus and mitotic spindle indirectly, are poorly understood. To better understand the forces generated by MTs during aster positioning, MT asters were assembled in hydrogel micro-enclosures (artificial cells) containing discrete volumes of cell-free extracts from *Xenopus laevis* eggs. Growing asters readily find the center of their enclosures, and once centered, asters spontaneously begin to rotate. For small cells this rotation is unidirectional and persistent, while for larger cells it is oscillatory with rotation periodically changing direction. In yet larger cells, rotation of any sort is not observed. We find that a minimal *in silico* model of astral MTs interacting through the cytoplasm and impinging upon the cell periphery explains these observations. For example, the model shows rotational switching results from the collective interplay between multiple bending modes of peripherally pinned MTs. A coarse-grain model of the collective dynamics of MT ensembles shows that the allowable bending modes are controlled by MT density; increased density can suppress the higher-order bending modes that drive switching. Both full simulations and experiments with increasing density of MTs confirm this prediction. This suggests that the MT aster can be conceptualized as a device assembly whose operating states arise from the interactions of its internal collective modes. Additionally, these studies demonstrate that the architecture of the MT aster allows pushing forces to be exerted over longer than expected distances, suggesting that MT interactions with cell boundaries must be tightly regulated in real cells.

B143/P1139

TPX2 dependent regulation of spindle architecture

G. Sepulveda[1], X. Zhou[1,2], L. Slevin[1,3], C. Brownlee[1,4], R. Heald[1]; [1]University of California, Berkeley, Berkeley, CA, [2]AbbVie, South San Francisco, CA, [3]Swedish Maternal and Fetal Specialty Center, Seattle, WA, [4]Stony Brook University, Stony Brook, NY

In all eukaryotes, the bipolar, microtubule-based spindle functions to segregate chromosomes to daughter cells during cell division, yet spindle size and microtubule organization vary dramatically across different species and cell types. In particular, meiotic spindles frequently lack astral microtubules at their poles, while mitotic spindles of many animal species possess long astral arrays that are most striking in the early embryonic divisions of a number of marine invertebrates. One candidate factor for modulating astral microtubule density and length is the microtubule-associated protein TPX2, which localizes to spindle poles and possesses microtubule nucleation activity regulated by the nuclear localization signal (NLS)-binding protein importin alpha. TPX2 also interacts with the mitotic kinase Aurora A through its N-terminus, and the kinesin-5 (Eg5) motor through its C-terminus. Although conserved among animals, TPX2 differs dramatically in primary sequence, with an intrinsically disordered region (IDR) in the amino terminal half of the protein capable of liquid-liquid phase separation. Through phylogenetic sequence comparison, we have identified TPX2 homologs in sea urchin (*S. purpuratus*) and sea squirt (*C. intestinalis*) that contain a significantly longer IDR. We hypothesize that this extended domain enhances co-condensation with tubulin, thereby increasing microtubule nucleation and aster size. Further, we have identified a conserved NLS motif located within this disordered region, KKLK in *X. laevis* TPX2, that when mutated to AALA results in significantly higher microtubule nucleation activity during spindle assembly. We are now expressing and purifying wild-type and NLS mutant TPX2 proteins from a variety of different species and testing their effects on spindle architecture and aster formation by adding them to *X. laevis* egg extracts, and determining the role of Aurora A and Eg5 in aster formation by treatment with specific inhibitors. Overall, these experiments will provide new insight into how TPX2 acts to modulate spindle architecture across species and during embryonic development.

Spindle dynamics and orientation depends in force generators configuration

V. Gomez Herrera[1], M. Anjur-Dietrich[2], D. Needleman[3], R. Farhadifar[4], M. Shelley[1]; [1]New York University, New York, NY, [2]Harvard, Cambridge, MA, [3]New York University, Cambridge, MA, [4]Flatiron Institute, New York, NY

During cell division, the mitotic spindle forms inside cells and segregates chromosomes. The spindle's position sets the division plane, which is essential for proper growth and development. Force mechanisms regulating the position of the spindle are not yet understood. Here, we develop a coarse-grained model of spindles in cells, which accounts for microtubule dynamics, pulling forces from cortically bounded motor proteins, and fluid drag. We show that the spindle's resistance to rotation is largely driven by pulling forces from the motor proteins rather than the drag imposed by the cytoplasm. We also show that the arrangement of motor proteins affects the spindle's resistance to rotation- for configurations where multiple motors stack at the same region, the spindle's resistance to rotation significantly reduces. Our findings are consistent with measurements in human tissue culture cells, where the spindle resistance to the rotation has been quantified.

In vivo interrogation of a nanoscale cytoskeleton-associated condensate using super-resolution microscopy

K. Morelli[1], S. M. Meier[2], M. Willis[1], A. Zhao[1], Y. Barral[2], J. Vogel[1]; [1]McGill Department of Biology, Montreal, QC, CANADA, [2]ETH Zürich Department of Biology, Zürich, SWITZERLAND.

Eukaryotic cells coordinate interactions between actin filaments and microtubules to serve various important cellular functions. One such function is positioning and alignment of the mitotic spindle during asymmetric cell division in budding yeast. To position the spindle, astral microtubules which are nucleated at the spindle pole bodies (SPBs, yeast centrosomes) and project into the cytoplasm interact with the polarized actin network which originates at the tip of the bud through the plus-end tracking (+TIP) Kar9. Recent work demonstrates that Kar9 and two other +TIPs, the EB1 homolog Bim1 and the CLIP170 homolog Bik1, form a liquid-like condensate which tracks the plus ends of growing and shrinking astral microtubules. However, directly observing predicted liquid-like behavior in living cells is challenging because Kar9 condensates have diameters around 200 nanometers or less in vivo. Therefore, we use lattice structured illumination microscopy super-resolution to study behaviors which emerge from material properties and determine condensate functions in vivo. Using time series with >15 frames per second, we develop a method to annotate dynamic microtubule behavior according to dynamic instability parameters using Kar9 as a plus end marker. Strikingly, shorter metaphase microtubules appear to grow and shrink along the contour of longer microtubules from the same SPB. These astral microtubules undergo rapid angular motions of astral microtubules relative to the SPB which most likely result from actin-bound myosin V pulling on Kar9 at their tips. Remarkably parallel microtubules remain linked during these motions. We conclude that microtubules are bundled by a mechanism that persists during phases of microtubule dynamic instability and rapid motion through the cytoplasm.

Ciliary/Flagellar motility

Intracellular connections between basal bodies promote the coordinated behavior of *Tetrahymena* motile cilia

A. Soh[1], L. Woodhams[2], A. Junker[1], C. Enloe[3], B. Noren[3], A. Harned[4], C. Westlake[5], K. Narayan[4], J. Oakey[3], P. Bayly[2], C. Pearson[1]; [1]University of Colorado Anschutz medical campus, Aurora, CO, [2]Washington University in St. Louis, St. Louis, MO, [3]University of Wyoming, Laramie, WY, [4]National Cancer Institute, Bethesda, MD, [5]National Cancer institute, Frederick, MD.

The generation of efficient fluid flow is crucial for organismal development and homeostasis, sexual reproduction, and cell motility. Multiciliated cells possess fields of motile cilia that beat with metachronal synchrony to propel fluid. Cilia-driven fluid flow produces extracellular hydrodynamic forces that synchronizes ciliary beating. However, hydrodynamic coupling between neighboring cilia is not the sole mechanism for ciliary synchrony. Cilia are nucleated by basal bodies (BBs) that link to each other and to the cell's cortex via BB-associated appendages. The intracellular BB and cortical network is hypothesized to couple cilia and transmit cilia coordination cues. The extent of intracellular ciliary connections and the nature of these stimuli remain unclear. How BB connections influence the dynamics

of individual cilia has not been established. Using FIB-SEM imaging in *Tetrahymena thermophila*, we show that cilia are both longitudinally and laterally coupled by the underlying BB and cortical cytoskeletal network. To visualize the behavior of individual cilia in live, immobilized *Tetrahymena* cells, we developed Delivered Iron Particle Ubiety Live Light- (DIPULL) microscopy. Quantitative analysis of ciliary dynamics reveals that BB connections influence ciliary waveforms, but not ciliary length or beat frequency. Loss of BB connections in the *disA-1* mutant causes shorter and slower ciliary power strokes. Computer modeling analysis predicts that short and slow power stroke trajectories lead to reduced ciliary force output. Consistent with this, cells with disconnected BBs exhibit slower cilia-driven fluid flow. Disruption to BB connections also causes inconsistent power strokes between adjacently positioned cilia, leading to elevated frequencies of ciliary tangles and slower cell motility. In summary, BB connections promote effective ciliary power strokes and synchronize ciliary beating for efficient fluid flow and cell motility.

B148/P1143

***In situ* cryo-electron tomography reveals the asymmetric architecture of mammalian sperm axonemes**

Z. Chen[1], G. A. Greenan[1], M. Shiozaki[2], Y. Liu[1], W. M. Skinner[3], X. Zhao[2], S. Zhao[2], R. Yan[2], Z. Yu[2], P. V. Lishko[3], D. A. Agard[1], R. D. Vale[2]; [1]University of California, San Francisco, San Francisco, CA, [2]Janelia Research Campus, Ashburn, VA, [3]University of California, Berkeley, Berkeley, CA.

In their quest for optimal efficiency, sperm have evolved exquisite engineering solutions to deliver their genetic information to oocytes. The flagella of mammalian sperm display non-planar, asymmetric beating, in contrast to the planar, symmetric beating of flagella from sea urchin sperm and unicellular organisms. The molecular basis of this difference is unclear. Here, we perform *in situ* cryo-electron tomography of mouse and human sperm, providing the highest-resolution structural information of the axonemes to date (up to 6.0 Å). Our subtomogram averages reveal mammalian sperm-specific protein complexes within the microtubules and regulatory complexes of dyneins. The structures and interaction network of these mammalian sperm-specific complexes suggest their potential roles in enhancing the mechanical strength of the axonemes and regulating dynein-based axonemal bending. Intriguingly, we find that each of the nine outer microtubule doublets is decorated with a distinct combination of sperm-specific complexes. We propose that this asymmetric distribution of proteins differentially regulates the bending and sliding of each microtubule doublet and may underlie the asymmetric beating of mammalian sperm flagella. How these complexities and asymmetries arise during mammalian sperm development will be the next key question.

B149/P1144

Hydrodynamic mechanism of formation of metachronal waves in arrays of cilia

B. Chakrabarti[1], S. Fürthauer[2], M. Shelley[3]; [1]Center for Computational Biology, Simons Foundation Flatiron Institute, New York, NY, [2]Institute of Applied Physics, TU Wien, Vienna, AUSTRIA, [3]Center for Computational Biology, Simons Foundation Flatiron Institute, New york, NY.

Motile cilia are slender, hair-like cellular appendages that spontaneously oscillate under the action of internal molecular motors and are typically found in dense arrays. These active filaments coordinate their beating to generate metachronal waves that drive long-range fluid transport and locomotion. Understanding the emergence and properties of such metachronal waves in ciliary arrays is a multiscale problem central to developmental biology, transport phenomena, and nonequilibrium physics, with

potential biomedical applications. Until now, our understanding of their collective behavior largely comes from the study of minimal models that coarse grain the relevant biophysics and the hydrodynamics of slender structures. Here we build on a detailed biophysical model to elucidate the emergence of metachronal waves on millimeter scales from nanometer-scale motor activity inside individual cilia. Our study of a one-dimensional lattice of cilia in the presence of hydrodynamic and steric interactions reveals how metachronal waves are formed and maintained. We find that, in homogeneous beds of cilia, these interactions lead to multiple attracting states, all of which are characterized by a conserved integer charge. This allows us to design initial conditions that lead to predictable emergent states. Finally, and very importantly, we show that, in nonuniform ciliary tissues, boundaries and inhomogeneities provide a robust route to metachronal waves. Due to the novelty of our modeling and computation, we have unraveled the spatiotemporal self-organization of nanometric motor proteins in coordinating collective dynamics spanning millimeters: bridging length scales over six orders of magnitude.

B150/P1145

FAP47, HYDIN and CPC1 in the central pair apparatus of *Chlamydomonas* flagella

Y. Tani[1], H. Yanagisawa[1], T. Yagi[2], M. Kikkawa[1]; [1]Graduate School of Medicine, University of Tokyo, Tokyo, JAPAN, [2]Department of Life Sciences, Faculty of Life and Environmental Sciences, Prefectural University of Hiroshima, Hiroshima, JAPAN.

Motile cilia have a so-called “9+2” structure, which consists of nine doublet microtubules and central pair apparatus. The central pair apparatus has two microtubules surrounded by several projections, which are thought to interact mechanically with radial spokes and control the flagellar beating. Recently, the components of the central pair apparatus of motile cilia have been identified by proteomic and genomic analysis. Still, the mechanism of how the central pair contributes to the flagellar motility has much to be revealed. Here, we focused on high molecular weight components of the central apparatus, FAP47, HYDIN, and CPC1, and studied the swimming phenotypes and 3D localizations of these components using *Chlamydomonas* mutants. First, the swimming speed of FAP47-deficient cells is equal to the wild type’s speed, and the HYDIN-deficient mutant shows slightly slower swimming than the wild type. *fap47 x cpc1* double mutant cells swim much slower than cpc1 single mutant cells, indicating that the lack of FAP47 makes the motility defect of *cpc1* worse. GFP-tagged FAP47 rescued this motility defect. Among these three proteins, FAP47 is less studied, so we focused on FAP47. The FAP47-deficient mutants swam straighter than the wild type, which indicates the regulation of the flagella is disordered. Second, we suspect that this malfunctioning of flagella is caused by structural defects of the central pair apparatus, so we also checked the structural contribution of FAP47 in the central pair apparatus. FAP47 localizes the entire length of axonemes in indirect immunofluorescence microscopy and cryo-electron tomography revealed that the FAP47-deficient strain partially lacks the C1-C2 bridge structure. In conclusion, the lack of FAP47 destabilizes the central pair apparatus and affects the regulation of flagellar beating.

B151/P1146

Basal body polyglutamylation is modulated by differential ciliary forces

E. Collet, C. Pearson; UNIVERSITY OF CO ANSCHUTZ MEDICAL CAMPUS, Aurora, CO.

Motile cilia are evolutionarily conserved structures that produce hydrodynamic forces through highly coordinated beating. These hydrodynamic forces are critical for generating fluid flow in multiciliated epithelial cells and in the motility of multiciliated single-celled organisms. Ciliary beating is accomplished through dynein-driven sliding of the microtubule doublets which run the length of the cilium, resulting in a prominent, asymmetric beat stroke. These microtubule doublets are nucleated and anchored to the cell cortex by basal bodies (BBs), which resist and stabilize cilia against these asymmetric forces. While several molecular components and microtubule post-translational modifications have been identified as BB-stabilizing factors, the mechanisms by which BBs are stabilized against differential ciliary forces remain largely unexplored. Through modulation of the ciliary forces experienced by the ciliate Tetrahymena thermophila, we find that the levels and distribution of microtubule polyglutamylation at the BB actively respond to differential ciliary forces. Increasing or decreasing ciliary forces results in a corresponding increase or decrease in BB polyglutamylation. Additionally, we show BBs exhibit a distinctly variable, yet asymmetric, pattern of polyglutamylation localization at average ciliary forces. When subjected to increased ciliary forces, this asymmetry is promptly lost. Furthermore, BBs experiencing reduced ciliary forces exhibit an asymmetric polyglutamylation pattern distinct from that of control BBs. We propose that an upregulation of BB polyglutamylation is required to protect against elevated ciliary forces, and that these forces result in a saturation of polyglutamylation which masks the asymmetry exhibited at lower force levels.

B152/P1147

Generation of a mouse IFT25GFP knock-in mouse model

W. Li, Y. Yap, A. Kearney, C. Kelly, Z. Zhang; Wayne State University, Detroit, MI

Intraflagellar transport 25 (IFT25) is a component of the IFT-B complex. In mice, even though this IFT component is not required for cilia formation in the somatic cells, it is essential for sperm formation. However, the intracellular localization of this protein in male germ cells is not known given no antibodies are available for histologic studies. To examine localization of the protein in male germ cells and further investigate the mechanism of IFT in sperm formation, particularly to look into the dynamic trafficking of the protein, we generated a mouse IFT25/GFP knock in mouse model using the CRISPR/cas9 system, with the mouse IFT25 protein fused with a GFP tag in the C-terminus. Three independent lines were analyzed. Western blotting using both anti-IFT25 and anti-GFP antibodies showed that the IFT25/GFP fusion protein has the same tissue distribution as the endogenous IFT25 protein, with the highest level in the testis. Examination of localization of the IFT25/GFP in isolated germ cells revealed that the fusion protein was present in the cytoplasm of spermatocytes and round spermatids and a strong signal was present in the developing sperm flagellar. Diffusion analysis of IFT25 within the manchette and developing flagellar revealed the presence of both mobile and immobile fractions. Preliminary fluorescence recovery after photobleaching (FRAP) data revealed 40% of the IFT25 were mobile with a diffusion rate of 0.5 $\mu m^2/s$ while the remaining 60% of the IFT25 were immobile and did not recover after photobleaching. On going analyses will assess varying IFT25 mobility throughout the developing sperm.

B153/P1148

Rapid changes in ciliary waveform and beat frequency produce jumping behaviors in the predatory marine ciliate *Strobilidium*

D. Galati, M. B. Olson, T. Ridgway, B. Morales, M. G. Campbell, W. Zwolinski; Western Washington University, Bellingham, WA

Marine ciliates link microbially derived organic carbon to crustacean zooplankton at the lowest trophic levels. To succeed at these lower trophic levels, marine ciliates use diverse motility behaviors to capture prey (microbes) and escape predators (zooplankton). These motility behaviors include persistent unidirectional swimming, helical trajectories, anchored "bobbing", seemingly random "meandering", and bursts of rapid acceleration known as "jumping." One of the most well-studied jumping marine ciliates is *Strobilidium*, which accelerates from rest to speeds greater than 50 mm/sec in less than one second. Although the ecological importance and swim speeds associated with *Strobilidium* jumping have been characterized, the ciliary processes the enable jumping are not clear. To overcome this, we investigated confined single *Strobilidium* cells with high-speed oblique illumination microscopy. We found that *Strobilidium* jumping is initiated by a near instantaneous change in ciliary waveform and beat frequency that occurs over several milliseconds. The change in waveform and beat frequency propagates around a ring of fused oral cilia before slowly returning to the pre-jump status. The pre- and post-jump ciliary states are nearly identical, and there is no observable change in cell shape prior to jumping. Collectively, these results suggest that a ciliary state-switching mechanism initiates at or near the fused oral cilia to allow *Strobilidium* to alternate between two different velocity states.

Ciliopathies

Characterization of a new ciliopathy-related disorder caused by mutations in WDR44 that affect RAB11-dependent ciliogenesis initiation

S. Shakya[1], A. Accogli[2], T. Yang[3], C. Insinna[1], S. Park[3], C. Westlake[1]; [1]Center for Cancer Research, NCI Frederick, Laboratory of Cellular and Developmental Signaling, Frederick, MD, [2]IRCCS Istituto Giannina Gaslini, Genova, ITALY, [3]Institute of Pharmaceutical Sciences, College of Pharmacy, Seoul National University, Seoul, KOREA, REPUBLIC OF.

Primary cilia are antenna-like structures required for developmental signaling pathways such as Hedgehog (Hh). These organelles are derived from the mother centriole (MC) through a complex process called ciliogenesis which is initiated by preciliary vesicle (PCV) trafficking and docking to the MC. Notably, ciliopathy disorders have been linked to defects in PCV-MC docking, but not PCV trafficking. RAB11 is required for PCV transport and interaction with WDR44 through its NH_2-terminal RAB11 binding domain (RBD) prevents ciliogenesis initiation by a poorly understood mechanism. Here we describe a new X-linked ciliopathy-related disorder caused by mutations in the RAB11 effector WDR44. We identified seven missense and one nonsense WDR44 variants in the COOH-terminal WD40 repeat domain from male patients that display ciliopathy-related features including musculoskeletal abnormalities, craniofacial dysmorphism, and kidney disease. Fibroblasts isolated from severely affected patients have aberrant ciliogenesis initiation and reduced Hh signaling implicating dysfunctional cilia as causative in disease. Zebrafish embryos expressing human WDR44 variants show ciliopathy-related phenotypes that correlate with the severity of the disease spectrum observed in these patients.

Moreover, the expression of WDR44 variants in human cells and zebrafish embryos reduces ciliation. Remarkably, missense variants associated with more severe disease show strongly reduced expression, which was unexpected based on the WDR44 function in blocking PCV trafficking. We discovered that the gain-of-function for these proteasome-sensitive WDR44 variants is associated with enhanced vesicular localization resulting from higher affinity binding to RAB11. Molecular structure predictions and coimmunoprecipitation studies support a direct interaction between the WDR44 RBD and the WD40 repeat domains, and strikingly the WDR44 patient missense variants disrupt these interdomain interactions. Together, our work demonstrates that WDR44 interdomain associations are important for regulating RAB11 effector binding, and the mutations observed in our patients alter these interactions resulting in impaired ciliogenesis initiation causing a ciliopathy-related disorder.

Bardet Biedl Syndrome Alters the Ciliary Localization of Appetite Signaling Proteins in the Paraventricular Nucleus

G. Canales[1], J. Reiter[1,2], C. Vaisse[3]; [1]Biochemistry and Biophysics, Cardiovascular Research Institute, University of California, San Francisco, San Francisco, CA, [2]Chan Zuckerberg Biohub, San Francisco, CA, [3]Department of Medicine, Diabetes Center, University of California, San Francisco, San Francisco, CA.

Obesity is a hallmark feature of Bardet-Biedl syndrome (BBS), a ciliopathy caused by loss of function of the ciliary GPCR trafficking complex called the BBSome. A ciliary GPCR in the paraventricular nucleus (PVN) of the hypothalamus, called Melanocortin 4 Receptor (MC4R), is the most common gene mutated in monogenic obesity. *Mc4r*$^{-/-}$ mice develop hyperphagia and obesity, revealing the role of MC4R in food intake and body weight regulation. Disrupting primary cilia in the mouse adult CNS is sufficient to cause hyperphagic obesity and neuronal primary cilia function can be affected by diet and Leptin levels. MC4R co-localizes and works with Adenylyl Cyclase (ADCY) at PVN primary cilia to control feeding in vivo. I hypothesize that ciliopathies cause obesity by disrupting ciliary MC4R signaling in the PVN. Using mouse ciliopathy models of BBS and an endogenously tagged MC4R-GFP, I will show that localization of ADCY3 to PVN cilia is significantly reduced, while MC4R localization is increased. Our findings hint that central regulation of appetite signaling in BBS may be perturbed by a loss of Adenylyl Cyclase in the PVN, a model that we are testing using conditional genetic approaches. We are also investigating how the ciliary trafficking of ADCY3 is perturbed in some neuronal cilia but not others. This work has important implications for how we treat obesity in BBS patients.

Loss of the Membrane-Binding Protein ciBAR1 in Mice Leads to Ciliary Defects

E. Kim[1], M. Hoque[1], J. Chen[1], F. Li[2], K. Takemaru[2]; [1]Molecular and Cellular Biology Graduate Program, Stony Brook University, Stony Brook, NY, [2]Department of Pharmacological Sciences, Stony Brook University, Stony Brook, NY.

Cilia—ubiquitous, microtubule-based organelles that protrude from the apical cell surface—play a variety of roles, including mechano- and chemosensation, cell signaling, and fluid dynamics. Dysfunction of cilia is associated with pleiotropic diseases, known as ciliopathies. The current body of literature suggests that the unique composition and morphology of the ciliary membrane are crucial for maintaining the function and homeostasis of cilia. However, the molecular players and mechanisms underlying the formation and maintenance of the ciliary membrane remain poorly understood. Previous

work by our lab and other groups demonstrated that the evolutionarily conserved coiled-coil protein Chibby1 (Cby1) localizes to the ciliary base and plays key roles in ciliogenesis in various model organisms. More recently, our lab reported that the membrane-binding proteins, Cby1-interacting BAR domain-containing 1 and 2 (ciBAR1 and 2; formerly known as FAM92A and B), physically interact with Cby1 to promote ciliogenesis. Bin/Amphiphysin/Rvs (BAR) domain-containing proteins are known to dimerize and form crescent-shaped structures that generate or preferentially bind to curved membranes to facilitate a plethora of cellular processes, such as endocytosis and vesicular fusion and fission. Coexpression of ciBAR and Cby1 induces membrane tubule-like structures in mammalian cultured cells. However, the *in vivo* functions of ciBAR1 and 2 are currently unknown. To elucidate the role of ciBAR1 in mammalian development, we have generated a ciBAR1$^{-/-}$ mouse model. We found that about 20% of ciBAR1$^{-/-}$ mice show embryonic lethality, and the rest appear runted but survive into adulthood with no gross morphological abnormalities. Consistent with the important role of ciBAR1 in ciliogenesis, ciBAR1$^{-/-}$ mouse embryonic fibroblasts (MEFs) exhibited a robust decrease in the number of primary cilia. In MEFs, ciBAR2 is not expressed, and Cby1 is detectable at the ciliary base in the absence of ciBAR1. Furthermore, we found that, like Cby1$^{-/-}$ mice, ciBAR1$^{-/-}$ mice develop cystic lesions in the pancreas most likely due to dysfunctional primary cilia. Taken together, our findings indicate that ciBAR1 plays a critical role in ciliogenesis, at least in certain ciliated cell types, in mice.

Characterization of the Disease-Causing Mechanism of KIF3B Mutations from Ciliopathy Patients

S. Rogers, J. Reid, R. Dasari, C. Goben, J. M. Adams, **M. F. Engelke**; School of Biological Sciences, Illinois State University, Normal, IL.

The heterotrimeric kinesin-2 motor KIF3A/KIF3B/KAP drives intracellular transport, which is essential for ciliogenesis and ciliary function. Two point mutations in the KIF3B subunit (E250Q and L523P) have recently been linked to human disease (Cogne et al., 2020, Am. J. Hum. Genet.). Heterozygous carriers of these mutations display retinitis pigmentosa and, in some cases, other classical ciliopathy phenotypes such as postaxial polydactyly, as well as hepatic fibrosis and heart malformation (E250Q) and kidney dysfunction (L523P). However, the molecular mechanism leading to disease is currently unknown. Here we use *Kif3b*-knockout 3T3 cells, which cannot make cilia, to characterize these mutations. We find that re-expression of wildtype KIF3B restored ciliogenesis in 79.4% of transfected cells. In contrast, expression of the mutants resulted in virtually no cilia: E250Q rescued ciliogenesis in 0% and L523P in 0.4% of transfected cells. Next, we functionally characterized motor complexes containing the disease-causing mutations. Fluorescent-tagging revealed that the L523P mutant localized diffusely throughout the cytoplasm, indistinguishable from wildtype KIF3B, while the E250Q mutant decorated microtubules. Further characterization of the E250Q mutation, located in the nucleotide-binding switch II element of the motor domain, revealed it to be a novel rigor mutation that causes motor complexes to tightly bind to but not move along microtubules. The L523P mutation falls within the coiled-coil stalk domain of the motor. Bioinformatic analysis suggests that this mutation causes a break in the alpha-helical structure of this domain, suggesting that this mutation might interfere with the formation of the trimeric KIF3A/KIF3B/KAP complex. To our surprise, protein interaction assays revealed that motor complex assembly is unaffected. Instead, induced activation of the L523P mutant by truncation of the tail domain did not result in the expected peripheral accumulation of the mutant motor and thus indicates a defect in processive motility along microtubules. In summary, this work elucidates the molecular effects of disease-causing mutations in the KIF3B subunit on the kinesin-2 holoenzyme. Future work will establish

how the impaired function of kinesin-2 leads to ciliary disease. This work is funded by the NIGMS grant 1R15 GM137248-01A1 to MFE.

B158/P1153

Screening of a small molecule library for chemicals that enhance motile ciliogenesis using zebrafish and mice

G. Chandrasekaran[1], H. J. Ryu[2], G. B. Lee[3], H. Lu[4], S. Roy[4], M. A. Bae[5], H. Hyun[1], J. H. Ahn[3], E. Y. Choi[2], S. Y. Choi[1]; [1]Biomedical Sciences, Chonnam National University Medical School, Hwasun 58128, KOREA, REPUBLIC OF, [2]Biomedical Sciences, University of Ulsan College of Medicine, Seoul 05505, KOREA, REPUBLIC OF, [3]Chemistry, Gwangju Institute of Science and Technology, Gwangju 61005, KOREA, REPUBLIC OF, [4]Institute of Molecular and Cell Biology, Proteos, 61 Biopolis Drive 138673, SINGAPORE, [5]Bio & Drug Discovery Division, Korea Research Institute of Chemical Technology, Daejeon 34114, KOREA, REPUBLIC OF.

Cilia are classified into primary (non-motile) cilia and motile cilia. Ciliopathies are a group of genetic disorders caused by dysfunctional cilia. Motile cilia play a vital role in clearing mucus and foreign matter along the trachea and bronchi, cerebrospinal fluid circulation, ova movement from the ovary, and sperm motility. Defects in the motile cilia result in hydrocephalus, chronic respiratory infections, and infertility. Restoring motile cilia with respect to structure and function is critical to treating motile ciliopathies. However, there has been little, if any, known empirical research and effective therapeutic modalities for motile ciliopathies to date. To develop small molecules that can increase motile cilia's number, length, or function, a high throughput small molecule library screen was performed using *Tg(foxj1a:eGFP)* zebrafish larvae. Foxj1 transcription factor is a master regulator of motile ciliogenesis. Eight hit compounds (HC) were identified by this screening. The HCs were further validated with anti-acetylated α-tubulin immunostaining on WT zebrafish and primary mouse tracheal epithelial cells (mTECs). Drug metabolism and pharmacokinetics (DMPK) studies also identified HC-2 as druggable. In fact, at the molecular level, HC-2 increased the expression of several essential genes involved in motile ciliogenesis. Moreover, HC-2 effectively rescued the ependymal motile cilia in a zebrafish genetic model with reduced motile cilia. Most importantly, the administration of HC-2 to chronic obstructive pulmonary disease (COPD) mice model restored the otherwise lost/reduced tracheal motile cilia and aided in reducing airway resistance. Finally, using a novel hydroxyapatite-dye bead-based affinity purification assay, the GEMC1/MCIDAS-DP1 protein complex was preliminarily identified as a potential molecular target of HC-2, warranting further investigation. Given the above, our findings show promising pharmacological properties of HC-2 and support the idea of using it as a direct pharmacological intervention against defective motile cilia to ameliorate motile ciliopathy.

mRNA therapy restores cilia function in a *ccdc40* zebrafish mutant model for Primary Ciliary Dyskinesia

M. Rasteiro, S. Lopes; Nova Medical School, Lisbon, Portugal

Primary ciliary dyskinesia (PCD) is an autosomal recessive disease characterized by neonatal respiratory distress, bronchiectasis, infertility, and *situs inversus*, all of these outcomes of defective cilia function. Mutations in more than 50 genes encoding cilia components have been confirmed to cause PCD. *ccdc40* is one of these genes that encodes a protein involved in the assembly of the internal dynein arms, the

nexin-dynein regulatory complexes, and the radial spokes, thus playing a crucial role in the correct assembly of the cilia ultrastructure and as a result impacting in the mucociliary clearance. The *CCDC40* gene has been described as causing a PCD variant resulting in more severe symptoms and a worse prognosis regarding respiratory complications than other PCD genes. Mucociliary clearance is essential to keep the lungs free of pathogenic agents. In PCD patients this mechanism is deficient or absent resulting in chronic respiratory infections. Up to the moment, there is no curative therapy available. PCD patients can only address their symptoms with antibiotics and physical therapy. Our animal model is a zebrafish with a mutation in the *ccdc40* gene presenting *situs inversus* and lack of cilia motility in the olfactory pit resulting from cilia ultrastructure disorganization observed by TEM. Zebrafish present a wide variety of ciliated organs, among them multiciliated epithelial tissues like the one present in the human respiratory system. When we administer a transient mRNA therapy (*CCDC40* human mRNA) coupled to a lipidic nanoparticle carrier into these zebrafish embryos, we are able to restore ciliary beat frequency and function in the olfactory pit to values indistinguishable from wild-type siblings. Our current results reinforce the human-zebrafish homology and show us that the transient gene therapy using this lipidic nanoparticle technology is effective in delivering the human *CCDC40* mRNA to the cells resulting in a strong rescue ability of the olfactory pit cilia movement. We believe that our findings are paving the way for future treatment for PCD patients.

B160/P1155

Neuronal primary cilia regulate postnatal pyramidal cell positioning to the deep and superficial sublayers in the mouse cortex

J. Yang, L. Qiu, K. Bicja, S. Mirhosseiniardakani, X. Chen; university of new hampshire, Durham, NH

It is well-recognized that primary cilia regulate embryonic neurodevelopment, but little is known about their roles during postnatal neurodevelopment. The hippocampal striatum pyramidal (SP) is subdivided into deep and superficial sublayers and gradually condensed into a compact lamina in the first postnatal two weeks, whereas simultaneously the volume of the neocortex greatly expands. It is elusive how pyramidal neurons position to two cortical sublayers postnatally. Here, we show that the axonemes of primary cilia in the deep and superficial sublayers of hippocampal SP point in the opposite directions, while neuronal cilia in neocortical sublayers display the same orientation. Neuronal primary cilia in the CA1 SP undergo marked changes in morphology and orientation from postnatal day 5 (P5) to P14, concurrent with cell positioning to two sublayers and with neural maturation. Surprisingly, the centrioles of late-born neurons migrate excessively to cluster at SP bottom before cilia protrusion and a reverse movement back to the main plate. Similarly, this “pull-back” movement of centriole/cilia is also identified on late-born cortical pyramidal neurons. We further reveal that ablation of neuronal cilia selectively in the mouse forebrain leads to significantly megalencephaly and increased superficial neurons positioned in the deep sublayer of the neocortex during the early postnatal stage. Together, this study provides the first evidence that primary cilia regulate pyramidal neuronal positioning in the mouse cortex and late-born pyramidal neurons undergo a reverse movement for cell positioning.

B161/P1156

Regulation of postnatal cortical development by neuronal primary cilia

K. Bicja, J. Yang, L. Qiu, X. Chen; University of New Hampshire, Durham, NH

Neuronal primary cilia (NPC) are small, centriole-based surface projections known to regulate embryonic neurodevelopment by multiple signaling pathways. However, whether NPC modulate postnatal brain development is not clear. The first objective of my research was to examine cilia orientation in the hippocampal dentate gyrus using transgenic mice overexpressing Arl13b, a protein regulating ciliogenesis, and overexpressing Centrin2, a protein marking the centriole base of cilia (Arl13b+ mice). Arl13b+ mice display elongated cilia in all regions of the hippocampus. In the postnatal dentate gyrus, the cilia showed a loosely opposite orientation, and they were generally perpendicular to the lamina of the granule cell layer. This result is consistent with our previous research about the opposite cilia orientation in the hippocampal CA1 region, which supports that directionality of NPC displays oppositely in compact laminated structure in the forebrain. The second objective was to determine cortical differences among control mice, Arl13b+ mice, and forebrain-specific cilia knockout mice (Ift88 flox/flox Emx1-Cre) via the tools of micro-CT and immunostaining. Interestingly, Ift88-Emx1 KO brains were slightly larger than their littermate brains, while Arl13b+ brains were slightly smaller than their control brains. Immunostaining was performed using anti-SATB2 and anti-CTIP2 antibodies, with SATB2 labeling the superficial sublayer and CTIP2 labeling the deep sublayer in the neocortex. Compared to controls, KO brains showed a higher SATB2 expression level in layer V, with a less clear border between layer V and IV. However, the cell density of controls and KO brains in layer V did not show significant differences. These preliminary results suggest that NPC play a critical role in regulating postnatal cortical development.

B162/P1157

The role of the retinal pigment epithelium in ciliopathy-mediated retinal degenerations

D. Reichert[1,2], C. Lewallen[1], R. Sharma[1], D. Ortolan[1], H. May-Simera[2], K. Bharti[1]; [1]NIH, Bethesda, MD, [2]JGU, Mainz, Germany

Primary cilia are microtubule-based antenna-like structures protruding from the cell surface of almost all cell types in the human body. Thought to be an evolutionary remnant, it was only recently discovered that primary cilia are cellular organelles critical for a wide range of physiological functions and developmental pathways. Mutations in ciliary proteins, that cause defects in cilia maintenance and function, are associated with a multitude of severe diseases, collectively termed ciliopathies. Retinal degeneration is the most common phenotype of syndromic and non-syndromic ciliopathies, subsequently leading to vision loss. The role of primary cilia in photoreceptors of the retina has largely been defined, however the function of primary cilia in other ocular tissues remains unknown. Of particular interest is the retinal pigment epithelium (RPE), a highly polarized monolayer in the back of the eye, essential for visual function. There is increasing evidence that the primary cilium and ciliary proteins are important in the development and function of the RPE. To discover the role of cilia in the RPE and how cilia defects affect RPE physiology in ciliopathy-mediated retinal degenerations, we generated induced pluripotent stem cell (iPSC) lines from seven ciliopathy patients with mutations in different cilia associated genes. These include Bardet-Biedl syndrome, Joubert syndrome, Leber's congenital amaurosis, Usher syndrome and PRPF31-mediated retinitis pigmentosa. All iPSC lines were successfully differentiated into mature iPSC-RPE. Flow cytometry showed that more than 95% of

differentiated cells expressed TYRP1 in all samples. RPE maturity was assessed by staining for RPE markers RPE65, Ezrin and Collagen IV. All lines formed a monolayer with transepithelial resistance of several hundred $\Omega*cm^2$. These newly generated lines will be compared to matched-control iPSC-RPE to understand the RPE disease phenotype. The generated lines will shed light on how the primary cilium impacts RPE differentiation, maturation, and function. This study provides the first human *in vitro* RPE disease models for a broad variety of ciliopathies, which can help develop treatment strategies for retinal degeneration in ciliopathy patients.

B163/P1158

Cep162 deficiency delays primary cilium formation through CP110 persistence at the mother centriole and causes retinal degeneration in humans

N. Nuzhat[1], J. Willer[1], H. Truong[1], E. D. Baere[2], H. J. Bolz[3], J. Pearring[1]; [1]University of Michigan, Ann Arbor, MI, [2]University of Ghent, Ghent, Belgium, [3]Senckenberg Center for Human Genetics, Frankfurt, Germany

In general, human mutations present in core ciliary components can involve virtually any organ, with frequent affection of the retina since the light-sensitive photoreceptor outer segment is an adapted primary cilium. Additionally, the process of ciliogenesis requires hundreds of proteins many of which also function outside of the cilium, such as playing key roles during cell cycle. In this study, we identified a homozygous *CEP162* frameshift variant, c.1935dupA (p.(E646R*5)), in two unrelated patients diagnosed with non-syndromic retinal dystrophy. CEP162 is a centrosome and microtubule-associated protein required for proper transition zone assembly during ciliogenesis and has been linked to neuronal development. Determining how the ciliary protein, CEP162, contributes to other cellular processes will help us to better understand the diversity of human ciliopathy phenotypes.
Using genetic, cell-based, and *in vivo* modeling, we found that even though mRNA levels were reduced, the truncated CEP162-E646R*5 protein was expressed and localized to the mitotic spindle during mitosis and directly bound to taxol stabilized microtubules. However, truncated CEP162 was absent from the basal body during ciliogenesis causing a delay in ciliation of patient derived primary fibroblasts. In these patient fibroblasts, we find ciliation is stalled due to the persistence of CP110 at the mother centriole; however, they ultimately extend abnormally long cilia that are missing key transition zone components. In *CEP162* knockdown cells, the truncated CEP162-E646R*5 protein was unable to restore the loss of cilia indicating it is unable to function at the cilium. CEP162 is expressed in human retina and we show that wild-type CEP162, but not truncated CEP162-E646R*5, specifically localizes to the distal end of centrioles in mouse photoreceptor cilia. Despite lack of CEP162-E646R*5 localization at the cilium, we find that both wild-type and truncated CEP162 were able to rescue photoreceptor cell loss induced by shRNA mediated knockdown of CEP162 in the developing mouse retina. Together, our data suggests that truncated CEP162-E646R*5 retains microtubule binding and association to the mitotic spindle that allows it to function during neuroretina development. However, it behaves like a loss of function mutation at the cilium leading to defects in recruitment of some transition zone proteins and ultimately leading to non-syndromic retinal dystrophy in patients.

Cytokinesis 1

B165/P1159

Mis-segregated DNA blocks an abscission promoting phosphatase pathway to halt cytokinesis

T. C. Panagiotou[1], A. Wilde[1,2]; [1]Molecular Genetics, University of Toronto, Toronto, ON, CANADA, [2]Biochemistry, University of Toronto, Toronto, ON, CANADA.

Cytokinesis is the final stage of cell division where the duplicated genome is equally segregated into two new daughter cells. Successful completion of cytokinesis is required for genome fidelity. Failure to correctly segregate chromosomes during cytokinesis leaves them trapped within the final intercellular bridge (ICB) that connects daughter cells[1]. If abscission - the physical separation of daughter cells - proceeds, chromosomal breakage can occur that leads to tumorigenesis[2]. To ameliorate this, cells activate a cell cycle checkpoint that inhibits the endosomal sorting complex required for transport (ESCRT) membrane-fissioning machinery within the ICB. This checkpoint is orchestrated by the kinase Aurora B that directly phosphorylates the ESCRT Chmp4C to stall abscission[3,4]. Differentially phosphorylated and localized pools of Chmp4C exist within the ICB, but it is only the unphosphorylated Chmp4C that localizes to the abscission site to promote scission[5]. Yet, once segregation errors have been rectified and cells commit to abscission, Aurora B activity persists in the ICB[6]. The molecular mechanism of how this checkpoint is overcome remains unclear. We report that the checkpoint is countered through a DNA-sensitive PP2A-B56ε phosphatase pathway. PP2A-B56ε is targeted to the ICB where it colocalizes with Chmp4C. The PP2A-B56ε phosphatase interacts with Chmp4C *in vitro* and *in vivo* during cytokinesis where it is required to properly localize Chmp4C to the abscission site. Depletion of B56ε delays the abscission process and results in an accumulation of hyper-phosphorylated, inactive Chmp4C in the ICB. Most strikingly, in cells treated with the segregation error inducing drug ICRF-193[7], PP2A-B56ε is absent from ICBs that harbor trapped chromosomes. Based on these findings, we propose that the PP2A-B56ε phosphatase effects a DNA-sensitive, abscission-promoting pathway by dephosphorylating Chmp4C to overcome the abscission checkpoint and complete cytokinesis.

B166/P1160

The requirement for anillin in cytokinesis changes with ploidy

A. Piekny, K. Larocque, S. Koh, M. C. Husser, C. Brancheriau; Biology, Concordia University, Montreal, QC, CANADA.

Cytokinesis is required to physically separate the daughter cells toward the end of mitosis. This process occurs due to the ingression of an actomyosin ring, which must be properly positioned to avoid aneuploidy. Recent studies from our lab suggest that reciprocal gradients of active Ran and importins coordinate ring position with the segregating chromosomes. Proteins with nuclear localization signals (NLSs) can bind to importins, which are released by active Ran. The RanGEF RCC1 is bound to histones and generates active Ran near chromatin, while RanGAP downregulates Ran in the cytosol. We found that the ring protein anillin, requires importin-binding for its cortical recruitment and function in HeLa cells. This led to a model where cells with higher ploidy rely on a differential gradient of importins in the equatorial plane to control anillin function for ring positioning. In support of this model, we found that

anillin's requirement correlated with ploidy among different cultured human cells. To determine if ploidy influences anillin requirement through importins, we used CRISPR-Cas9 to integrate mNeonGreen into the anillin locus in HCT116 (colorectal carcinoma) cells, which have near-diploid modal chromosomal numbers. Only 15% of anillin was required to support cytokinesis in these cells, which displayed either failed ingression or failed abscission. After increasing ploidy, 50% of anillin was required for cytokinesis and all cells failed ingression or had oscillation phenotypes. In addition, anillin was cortically localized in HCT116 cells prior to mitotic exit, with broad localization at the equatorial cortex, while it was only localized to the equatorial cortex in cells with high ploidy. To determine if anillin's requirement for cytokinesis depends on importin-binding, we used a bicistronic plasmid to co-express RNAi-resistant NLS-mutant anillin and anillin shRNAs to knockdown endogenous protein. In HCT116 cells expressing this plasmid, NLS-mutant anillin failed to localize to the cortex prior to mitotic exit, but still localized to the equatorial cortex and cytokinesis was successful, while in cells with high ploidy, NLS-mutant anillin recruitment was delayed and localized with a narrower breadth, and cytokinesis failed. Our findings suggest that ploidy is one of the parameters controlling anillin's requirement in cells, which is largely through importin-binding.

B167/P1161

Diverse mechanisms regulate contractile ring assembly for cytokinesis in the two-cell *Caenorhabditis elegans* embryo

I. Ozugergin, M. Husser, A. Piekny; Concordia University, Montreal, QC, CANADA.

Cytokinesis occurs at the end of mitosis to physically separate a cell into two. This process occurs through the ingression of an actomyosin ring that cleaves the cell. Although the core cytokinesis machinery is conserved among metazoans, it is regulated by multiple pathways that appear to vary among cell types and organisms. Since few studies have compared cytokinesis between two cell types in the same model system, we performed the first in-depth characterization of cytokinesis in the two-cell *C. elegans* embryo. The embryo at this stage is ideal for comparative studies, as the larger AB cell is fated to be somatic tissue and the smaller P_1 cell is fated to be germline. We found that these cells have different cytokinesis kinetics supported by distinct myosin levels and organization, and that P_1 cells have a notable delay in ring assembly. Through perturbation of RhoA or polarity regulators and the generation of tetraploid strains, we found that ring assembly is influenced by multiple factors. We observed a negative correlation between size and assembly in P_1 cells, which also have lower levels of myosin. Since size could affect chromatin-associated cues that control actomyosin organization, we tested the role of the Ran pathway in these cells. Prior studies from our group found that active Ran forms an inverse gradient with importins that control the cortical recruitment of the ring scaffold, anillin, in HeLa cells. We found that while active Ran regulates ring assembly in AB and P_1 cells, it functions through ANI-1/anillin in AB cells, but not in P_1 cells. We propose that Ran signaling and low myosin levels delay ring assembly in P_1 cells to coordinate the timing of ring closure with their somatic neighbors. Our findings prompted us to characterize cytokinetic differences in mammalian cells. By generating multiple endogenously tagged cell lines to follow cytokinesis, we observe differences in the breadth and accumulation of cytokinesis proteins, and in the duration and symmetry of ring closure. We are determining how these differences arise, as well as their relevance for controlling different aspects of ring closure. Taken together, our findings show that it is imperative to utilize a wider range of cell types - both cultured and *in vivo* - to reveal the cytokinetic diversity across life forms and the mechanisms controlling this diversity.

B168/P1162

Endogenous tagging of anillin, Ect2 and RhoA reveals cytokinetic diversity in mammalian cells

M. C. Husser, I. Ozugergin, V. J. J. Martin, A. Piekny; Concordia University, Montréal, QC, CANADA.

Cytokinesis physically separates a cell into two daughter cells at the end of mitosis. This process occurs via the ingression of a RhoA-dependent actomyosin ring that assembles in the equatorial plane between the segregating chromosomes. The GEF (guanine nucleotide exchange factor) Ect2 generates active RhoA at the equatorial cortex, where it binds to effectors to generate actomyosin filaments. Another RhoA effector, anillin, acts as a scaffold to connect actomyosin with the plasma membrane for ring positioning. Different pathways regulate ring assembly and positioning in mammalian cells, but most studies were done using overexpressed transgenes in HeLa cells, and the contribution of these pathways in different cell types is not known. First, we used CRISPR/Cas9 to endogenously tag key cytokinesis regulators RhoA, Ect2 and anillin with mNeonGreen in HeLa cells, and characterized their spatiotemporal localization during cytokinesis in live cells. Then, to compare cytokinesis among cell types, we tagged endogenous anillin with mNeonGreen in cell lines that are not typically used to study cytokinesis: HEK293 (human embryonic kidney), HCT116 (colorectal cancer), HepG2 (hepatocellular carcinoma) and MDCK (Madin-Darby canine kidney) cells. Comparing anillin localization as well as the timing and symmetry of ring closure revealed diversity in how these cell types undergo cytokinesis. We found that: 1) anillin was cortically localized prior to mitotic exit in cells that had lower ploidy and/or were larger; 2) cells with broader anillin localization had faster ring closure, supporting a role for breadth in the alignment or removal of filaments for efficient ingression; and 3) cells capable of adopting apicobasal polarity had more extreme asymmetric ring closure, supporting a role for this machinery in controlling ingression. Combining the use of endogenous tags with quantitative measurements helped us capture cytokinetic diversity across a broader range of mammalian cell types and generate new knowledge of the mechanistic differences regulating cytokinesis in different cell types. The tools and protocols for the endogenous tagging of RhoA, Ect2, anillin and other proteins in human cells are available to the community.

Aurora A kinase promotes clearing of contractile ring components from the cell poles in human cells

F. Wolff[1], E. Zanin[2]; [1]Ludwig-Maximilians-Universität München, Munich, GERMANY, [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, GERMANY.

In the last step of cell division, called cytokinesis, the genetic material as well as other cellular content gets distributed from the mother cell among the two daughter cells. To ensure correct distribution, it is of major importance that cytokinesis is precisely controlled in time and space. During cytokinesis, the GTPase RhoA is active at the cell equator in a narrow zone, where RhoA induces assembly of the contractile ring underneath the plasma membrane. The formation and positioning of the contractile ring is directed by stimulatory signals from the spindle midzone, and inhibitory signals associated with the astral microtubules. Whereas the stimulating signals from the midzone are well characterized, the molecular nature of the aster-based inhibitory signals is unclear. We have recently shown that the kinase Aurora A, which localizes to the centrosomal asters, clears contractile ring components from the poles in *C. elegans*. Here we analyzed, whether Aurora A function in polar clearing is conserved in human cells. To address this, we inhibited Aurora A kinase in HCT116 and HeLa cells, and monitored the

localization of the active RhoA-binding protein anillin during anaphase. We found that after Aurora A inhibition anillin levels are increased at the cell poles and the equatorial anillin zone is wider. Together this suggests that the inhibitory role of Aurora A kinase in clearing contractile ring components from the poles and restricting them to a narrow equatorial zone is conserved from worms to humans. Currently, we are following a candidate-based approach to identify Aurora A phosphorylation targets during cytokinesis in human cells.

B170/P1164

The nuclear localization of Ect2 is required for abscission

N. Pham, J. Del Corpo, M. Husser, A. Piekny; Biology, Concordia University, Montreal, QC, CANADA.

Cytokinesis is the physical separation of a cell into two daughters by the ingression of an actomyosin ring. This process is tightly controlled to prevent aneuploidy. In anaphase, the centralspindlin complex recruits and activates the guanine nucleotide exchange factor (GEF) Ect2 at the equatorial cortex to generate active RhoA for ring assembly. After the ring ingresses in telophase, it transitions to form a midbody that is required for abscission. Ect2 localizes to the midbody, but then leaves and accumulates in the daughter nuclei, while centralspindlin remains at the midbody. Here, we show that the localization of Ect2 to the nuclei is required for abscission. A prior study showed that the over-expression of an N-terminal Ect2 fragment that localizes to the central spindle and competes with endogenous Ect2 causes cells to fail abscission. Another study showed that after Ect2 leaves the midbody, centralspindlin forms a complex with Fip3, which mediates secondary ingression and abscission. Thus, the levels of Ect2 at the midbody are important for late cytokinesis, but it is not clear why since the role of RhoA at this stage is not understood. One hypothesis is that Ect2 removal causes a decrease in active RhoA for cortical remodelling and abscission. Another not mutually exclusive hypothesis is that the removal of Ect2 frees Cyk4 to form complexes with Fip3 and/or proteins required for secondary ingression and abscission. To visualize changes in RhoA during cytokinesis, we used CRISPR-Cas9 editing to endogenously tag RhoA with mNeonGreen in HeLa cells. RhoA is enriched in the furrow as expected and remains visible at the midbody until around the same time that Ect2 localizes to the nuclei. To show that the localization of Ect2 is required for its function, we mutated the nuclear localization signal (NLS) in the S-loop domain to abolish its nuclear localization. Indeed, in the absence of endogenous Ect2, NLS mutant Ect2 fails to localize to the daughter nuclei and persists at the midbody causing cytokinesis failure. The timing of this failure is consistent with when RhoA levels decrease at the midbody. To further characterize this phenotype, we are measuring changes in the levels of endogenous RhoA at the midbody with mutant Ect2, and will monitor changes in the localization of Fip3 as well as other midbody proteins required for abscission.

B171/P1165

Intrinsic and extrinsic inhibition of cortical flow underlies symmetry-breaking of unilateral cytokinesis

K. Sugioka, C. Hsu, G. Sangha, W. Fan; Department of Zoology/Life Sciences Institute, University of British Columbia, Vancouver, BC, CANADA.

The contractile ring is supramolecular machinery critical for physical partitioning of the dividing cell. Eccentric closure of the contractile ring, called unilateral cytokinesis, often orients along the body axis to maintain tissue integrity. Despite the identification of unilateral cytokinesis regulators, the initial symmetry-breaking mechanism remains elusive. Here, we report that intrinsic and extrinsic inhibition of

the cortical flow breaks cytokinesis asymmetry in *Caenorhabditis elegans*. By coupling high-resolution 4D imaging and *in vitro* cell contact reconstitution assay, we found that unilateral cytokinesis of the zygote P_0 and the two-cell stage AB are regulated by the actin-dependent and adhesion-dependent mechanisms, respectively. In P_0 and AB, intracellular compression and intercellular adhesion locally inhibit the furrow-directed cortical flow and cleavage furrow ingression, respectively, resulting in the eccentric ring closure. Our study demonstrates that the local mechanical suppression of the ring-dependent cell cortex pulling is a common symmetry-breaking cue underlying the different modes of unilateral cytokinesis.

B172/P1166

Investigating the role of importin-β during cytokinesis

C. Brancheriau, K. Larocque, S. Pokharel, A. Piekny; Biology, Concordia University, Montréal, QC, CANADA.

Cytokinesis is the separation of a cell into two daughter cells at the end of mitosis. It occursdue to the assembly and ingression of a contractile ring controlled by multiple pathways. Thisprocess must be tightly controlled to prevent changes in cell fate or aneuploidy, which cancause disease. We found that a chromatin-sensing pathway positions the ring between thesegregating chromosomes. The GEF RCC1, which is bound to histones, generates Ran-GTPnear chromatin, while RanGAP inactivates Ran in the cytosol, creating a Ran-GTP gradient.Typically, importins bind to proteins with nuclear localization signals (NLS) and Ran-GTPreleases them. We found that importins bind to the NLS of anillin, a ring protein, and isrequired for its recruitment to the division plane where it functions to position the ring inHeLa cells. Anillin's requirement for cytokinesis varies widely, and we hypothesize that thismechanism may play a stronger role in cells where Ran-GTP levels are higher due toparameters such as fate, ploidy, cell size, or shape. In support of this model, we found thatincreasing ploidy in HCT 116 cells, which have lower requirements for anillin compared toHeLa cells, caused changes in anillin's localization and requirement. We are now obtainingevidence to show that importins and their control of anillin function changes in response toploidy. This includes using the Rango4 FRET probe generated by Dr. Kalab, which contains theimportin-β binding domain from snurportin sandwiched between a CFP-YFP pair, and FREToccurs when importin-β cannot bind due to high Ran-GTP. With this probe, we will showwhere importin-β is free to bind to NLS-proteins during anaphase, and how the levels of freeimportin-β change with ploidy. We are also endogenously tagging the KPNB1 locus withmNeonGreen in HeLa and HCT 116 cells to determine how the localization of endogenousimportin-β compares after increasing ploidy in HCT 116 cells. In addition, we are building anoptogenetic tool to control the activity of importin-β during cytokinesis by fusing it to a shortpeptide, CRY2, which is capable of rapid and efficient homo-oligomerization upon blue lightexposure. By activating this tool in specific regions of the cell, we can induce spatiotemporalchanges in importin-β and determine its requirement for cytokinesis.

B173/P1167

The number of cytokinesis nodes in mitotic fission yeast scales with cell size.

W. Sayyad, T. Pollard; Yale University, New Haven, CT.

Cytokinesis nodes are assemblies of stoichiometric ratios of proteins associated with the plasma membrane, which serve as precursors for the contractile ring during cytokinesis by fission yeast. The total number of nodes is uncertain, because of the limitations of the methods used previously. Here we

used the ~140 nm resolution of Airyscan super-resolution microscopy to measure the fluorescence intensity of small, unitary cytokinesis nodes marked with Blt1-mEGFP in live fission yeast cells early in mitosis. The ratio of the total Blt1-mEGFP fluorescence in the broad band of cytokinesis nodes to the average fluorescence of a unitary node gives about 190 unitary cytokinesis nodes in wild type fission yeast cells early in mitosis. Most, but not all of these nodes condense into a contractile ring. The number of cytokinesis nodes scales with cell size in four strains tested, although large diameter *rga4Δ* mutant cells form somewhat fewer cytokinesis nodes than expected from the overall trend. The Pom1 kinase restricts cytokinesis nodes from the ends of cells, but the surface density of Pom1 on the plasma membrane around the equators of cells is similar with a wide range of node numbers, so Pom1 does not control cytokinesis node number. However, varying concentrations of either kinase Pom1 or kinase Cdr2 with the *nmt1* promoter showed that the numbers of cytokinesis nodes increase above a baseline of about 190 with the total cellular concentration of either kinase.

B174/P1168

Speed oscillations in cytokinetic ring ingression suggest interplay between mechanical and biochemical feedback

M. E. Werner[1], D. Ray[2], C. Breen[3], F. Jug[4], A. Maddox[1]; [1]Biology, University of North Carolina, Chapel Hill, NC, [2]University of North Carolina, Chapel Hill, NC, [3]University of Wisconsin, Madison, WI, [4]Human Technopole, Milan, ITALY.

The cytokinetic ring is a transient contractile structure that provides the mechanical force to separate two nascent daughter cells. It assembles in the division plane in response to local activation of the small GTPase RhoA via the local recruitment and reorganization of cortical actomyosin and associated regulators and crosslinkers. Recent theoretical work predicted that complex contractile dynamics could result from the interaction between cortical mechanics and the biochemical feedback loops known to underlie oscillations of RhoA activity and the abundance of its downstream cytoskeletal targets. To explore how cytokinetic ring organization and composition contribute to ring ingression, we used a combination of high resolution four-dimensional fluorescent microscopy combined with computer vision based analysis to follow cytokinetic ring ingression with unprecedented temporal resolution. We observed that ring ingression kinetics are spatially and temporally non-uniform. Specifically, ingression follows an oscillatory pattern of acceleration and deceleration in ingression speed rather than a constant speed as previously suggested. Quantification of the amplitude and frequency of ingression speed oscillations revealed a period of 20 seconds, which corresponds to that of RhoA activity pulses we measured in the cleavage plane during early anaphase using a RhoA activity biosensor. 20-second oscillations co-exist with longer and shorter periods, with slower oscillations becoming more prevalent as furrowing progresses. Faster- ingressing segments exhibited speed oscillations with both higher amplitude, lower frequency, and higher correlation of oscillation parameters with neighboring segments when compared to slower ingressing parts of the same ring. Both speed oscillation frequency and amplitude are sensitive to perturbations of RhoA or myosin activity. Taken together, our results support the hypothesis that contractility within local, semi-autonomous units dictates the overall dynamics of the cytokinetic rings. Our findings also provide experimental evidence for the proposed influence of material properties and force generation on the biochemical feedback regulation of non-muscle actomyosin contractility.

Distortion of meiotic midbody retains translated proteins in mouse oocyte

G. Jung[1], S. Park[2], A. Skop[2], K. Schindler[1]; [1]Department of Genetics, Rutgers University, Piscataway, NJ, [2]Laboratory of Genetics, University of Wisconsin-Madison, Madison, WI.

Oocyte meiosis leads to the formation of a healthy egg that supports the foundation of new life. Cytokinesis of meiosis I is critical for egg quality because it is necessary for physical separation of progeny cells and for preventing polyploidy. Moreover, cytokinesis leads to the formation of the midbody (MB), a transient, membrane-less organelle with translationally active ribonucleoprotein (RNP) granule qualities. Mitotic cells release MBs via symmetric abscission but can then uptake MBs through phagocytosis. MB uptake correlates with cell fate determination, stemness, and tumorigenicity, consistent with MBs being RNP granules. However, mammalian oocytes undergo asymmetric divisions during meiosis, suggestive of asymmetric cytokinesis and abscission. Whether oocytes have MBs and, if so, what function they have is not known. Because MBs can influence somatic cells, we hypothesized that inheriting a meiotic MB is critical to sustain pre-implantation embryonic development and to acquire totipotency after fertilization. To address these gaps, we first identified MB structures in mouse oocytes based on the localization of key structural proteins MKLP2 (arms), PRC1 (core), and MKLP1 (ring) described in mitotic cells. We found a unique distortion to the midzone spindle and MB ring not observed in mitosis. To determine the cause of the ring distortion, we tested the hypothesis that microtubules exert uneven forces during cytokinesis. By high-resolution live-cell imaging, we found that the abundance of microtubules on the egg side is greater than on the polar body, indicating microtubule asymmetry drives the distortion. We next asked if meiotic MBs are also RNP granules. By conducting fluorescence *in situ* hybridization and immunocytochemistry, we found that polyadenylated RNAs and ribosomal proteins are enriched at the MB ring, in line with the localized translation we detected in this region. Finally, we asked if the distortion-derived cap acts as a barrier that prevents nascent proteins from leaving the egg and escaping into the polar body. We evaluated translation signal localization after disrupting the cap with nocodazole. Unlike control eggs which retained translation in the egg, eggs with no cap showed translation signal leakage into the polar body. To expand on the potential role of MBs in ensuring developmental competence, we are parthenogenetically activating eggs with and without cap disruption and comparing the development efficiency to the blastocyst stage. Together, these data show asymmetries at the subcellular level distort the MB in mouse oocytes and highlight the potential role the distortion has in guaranteeing egg quality and developmental competence.

Building the Cytokinetic Contractile Ring in an Early Embryo: Composition and Organization of Initiating Myosin II Clusters

G. Reyes[1,2], Q. W. McKim[3,2], H. Y. Herzon[3,2], K. Herrera[3,2], N. T. Lo[3,2], C. B. Shuster[1,2], J. H. Henson[3,2]; [1]Biology, New Mexico State University, Las Cruces, NM, [2]Friday Harbor Labs, University of Washington, Friday Harbor, WA, [3]Biology, Dickinson College, Carlisle, PA.

Significant questions remain regarding the assembly and structural progression of the cytokinetic contractile ring (CR) in animal cells. We have investigated the nanoarchitecture and dynamics of the CR in early sea urchin embryos using super resolution light microscopy (3D-SIM, STED and iPALM) and platinum replica TEM. The sea urchin experimental system offers the distinct advantage of being able to examine the CR in both first division whole embryos and isolated cortices. To date our studies have

indicated that the CR initiates as a broad stripe of clusters containing myosin II, actin, septin and anillin, which then congress over time into a narrower, more linearized and contractile array within the cleavage furrow. Our present work indicates that MKLP1, the kinesin-like microtubule motor component of the Rho-activating Centralspindlin complex, colocalizes with these initiating clusters and the nascent CR in whole embryos and isolated cortices, although this colocalization diminishes with CR maturation. Conversely, the actin cross-linker alpha-actinin colocalizes with late stage CRs but not with the initiating clusters. This is consistent with our previous results showing that these clusters assemble in the absence of actin filaments, and using para-aminoblebbistatin (PAB) - a more soluble and photostable derivative of blebbistatin - we have now demonstrated that clusters can also assemble in the presence of myosin II ATPase inhibition. Embryos treated with PAB undergo nuclear divisions and can exhibit anaphase B-like elongation and early telophase shallow furrowing but become binucleate and eventually progress through the 2-4 cell nuclear division. Embryos retain cytokinesis competence in the presence of PAB as shown by the cell division displayed by embryos washed out of the drug or exposed to photo-inactivation. Collectively these results highlight the importance of the initiating myosin II clusters in setting up the organization of the embryo's CR, in the targeting of Rho-activation via Centralspindlin, and the absence of a requirement for actin filaments or myosin II ATPase function in CR assembly.

B177/P1171

Inhibition of polymeric SUMO-2/3 chain signals induces the formation of chromatin bridges

X. Zhang[1], T. Chen[1], R. Zhang[2], A. Noor[1]; [1]Biology, SUNY Buffalo State College, Buffalo, NY, [2]Troy High School, Troy, MI.

Polymeric SUMO-2/3 chain modification of various protein targets acts as the signals for recruiting the SUMO-targeted ubiquitin E3 ligases, including RNF4 and RNF111, leading to their ubiquitination and proteasomal degradation in mammalian cells. However, the functional significance of poly-SUMO-2/3 chain modification is not well understood. To address this question, we specifically blocked the poly-SUMO-2/3 chain signals by overexpressing a GFP-tagged RNF4 N-terminal fragment containing four tandem SUMO-interacting motifs (GFP-SIMs) with a high-affinity binding to poly-SUMO-2/3 chain signals. We found that the GFP-SIMs proteins are largely associated with poly-SUMO-2/3 chain modified proteins at PML nuclear bodies in human HeLa cells, especially after a treatment with arsenic trioxide known to stimulate poly-SUMO-2/3 chain modification of PML proteins. In addition, the transient expression of GFP-SIMs induced the formation of chromatin bridges and caused an accumulation of poly-SUMO-2/3 chain modified proteins at the midbody in cells with chromatin bridges. Consistent with the defect triggered by blocking the poly-SUMO-2/3 chain signals, global inhibition of SUMOylation by treating cells with ML-792, a specific inhibitor of the SUMO-activating E1 enzyme, increases the DNA damage foci during interphase and the chromatin bridges during mitosis and cytokinesis. Therefore, poly-SUMO-2/3 chain signals are critical for ensuring accurate chromosome segregation and maintaining genome stability.

B178/P1172

Structure-function analysis of RGA-3/4, a cytokinetic Rho GAP

S. Kim, W. M. Bement; University of Wisconsin, Madison, WI.

Traditionally, cytokinesis has been viewed as essentially linear, with Rho being activated in the beginning of the process to drive contractile ring formation, and then inactivated once cytokinesis is complete.

However, propagating waves of Rho activation and inactivation and complementary waves of F-actin assembly and disassembly - referred to as cortical excitability - are focused at the equatorial cortex during cytokinesis in amphibian and echinoderm embryos, indicating that Rho is undergoing continual flux through the GTPase cycle. Cytokinetic cortical excitability is proposed to result from Ect2-dependent Rho activation coupled with delayed F-actin-dependent Rho inactivation. RGA-3/4, a GTPase activating protein (GAP) for RhoA, is an excellent candidate as a link between F-actin and Rho inactivation during cytokinetic cortical excitability. RGA-3/4 is required for cytokinesis and gets recruited to the equatorial cortex prior to the onset of furrowing. It colocalizes with F-actin in the cytokinetic apparatus and depends on F-actin for its cortical localization. In spite of its importance in cytokinesis and implication in cytokinetic cortical excitability, the mechanism to how RGA-3/4 interacts with F-actin and how it is being regulated is completely unknown. To further our knowledge about RGA-3/4, we have performed structure and function analysis. RGA-3/4, when expressed alone in *Xenopus* oocytes, localizes to and reorganizes the cortical actin network into interlocking cables. This activity is independent of its GAP activity, but requires the amino terminal portion of RGA-3/4 as well as the last 20 aas of the GAP domain. When co-expressed with Ect2 in *Xenopus* oocytes, RGA-3/4 induces cortical excitability. In contrast to actin reorganization, this activity requires GAP activity as well as the portions of the protein needed for actin reorganization. Further, induction of cortical excitability also requires a minimum of ~120 aas of the region immediately downstream of the GAP domain (aa234-350). To better understand how actin reorganization and cortical excitability are induced by RGA-3/4, I am in the process of studying RGA-3/4-F-actin interaction in vitro.

B179/P1173

Early zygotic gene product Dunk interacts with anillin to regulate Myosin II during *Drosophila* cleavage

J. Chen, B. He; Biological Sciences, Dartmouth College, Hanover, NH.

Drosophila cellularization is a special form of cytokinesis that partition the peripherally localized syncytial nuclei into individual cells. Similar to typical animal cytokinesis, an early event in cellularization is the recruitment of non-muscle myosin II (“myosin”) to the cleavage furrows, where myosin forms an interconnected basal array before reorganizing into individual basal cytokinetic rings. The initial recruitment and organization of basal myosin are regulated by *dunk*, a cellularization-specific gene, but the mechanism is unclear. In a genome-wide yeast two-hybrid screen, we identified anillin (Scraps in *Drosophila*), a conserved scaffolding protein in cytokinesis, as the primary binding partner of Dunk. Anillin has been previously shown to regulate the assembly and function of the basal cytokinetic rings during mid- to late cellularization, but its role and regulation in early cellularization are unexplored. We show that anillin colocalizes with myosin as early as at the onset of cellularization, when anillin and myosin localize together in discrete puncta at the apical cortex and co-move towards the newly formed furrow, facilitating the formation of basal myosin array. Loss of anillin results in myosin localization defects at the basal array that closely resembles the myosin phenotype in *dunk* mutant embryos. Furthermore, we show that anillin colocalizes with Dunk at the cleavage furrows during the early cellularization. Loss of Dunk does not prevent the recruitment of anillin to the cleavage furrows but affects the spatial distribution of anillin. Finally, we present evidence that Dunk functionally interacts with anillin during cellularization in regulating the integrity of the myosin array. Based on these results, we propose that Dunk regulates myosin recruitment and organization during early cellularization by binding and regulating anillin. Our work demonstrates a previously unappreciated role for anillin in regulating cortical myosin dynamics in early cellularization. The interaction between a cellularization-

specific protein and the conserved cytokinetic machinery may shed light on how the latter can be adapted in evolution to achieve specific, non-canonical forms of cytokinesis.

B180/P1174

A checkpoint system enforces the staging of secretory events in cytokinesis

E. L. Weiss, J. L. Brace, T. A. Volpe; Molecular Biosciences, Northwestern University, Evanston, IL.

Checkpoint pathways create dependency relationships in temporally staged events of cell division. We have defined such a system in budding yeast cytokinesis, where cytokinetic actomyosin ring contraction, synthesis of an extracellular septum, and abscission are quickly followed by a sharp burst of hydrolytic enzyme secretion that destroys the septum to allow separation of mother and daughter cells. While these enzymes are produced in early cytokinesis, septum destruction never begins before abscission is complete. Notably, we find that secretion of septum destruction enzymes is blocked when cytokinesis is impaired. This strong delay of late cytokinetic secretion requires Fir1, an intrinsically disordered protein that contains numerous short conserved protein intearaction motifs. In the absence of Fir1 treatments that perturb early septation and actomyosin ring function cause complete and lethal failure of cytokinesis, a far more severe phenotype. Fir1, localizes to the cytokinesis site and is quickly proteolyzed upon septum completion, but is profoundly stabilized when septation is aberrant. Fir1 appears to block separation enzyme secretion in part by inhibiting the NDR/LATS kinase Cbk1, a key component of a "hippo" signaling pathway that induces mother-daughter separation. We find that disruption of cytokinesis triggers activation of a MAPK pathway that likely potentiates Fir1-dependent secretion block. Intriguingly, we also find that only daughter cells are capable of secreting post-abscission septum destruction enzymes in mother-daughter pairs that uniformly express the proteins. Thus, these cells protect the phased process of cytokinesis with exacting spatial regulation and checkpoint-mediated temporal staging.

B181/P1175

The impact of polarized adhesion on the efficiency of epithelial cytokinesis

M. Gonçalves[1,2], C. Ramos[1], M. Osswald[1], C. Lopes[1], C. Sunkel[3,2], M. Eurico[1]; [1]Epithelial Polarity and Cell Division Lab, IBMC/i3S - Instituto De Investigação E Inovação Em Saúde, Porto, PORTUGAL, [2]Doctoral Program in Molecular and Cell Biology (MCBiology), ICBAS - Instituto de Ciências Biomédicas Abel Salazar, Porto, PORTUGAL, [3]Cell Division and Genomic Stability Lab, IBMC/i3S - Instituto De Investigação E Inovação Em Saúde, Porto, PORTUGAL.

Epithelial tissues are a critical barrier in multicellular organisms. Its proper function relies on the distribution of adhesion complexes along an apical-basal axis, which ensures epithelial integrity. During development and throughout adult life, epithelial tissues undergo mitotic proliferation, which demands coordination of adhesion with the dramatic shape and cytoskeleton changes that are necessary to allow daughter cell separation. However, it is still unclear how the adhesion complexes impact the robustness of cell division in this polarized and multicellular environment. To tackle this question, we performed an *in vivo* RNAi screen in the *Drosophila* follicular epithelium to determine which cell adhesion molecules impact epithelial cytokinesis. One promising hit was the extracellular matrix receptor Dystroglycan (Dg), which we found to promote cytokinesis robustness. Live imaging uncovered the spatial redistribution of Dg-GFP, which is enriched in the basal side of ingressing cleavage furrow since the beginning of ring constriction. This was also observed for Dystrophin (Dys), the intercellular linker by which Dg interacts

with the actin cytoskeleton. We are now characterizing how the Dg-Dys complex ensures epithelial cytokinesis robustness. Current data shows that the Dg-Dys complex promotes the constriction of the actomyosin ring and also facilitates abscission. Altogether, these results pave the way to understand how cytokinesis is coupled with adhesion in order to ensure the correct genetic ploidy of epithelial cells during growth and development.

Myosin XI motors participate in a cortical cytoskeletal assembly to orient plant cytokinesis

C. Huang[1], F. Peng[2], Y. Lee[1], B. Liu[1]; [1]University of California, Davis, Davis, CA, [2]University of Pennsylvania, Philadelphia, PA.

Plant cells are immobile, surrounded by the cell wall such that anisotropic growth is brought about by the production of new cells in formative orientations. Plant growth and form are dependent on oriented cell divisions that employ the cortical microtubule array, preprophase band (PPB), to predict cell plate placement. It has been elusive how this transient cytoskeletal array imprints the spatial information at the cell cortex for later stages of mitotic cell division. We discovered in *Arabidopsis thaliana* that the Myosin XI motor MYA1 localized to the cortical division site (CDS), previously occupied by the PPB. Furthermore, the CDS-localized kinesin motor, POK1, assembles with MYA1 to form into a ring of macromolecular assemblies that guide cell plate deposition. This finding uncovered the mechanism of how the two cytoskeletal networks interact to regulate division plane orientation during vegetative growth in flowering plants.

B183/P1177

Cdc42 GTPase activating proteins Rga4 and Rga6 coordinate septum synthesis and membrane trafficking at the division plane during cytokinesis

B. F. Campbell[1], B. S. Hercyk[2], A. R. Williams[2], E. San Miguel[2], H. G. Young[2], M. E. Das[1]; [1]Biology, Boston College, Chestnut Hill, MA, [2]Biochemistry & Cellular and Molecular Biology, The University of Tennessee - Knoxville, Knoxville, TN.

Fission yeast cytokinesis is driven by simultaneous septum synthesis, membrane furrowing, and actomyosin ring constriction. The septum consists of a primary septum flanked by secondary septa. First, delivery of the glucan synthase Bgs1 and membrane vesicles initiate primary septum synthesis and furrowing. Next, the glucan synthase Bgs4 is delivered for secondary septum formation. It is unclear how septum synthesis is coordinated with membrane furrowing. The Rho GTPase Cdc42 promotes delivery of Bgs1 but not Bgs4. We find that after primary septum initiation, Cdc42 inactivators Rga4 and Rga6 localize to the division site. In rga4Δrga6Δ mutants Cdc42 activity is enhanced during late cytokinesis and cells take longer to separate. Electron micrographs of the division site in these mutants exhibit malformed septum with excess primary septum and irregular membrane structures. These mutants have a larger division plane with enhanced Bgs1 delivery but fail to enhance accumulation of Bgs4 and several exocytic proteins. Additionally, these mutants show endocytic defects at the division site. This suggests that Cdc42 regulates primary septum formation and only certain membrane trafficking events. As cytokinesis progresses, Rga4 and Rga6 localize to the division site to decrease Cdc42 activity to allow coupling of Cdc42-independent membrane trafficking events with septum formation for proper septum morphology.

B184/P1178

Spatiotemporal dynamics of cell plate development during plant cytokinesis

R. Sinclair[1], M. Wang[1], Z. Jawaid[1], S. Wong[1], D. Cox[1], J. Heddleston[2], E. Wait[2], J. Aaron[2], T. Wilkop[1], **G. Drakakaki**[1]; [1]University of California Davis, Davis, CA, [2]Janelia Research Campus, Ashburn, VA

Cytokinesis in plants is fundamentally different from that in animals and fungi. In plant cells, a cell plate forms through the fusion of cytokinetic vesicles and ultimately develops into the new cell wall, partitioning the cytoplasm of the dividing cell. The formation of the cell plate entails multiple stages that involve highly orchestrated vesicle accumulation, fusion and membrane maturation, which occur concurrently with the timely deposition of polysaccharides such as callose, cellulose and cross-linking glycans. The polysaccharide callose is thought to play a vital role in stabilizing the cell plate during its expansion, however many fundamental questions remain unanswered. Overcoming genetic lethality, we used the pharmacological probe endosidin 7 to specifically inhibit callose deposition during cytokinesis. Using 4D imaging, employing lattice light sheet microscopy, we interrogated the temporal dynamics at the cell plate in the presence and absence of callose. We approximated cell plate sub-structures with testable shapes and adopted the Helfrich-free energy model for membranes, including a stabilizing and spreading force, to understand the transition from a vesicular network to a fenestrated sheet and mature cell plate. Quantitative analysis along with biophysical modeling enabled the dissection of stage transition at the cell plate and identified key transition points at which different components such as callose are critical for cell plate development. Further isolation of cytokinetic vesicles followed by multi-platform analysis identified cargoes targeted to cell plate. In total, the combination of the described approaches provided insights cell plate formation during plant cell division.

Centrosome Assembly and Functions

Mammalian Spermatocytes have the Capacity to Segregate Chromosomes without Centriole Duplication and Centrosome Separation

M. W. Skinner[1,2], C. Simington[1], P. López-Jiménez[3], K. Baran[1], J. Xu[1], J. Page[3], R. Gómez[3], A. Holland[4], P. Jordan[2,1]; [1]Biochemistry and Molecular Biology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD, [2]Biochemistry and Molecular Biology, Uniformed Services University of the Health Sciences, Bethesda, MD, [3]Autonomous University of Madrid, Madrid, SPAIN, [4]Johns Hopkins University School of Medicine, Baltimore, MD.

Centrosomes are the canonical microtubule organizing centers (MTOCs) of most mammalian cells, including spermatocytes. Centrosomes are comprised of a centriole pair within a structurally ordered and dynamic pericentriolar matrix. To segregate homologs during meiosis I and sister chromatids during meiosis II, centrioles undergo two rounds of duplication and centrosomes mature and separate twice. The first centriole duplication event occurs during leptonema at the same time meiotic double-strand breaks are formed. Centrosomes mature during latter stages of meiotic prophase, then separate at diakinesis to opposite sides of the nucleus. When the nuclear envelope breaks down, separated centrosomes serve as bipolar nucleation sites for the microtubules responsible for segregation of homologous chromosomes during meiosis I. At interkinesis, centrioles are duplicated, and centrosomes are separated again to facilitate segregation of sister chromatids during meiosis II. Using mouse mutant models and chemical inhibition, we have blocked centriole duplication and centrosome separation

during spermatogenesis and discovered that spermatocytes adopt a backup mechanism for chromosome segregation. Strikingly, this mechanism is unique from the acentriolar MTOCs that form bipolar spindles in oocytes, which require canonical centrosome components, including gamma-tubulin, pericentrin, and CEP192. From our in-depth analysis, we have discovered microtubule-associated proteins involved in the acentrosomal microtubule organization that are capable of mediating chromosome segregation during spermatogenesis.

Identifying New Regulators of Centriole Biogenesis

C. Peneda, M. Bettencourt-Dias; Instituto Gulbenkian De Ciência, Oeiras, Lisbon, PORTUGAL.

Centriole biogenesis is a highly regulated process and has been widely studied. Several key proteins and molecular mechanisms involved in centriole number and length control have been identified. However, how these processes are regulated is still not fully understood. Therefore, the aim of our project was to identify new regulators of centriole biogenesis. In our work, we used light microscopy, super resolution and electron microscopy techniques and were able to identify LZTS2 as a new regulator of centriole elongation. Our results will thus help to unravel new regulatory pathways governing centriole elongation.

B187/P1181

E3 ubiquitin ligase, FBXW7 targets centriole duplication protein, STIL for degradation

U. Anand, B. Badarudeen, A. Muliyil, M. Ebrahim, A. Asokan, R. Khurup, T. K. Manna; IISER TVM, Thiruvanathapuram, INDIA.

Centrosomes are the main microtubule organizing centers in animal cells. During the cell cycle, centrosomes duplicate only once during S phase to ensure that at mitotic onset, a cell carries two centrosomes, that are required for serving as poles of the mitotic spindle. Initiation of new centriole biogenesis involves recruitment of a ring-like oligomeric structure consisting of CEP152 and its associated proteins onto the proximal end of the mother centriole, which follows recruitment and activation of polo-like kinase 4 (Plk4). Plk4 kinase seeds the new centriole by phosphorylating pro-centriole protein STIL (SCL/TAL1 interrupting locus) and facilitating formation of the cartwheel-like template by recruiting SAS-6. Elevated expression of several of these factors, notably STIL, SAS-6 and Plk4 induces centriole over-duplication and multipolar defects. Mechanisms how the levels of centriole duplication factors are maintained are poorly understood. Here we find that E3-ubiquitin ligase. SCF-FBXW7 with its substrate targeting subunit FBXW7 regulates level of STIL in cultured human cells. siRNA-mediated depletion of FBXW7 increased the level of STIL, more prominently during the G1/S phase, the time when new centriole formation begins. FBXW7 over-expression results in down-regulation of STIL level and further, it is rescued, when the substrate-binding WD40 of FBXW7 was deleted. Concordant with these findings, we also found that localization STIL at the centrioles is reduced, when the ligase is overexpressed. Biochemical results showed that FBXW7 interacts with and ubiquitinates STIL via its WD40 domain. Pharmacological inhibition of PLK4, which phosphorylates STIL, suppressed FBXW7-mediated STIL degradation suggesting its role in this process. Inhibition of Plk4 kinase activity also compromised the binding between FBXW7 and STIL, suggesting a role of the kinase in mediating STIL-FBXW7 interaction. We also found that STAN domain of STIL, which binds to SAS-6 to form centriole

cartwheel, is involved in FBXW7-mediated degradation and interaction with FBXW7. Results suggest that STIL STAN domain degradation by SCF-FBXW7 could be involved in controlling new centriole assembly.

MPS1-mediated potentiation of Aurora A activity causes spindle orientation defects in the *Drosophila* follicular epithelium

N. Leça[1,2], M. Osswald[3], C. E. Sunkel[1,2], E. Morais-de-Sá[3], C. Conde[1]; [1]Cell Division and Genomic Stability group, i3S - Institute for Research and Innovation in Health, Porto, PORTUGAL, [2]ICBAS - Institute of Biomedical Sciences Abel Salazar, Universidade do Porto, Porto, PORTUGAL, [3]Epithelial Polarity and Cell Division group, i3S - Institute for Research and Innovation in Health, Porto, PORTUGAL.

Proper orientation of the mitotic spindle during cell division is critical for determination of the progeny fate and for accurate tissue architecture. Here, we show that overexpression of the master mitotic checkpoint kinase MPS1 in *Drosophila* follicular epithelium cells leads to massive defects in spindle orientation and to the formation of a multilayered tissue. Live cell imaging and immunofluorescence analysis of *Drosophila* S2 cells revealed that increased activity of centrosome-tethered MPS1 is sufficient to induce pronounced rotation of the mitotic spindle through mis-regulation of the canonical Mud-Dynein/Dynactin orientation machinery. Correct distribution of Mud-Dynein/Dynactin at the cell cortex is established by tightly-regulated phosphorylation of Pins by Aurora A. We found that centrosomal activity of Aurora A is significantly incremented following MPS1 overexpression and *in vitro* kinase assays revealed that MPS1 activity directly potentiates Aurora A T-loop auto-phosphorylation. Notably, expression of constitutively active Aurora A or of a phosphomimetic version of Pins recapitulates the abnormal spindle rotation phenotype. Importantly, depletion or chemical inhibition of Aurora A efficiently prevent the rotation of the mitotic spindle in cells overexpressing MPS1. Furthermore, follicular epithelium multilayering caused by MPS1 overexpression is significantly reduced in *Drosophila* heterozygous mutants of Aurora A. We propose that, when overexpressed, a cytosolic pool of MPS1 is able to reach the centrosomes and potentiate Aurora A auto-activation. This likely causes unbalanced hyperphosphorylation of Pins, thus precluding correct localization of Mud-Dynein/Dynactin at the cell cortex and consequently resulting in the ectopic cortical accumulation of astral microtubule pulling forces that drive spindle rotation. Our results unravel a novel and unanticipated cross-talk between the mitotic checkpoint and the spindle orientation signaling pathways.

Investigating Centrosome Inactivation during Cellular Differentiation

R. K. Ng, J. Magescas, J. L. Feldman; Biology Department, Stanford University, Stanford, CA.

Centrosomes are membrane-less organelles composed of a pair of microtubule-based centrioles surrounded by proteins known collectively as the pericentriolar material (PCM). In animal cells, centrosomes act as microtubule-organizing centers (MTOCs) by nucleating and localizing microtubules to form the mitotic spindle. Centrosomes become “activated” as MTOCs through the mitotic kinase-dependent accumulation of PCM proteins around centrioles. In telophase, centrosomes become “inactivated” through the loss of MTOC activity by the disassembly of PCM proteins and microtubules through phosphatase activity. Centrosome inactivation is a feature of all cycling animal cells, a hallmark of cellular differentiation, and centrosome hyperactivity has been associated with many types of cancers. However, the mechanisms underlying centrosome inactivation and the function of centrosome

inactivation during cellular differentiation is unknown. To understand the normal function of centrosome inactivation during differentiation, we are using two approaches to activate centrosomes in *C. elegans* differentiated cells and are assessing the associated cellular and tissue-level phenotypes. First, we inhibited PP2A, a phosphatase implicated in centrosome inactivation, specifically in embryonic intestinal cells which resulted in aneuploidy, mitotic arrest, and centrosome hyperactivity. In addition, intestinal cells no longer polarized, preventing proper intestinal connectivity with the rest of the digestive tract and resulting in larval lethality. As a second approach, we developed a nanobody-based targeting strategy to drive the active mitotic kinase PLK-1 to the centrosome. Expression of this CAP-Trap (Constitutively-Active PLK-1-Trap) in embryonic intestinal cells reactivated interphase centrosomes as demonstrated by the presence of growing microtubule plus-ends emanating from the centrosome, and we are currently assessing the impact of this reactivation. Expression of CAP-Trap in differentiated phasmid neurons caused defects in neuronal morphology and the perdurance of centriole proteins. Together, these data indicate that the regulation of PP2A and PLK-1 activity are involved in centrosome inactivation in differentiating intestinal cells and neurons *in vivo*, and future studies will determine if centrosome inactivation is required for proper intestinal and neuronal differentiation and function.

Centrosomal localization of Plk4 during centriole duplication and amplification

C. Sullenberger, P. Avazpour, D. Luvsanjav, D. Kong, J. Loncarek; National Cancer Institute at Frederick, Frederick, MD.

Background: Dividing somatic cells restrict the number of centrosomes to two per cell, which is critically important for the formation of bipolar mitotic spindles and accurate chromosome segregation, in addition to other centrosome-related cellular events. Centrosome number relies on a precise duplication pattern of two resident mother centrioles, which duplicate only once at the beginning of S phase by each initiating only one new centriole (procentriole) in their vicinity. Procentrioles initiate when polo-like kinase 4 (Plk4) binds to and phosphorylates STIL, which, in turn promotes its association with SAS-6, and the formation of a Plk4/STIL/SAS-6 complex, as a basis for procentriole assembly. **Aim:** To we dissect the dynamics and spatial organization of centrosomal Plk4 during procentriole initiation during centriole duplication and amplification with improved resolution. **Methods:** We used human cultured cells, some inducibly expressing Plk4, and examined Plk4 centrosomal dynamics by employing super resolution microscopy approaches that allow spatial resolution of at least 25 nm. Additionally, biochemical methods were used to investigate cytosolic levels of Plk4, and a specific Plk4 inhibitor centrinone was used to modulate Plk4 activity. **Results:** Super resolution imaging revealed a detailed Plk4 pattern in G1 and early S phase cells, which further details a previously observed ring-to dot Plk4 centrosomal pattern during procentriole initiation. Our findings raise the question of whether Plk4 focusing proceeds or follows procentriole initiation. In addition, we show that overaccumulation of active and inactive Plk4 on centrosomes follows different centrosomal dynamics and we speculate possible reasons for this observation. Our study provides new insights into the behavior of elusive Plk4, which is critically important for centrosome homeostasis and human health.

B191/P1185

Characterization of Orb2-dependent microcephaly in *Drosophila*

T. Hailstock, D. A. Lerit; Cell Biology, Emory University, Atlanta, GA.

Neural stem cells (NSCs) maintain a balance between self-renewal versus neurogenesis by asymmetric cell division, where dysregulation of this homeostatic state leads to neurodevelopmental disorders, such as microcephaly. NSC centrosomes play an important role in the regulation of this process by aligning the mitotic spindle along an invariant apical-basal axis to generate a self-renewing stem cell and a daughter cell. We recently identified the RNA-binding protein *Drosophila* Orb2 as a putative regulator of centrosome-enriched mRNAs. As an ortholog of human cytoplasmic polyadenylation element binding (CPEB) proteins, its implications in mRNA localization and translational control suggest a role for Orb2 in NSC spindle organization and neuronal specification. Preliminary work in our lab reveals Orb2 subcellular localization to the NSC cytoplasm, a broader cellular localization within the optic lobe region of larval brains at the neuroepithelial ridge and axons, and colocalization with glia-specific markers such as anti-Repo. These findings support the hypothesized role of Orb2 in supporting asymmetric centrosome maturation in NSCs while apparent enrichment in glia cells suggests expression outside of NSCs. Due to an apparent developmental delay, we defined a protocol to systematically compare brain volumes in age-matched *orb2* null animals relative to controls. These studies indicated loss of *orb2* results in microcephaly, suggesting an underlying requirement for Orb2 in regulating brain size. However, the specific contribution and mechanism of Orb2 in regulating neurodevelopment remains unknown. To examine our central hypothesis that glia cell dysfunction contributes to *orb2*-dependent microcephaly, current work to deplete *orb2* via RNAi in defined cell types including glia cells and/or neuroepithelial precursors is underway. Future directions include determination of developmental stage-specific requirements for Orb2. Advanced characterization of reproductive and behavioral variance observed in *orb2* mutants is also an exciting area of interest. Together with the utility of our colorimetric age-matched regime in *Drosophila*, resulting findings will provide insight into the neurodevelopmental basis of microcephaly.

Architectural basis for cylindrical self-assembly governing Plk4-mediated centriole duplication in humans

J. Ahn, L. Zhang, H. Ravishankar, K. Kirsch, Y. Zeng, J. Park, **K. Lee**; Cancer Innovation Laboratory, National Cancer Institute, National Institutes of Health, BETHESDA, MD.

As the main microtubule-organizing center in animal cells, the centrosome is critically required for normal cell division and proliferation. How the pericentriolar material (PCM) surrounding the barrel-shaped centriole is organized to form a functional centrosome remains elusive. We found that two long coiled-coil proteins, Cep63 and Cep152, interact with each other to form a 2:2 heterotetrameric complex that can self-assemble into a nanoscale cylindrical architecture *in vitro*, and whose organizational dimension and arrangement pattern closely mirror those of its respective endogenous proteins around the centriole. Additionally, we performed size-exclusion chromatography, sedimentation equilibrium ultracentrifugation, and interferometric scattering mass spectrometry and showed that the heterotetrameric building block generates octameric and hexadecameric complexes in a concentration-dependent manner, suggesting that the cylindrical self-assembly is formed through stepwise processes. By using MINFLUX nanoscopy, which offers low-nanometer-scale localization

precision in a three-dimensional space, we further showed that mutants defective in forming the Cep63•Cep152 heterotetramer exhibited crippled pericentriolar Cep152 organization, consequently failing to promote polo-like kinase 4 (Plk4)'s dynamic relocalization from around the centriole to the future procentriole assembly site as well as Plk4-mediated centriole duplication. Remarkably, the entire self-assembly process could be driven by two short, uncharacterized regions (which we named "self-assembly modules") in Cep63 and Cep152 capable of cophase-separating and generating cylindrical self-assemblies *in vitro*. Fluorescence recovery after photobleaching revealed that the self-assembled architecture is highly dynamic, undergoing internal rearrangement within the assembly while exchanging its components with those in the surroundings. Dynamic turnover of pericentriolar Cep63 and Cep152 has also been observed in human centrosomes. Taken together, given the evolutionarily conserved organization of PCM, this work could serve as a paradigm for investigating the structure and function of centrosomal scaffolds in other organisms, while offering a new direction for probing organizational defects in PCM-related human diseases.

B193/P1187

The *Caenorhabditis elegans* Centrosome is Surrounded by a Membrane Reticulum, the Centriculum, that Affects Centrosome Size and Function

S. Drey[1], R. Maheshwari[1], M. Rahman[1], M. Onyundo[1], O. Cohen-Fix[1], G. Fabig[2], T. Müller-Reichert[2]; [1]National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), NIH, Bethesda, MD, [2]Faculty of Medicine Carl Gustav Carus, Technische Universität Dresden, Dresden, GERMANY.

Centrosomes serve as the primary microtubule organizing centers during animal cell division. At the core of each centrosome is a pair of centrioles that recruits the pericentriolar material (PCM), which anchors and nucleates microtubules. Despite being considered membraneless organelles, the centrosomes of many cell types, including human cells, are surrounded by endoplasmic reticulum-derived membranes of unknown structure and function. We sought to characterize the centrosome-associated membrane and its possible regulation of centrosomes and microtubules. Using volume electron microscopy, we show that the *C. elegans* centrosome is surrounded by a membrane reticulum that we call the centriculum, for centrosome-associated membrane reticulum. Our current investigation reveals that microtubules collide with the centriculum, indicating the centriculum may serve as a microtubule "filter" by limiting the number of microtubules that fully elongate. Furthermore, we see that the centriculum fuses with the nuclear envelope as mitosis progresses, pointing toward a possible role in anchoring the centrosomes to the nuclear envelope and transducing the pulling forces of microtubules to the nuclear membranes to promote nuclear envelope breakdown. In addition to its possible functions in centrosome anchoring and force transduction, the centriculum may also affect centrosome size. The centriculum can be enlarged by disrupting ER membrane junction formation or increasing microtubule stability. These conditions result in expansion of the PCM and increased microtubules in the vicinity of the centrosome, suggesting that the centriculum affects centrosome structure and function. In converse, the centriculum collapses around the centrosome and condenses the PCM after induction of microtubule catastrophe. In conclusion, we show that centrosomes are surrounded by a reticular network of ER-derived membrane which may play roles in centrosome anchoring to the nuclear envelope, force transduction of the mitotic spindle to the nuclear membranes, and regulation of centrosome size and function.

Pericentrin-Like-Protein is a Kinesin-1 InteractorThat Drives Centriole Motility.

M. R. Hannaford, R. Liu, N. Billington, C. J. Fagerstrom, B. J. Galletta, J. R. Sellers, N. M. Rusan, N. M. Rusan; NHLBI, NIH, Bethesda, MD.

Centrosomes are one of the primary organizers of the microtubule (MT) cytoskeleton within cells. They comprise a pair of centrioles which act as a platform for a matrix of proteins termed the pericentriolar material (PCM). PCM is required for the nucleation and anchoring of MTs. Through MT organization, centrosomes are important for the mitotic spindle, cilia and flagella. To fulfill these varied functions, centrosomes must achieve proper positioning within the cell. Therefore, centrosomes must be motile. Typically, centrosomes are thought to position themselves via motor proteins pushing or pulling on the MTs anchored at the centrosome. However, in some cases, centrioles are motile without the presence of PCM or anchored microtubules, we refer to these as inactive centrioles. In this work we investigated how inactive centrioles are able to move through interphase cells. We reveal that these centrioles are cargo, being transported along the interphase microtubule array. We show that Kinesin-1 localizes to the centriole and is important for motility via an interaction between the Kinesin cargo binding tail and Pericentrin Like Protein (PLP); a coiled-coil rich protein which localizes to the outer centriole. Reverse yeast-2-hybrid screening allowed us to identify specific mutations which block the interaction between Kinesin-1 and PLP, live cell imaging then demonstrated that these mutations block interphase centriole motility. Reconstitution of this protein complex *in vitro* revealed that interaction with PLP is dependent upon the relief of Kinesin-1 autoinhibition. In this work we propose the first detailed mechanism of how centrioles can move independently of their role as an MTOC. We will further discuss our recent in vitro and in vivo efforts to dissect the mechanism of Kinesin-1 activation by kinesin activators, which promote PLP binding and efficient centriole motility.

A complex pattern of ZYG-1-mediated phosphorylation of SAS-5 controls centriole assembly

P. Sankaralingam[1], S. Wang[2], K. F. O'Connell[1]; [1]National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, MD, [2]Janelia Research Campus, Howard Hughes Medical Institute, Ashburn, MD.

Centrioles are microtubule-based cylindrical structures which act as a platform to concentrate microtubule nucleating machinery, thus forming the centrosome, the cell's major Microtubule-Organizing Center (MTOC). In dividing cells, centriole duplication is a tightly linked to the cell cycle and happens once every S phase. Mis-regulation of the process is linked several pathological conditions such as cancer and microcephaly. In *C. elegans*, centrioles are built by the sequential addition of several proteins - SAS-7, SPD-2, ZYG-1, SAS-5 & SAS-6 and SAS-4. While, the homologs and the general theme of assembly are highly conserved, the molecular mechanism of centriole biogenesis is not completely understood. In particular, how the kinase activity of ZYG-1 regulates the entire process is unknown. We addressed this question using *in vitro* refolded recombinant centriolar proteins. We found that ZYG-1 physically interacts with and preferentially phosphorylates SAS-5 *in vitro*. Using mass spectrometry, we identified 14 Ser/Thr residues that were phosphorylated *in vitro*. Intriguingly, many of these residues are conserved among nematodes. Mutational scanning of endogenous *sas*-5 using CRISPR/Cas9 genome editing revealed that S10 and S331/338/340 are indispensable for proper SAS-5 function *in vivo*. Replacing S10 or S331/338/340 with alanine or glutamate led to a fully penetrant loss of function

phenotype. The mutants could be conditionally rescued using a RNAi-resistant *sas*-5 transgene. Upon knocking down the transgene, SAS-5$^{S10A/S10E}$ embryos exhibited monopolar spindles during the early embryonic divisions. Conversely and unexpectedly, we found that SAS-5$^{S331/338/340A\ (3A)}$ embryos exhibit multipolar spindles. Consistent with an overactive centriole assembly pathway in this mutant, we found that the level of SAS-5^{3A} protein was significantly elevated. In contrast, SAS-5$^{S10A/S10E}$ levels were unaffected. Using S10-phospho specific antibodies, we found that SAS-5 is phosphorylated at centrioles *in vivo* and that the cell-cycle dependent pattern of phosphorylated SAS-5 differs significantly from the behavior of bulk centriole-associated SAS-5. Overall, our results suggest that ZYG-1 both positively and negatively regulates SAS-5 through phosphorylation to stringently control centriole biogenesis.

Mechanism of centrosomal protein recognition and regulation by the ubiquitin ligase TRIM37

A. Bellaart[1,2], **A. Brambila**[1,2], F. Meitinger[1,2,3,4], K. Oegema[1,2,3], M. Ohta[1,2,3,4], A. Desai[1,2,3]; [1]Department of Cell and Developmental Biology, School of Biological Sciences, University of California San Diego, La Jolla, CA, [2]Ludwig Institute for Cancer Research, La Jolla, CA, [3]Department of Cellular and Molecular Medicine, University of California, San Diego, La Jolla, CA, [4]Okinawa Institute of Science and Technology, Onna, JAPAN.

Centrosomes, small cellular organelles comprised of a centriolar core that is decorated with appendages and surrounded by a pericentriolar protein matrix that nucleates microtubules, are composed of more than 100 interacting components. How centrosomal protein assemblies are confined to the vicinity of centrioles and prevented from forming in the cytoplasm is not well understood. TRIM37 is a tripartite motif (TRIM) family ubiquitin ligase that serves as a guardian of centrosomal singularity, preventing the formation of ectopic centrosomal protein assemblies. When TRIM37 is absent, one of the ectopic assemblies that forms is a highly organized condensate containing the centrosomal protein centrobin. Centrobin-scaffolded condensates frequently nucleate microtubules in mitosis, leading to defects in chromosome segregation that may underlie abnormalities observed in the TRIM37 loss-of-function human disorder mulibrey nanism. These observations raise the question of how TRIM37 recognizes its centrosomal substrates to prevent their interaction/overaccumulation and how it simultaneously prevents the formation of ectopic assemblies while permitting the formation of normal assemblies at centrioles. Unique among TRIM family ligases, TRIM37 has a TRAF domain predicted to mediate protein-protein interactions. To understand how TRIM37 identifies its centrosomal substrates, we are investigating how it regulates two centrosomal proteins, centrobin and CEP192. In *in vitro* interaction assays following co-expression in FreeStyle 293-F cells, we found that TRIM37 associates with both centrobin and CEP192 and that binding is reduced by mutation of the TRAF domain. By testing a series of centrobin truncation mutants, we identified a 200 amino acid region of centrobin that mediates its interaction with TRIM37. Alphafold modeling identified short motifs within this region that are predicted to mediate TRAF domain binding. A truncation removing one motif partially reduced binding while a truncation removing all 3 motifs abrogated binding. Similar efforts are being pursued to understand the TRIM37-CEP192 interaction. Efforts to identify TRIM37 ubiquitination sites within centrobin and CEP192 and to employ in vivo replacements to examine the function of the TRIM37 TRAF domain and of specific interaction/ubiquitination regions of centrobin and CEP192 are also ongoing.

B197/P1191

Evolution of cell populations with different levels of centriole amplification

M. Dias Louro[1], C. Bank[1,2,3], M. Bettencourt-Dias[1]; [1]Instituto Gulbenkian De Ciência, Oeiras, PORTUGAL, [2]Institut für Ökologie und Evolution, Universität Bern, Bern, SWITZERLAND, [3]Swiss Institute of Bioinformatics, Lausanne, SWITZERLAND.

Understanding how cellular features evolve is a fundamental, but understudied problem, in biology. In the context of somatic cell evolution, many of these features show atypical levels of phenotypic variation, which have been associated with the development of human diseases such as cancer. One such feature is the abundance of subcellular structures, such as centrioles.
Whereas centriole number is usually constant in healthy proliferating cells, it is highly heterogeneous in cancer cells, with a tendency for abnormally high numbers, a condition known as centriole amplification. Centriole amplification is associated with hallmarks of cancer such aneuploidy and increased invasion, but its role in cancer initiation remains contentious. It has been proposed that low numbers of extra centrioles can trigger tumorigenesis whereas high numbers are excessively deleterious and suppress tumor formation. However, the relationship between the number of extra centrioles and/or the relative frequency of cells with abnormal numbers and the evolutionary dynamics of cells in the process of cancer evolution is poorly understood.
Here, we performed experimental evolution of human cell populations with different degrees of centriole amplification. Our goal was to quantify how centriole number and fitness changed over time depending on the initial degree of centriole amplification. Using a breast cancer model carrying a doxycycline-inducible Plk4 overexpression system, a key regulator of centriole biogenesis, we obtained ancestral populations with different levels of centriole amplification, which we evolved for two months in the presence of doxycycline. We observed that doxycycline-treated cell populations suffered a relative fitness penalty, proliferation deficit, and cell cycle disruption, proportional to the dose of doxycycline. Eventually, the relative fitness and population size of doxycycline-treated populations converged to those of control populations. We observed that cells with extra centrioles were progressively lost during experimental evolution, in a manner which depended on the concentration of doxycycline. Centriole number decrease was correlated with the upward trend in relative fitness and population size, indicating that doxycycline-treated populations adapted due to negative selection against cells with extra centrioles. Surprisingly, Plk4 mRNA levels were elevated both in the ancestral and evolved populations, suggesting that selection acted downstream of Plk4 overexpression. Our results showed that extra centrioles could not be maintained during experimental evolution despite constant Plk4 overexpression, suggesting that additional mechanisms may be required to sustain centriole amplification in live tumors.

The Unkempt RNA-binding, satellite protein promotes PLK4 induced centriole over-duplication

A. Martinez, A. J. Stemm-Wolf, R. M. Sheridan, C. G. Pearson; University of Colorado Sch Med, Aurora, CO.

Centriole duplication drives the assembly of the centrosome, the microtubule organizing center (MTOC). PLK4 is a master regulator of centriole duplication that controls early events in centriole assembly, centrosome assembly, and centriolar satellite integrity. Maintenance of the number of procentrioles formed is necessary for ensuring only one centrosome is assembled during S phase. Overduplication of

centrioles can lead to centrosome amplification (CA) multipolar mitosis, chromosomal instability (CIN), and aneuploidy. PLK4 overexpression promotes centriole over-duplication by dysregulating assembly factors such as centriole structural proteins, satellites, and the PCM. How PLK4 dysregulates centrosome assembly factors to promote centriole overduplication remains unclear. We find that Unkempt (UNK), an RNA-binding zinc finger protein, is upregulated when PLK4 is artificially overexpressed in RPE-1 cells, suggesting that UNK modulates PLK4 induced centriole overduplication. We show that UNK localizes to the centrosome and to centriolar satellites. Using PLK4 overexpression in RPE-1 cells, UNK knockdown attenuates centriole over-duplication, suggesting that UNK promotes PLK4 induced centriole over-duplication. In addition, early centriolar assembly proteins, CEP192, CEP152, PLK4, and SAS6 are not effectively recruited during centriole assembly. Moreover, we show that UNK promotes localization of centriolar satellite scaffold proteins, PCM1 and CEP131, required for trafficking centrosomal proteins and centriole over-duplication. In summary, these data suggest that UNK promotes the localization of early centriole assembly proteins needed for PLK4 induced centriole over-duplication.

Pericentrin is Essential for Differentiation in Rhabdomyosarcoma Cells

T. Allsage, T. Alahdadi, G. Bertram, Z. Gromley, **A. Gromley**; Lincoln Memorial University, Harrogate, TN.

One of the most common pediatric soft tissue cancers is rhabdomyosarcoma, comprising nearly 5% of all cancers in children. This cancer arises due to a defective myoblast differentiation process (myogenesis) that is thought to be caused by a disruption in the normal functions of the centrosome and primary cilia. Our previous studies have shown that the centrosome protein centriolin may play an important role in the normal function of the primary cilia and myogenesis, as disruption of the centriolin gene leads to cell cycle arrest, cell death, and impaired differentiation in cultured rhabdomyosarcoma cells. This suggests that specific components of the centrosome and the primary cilia could play crucial roles in the differentiation process of these cells. It is known that centriolin is localized to the maternal centriole within the centrosome, but many other proteins also contribute to the structure and function of this organelle. To determine if the effects we have seen previously are specific to centriolin or if other centrosome proteins have a similar role in myogenic differentiation, the CRISPR/Cas9 gene editing system was used in cultured human rhabdomyosarcoma cells to eliminate pericentrin, a centrosome protein that is located within the pericentriolar material surrounding the centriole. Upon disruption of the pericentrin gene using CRISPR/Cas9, cellular differentiation of rhabdomyosarcoma cells was affected, mirroring the phenotypes seen with centriolin loss. However, cell viability appeared to be unchanged. This is in stark contrast to the cell death that is characteristic of centriolin CRISPR treated cells. Our findings provide evidence that multiple proteins of the centrosome, each residing in distinct locations, are required for normal differentiation in rhabdomyosarcoma and, further, disruption of specific centrosome components can lead to programmed cell death. We propose that manipulation of individual centrosome components may be an effective means of tempering the growth of rhabdomyosarcoma and may be a viable approach for the treatment of this disease. Future studies will focus on identifying any additional centrosome proteins with similar properties.

B200/P1194

RNA binding proteins coordinate the post-transcriptional regulation of centrosomal *Plp* mRNA

J. Fang, D. Lerit; Emory University School of Medicine, Atlanta, GA.

The deregulation of centrosomes is associated with developmental disorders, including microcephaly, ciliopathy, and cancer. As major microtubule-organizing centers, centrosomes are composed of a pair of centrioles surrounded by pericentriolar material (PCM), a matrix of proteins required for microtubule nucleation. Also localizing to centrosomes are a small number of mRNAs. However, how and why RNAs localize to centrosomes remain critical unanswered questions. Conserved among the RNAs localizing to centrosomes is *pericentrin (PCNT)*-like protein (*Plp*). *Drosophila* PLP is a key component of the centrosome required for PCM scaffolding and microtubule organization. The disruption of *Plp* in *Drosophila* results in embryonic lethality, while the deregulation of *PCNT* in humans is associated with MOPD II and ciliary defects associated with Trisomy 21. To investigate mechanisms of *Plp* mRNA localization to centrosomes, we examined the contributions of two RNA-binding proteins during *Drosophila* embryogenesis. Our recent work shows oo18 RNA binding protein (Orb) interacts with *Plp* mRNA, contributes to *Plp* mRNA polyadenylation, and promotes PLP protein expression. Moreover, overexpression of full-length PLP can recover the PCM disorganization, cell division defects, and embryonic lethality caused by *orb* depletion, demonstrating *Plp* is an important downstream target of Orb. However, Orb is dispensable for robust *Plp* mRNA localization to centrosomes. To understand how *Plp* mRNA localizes to centrosomes, we investigated another multifunctional RNA binding protein, FMRP, the product of the fragile X mental retardation 1 gene (*Fmr1*). Our preliminary data indicate FMRP interacts with *Plp* mRNA and promotes its localization to centrosomes. These data support the idea that different RNA binding proteins coordinate centrosomal mRNA localization and translation. In addition, we observed the *Plp* coding region is required and sufficient for mRNA localization, and we will present our efforts to uncover the minimal localization element. Consistent with a model requiring active polysome transport, we found that treatment with translation inhibitors impairs *Plp* mRNA localization. This work lends mechanistic insights into RNA localization to centrosomes, which may be involved in the etiology of human diseases.

***Spd-2* gene duplication reveals cell type-specific assembly of pericentriolar material**

R. S. O'Neill[1], F. C. Welsh[2], A. Sodeinde[3], C. J. Fagerstrom[1], B. J. Galletta[1], N. M. Rusan[1]; [1]NHLBI, NIH, Bethesda, MD, [2]University of Washington, Seattle, WA, [3]Yale, New Haven, CT.

The centrosome is the major microtubule organizing center (MTOC) of the cell, ensuring proper spindle formation during cell division by recruiting pericentriolar material (PCM) proteins which in turn nucleate microtubules. In the most general sense, centrosomes are assumed to function similarly across cell types during division; however, a more nuanced view is emerging that PCM proteins and MTOC activity are differentially regulated across cell types, leading to functionally important diversity among different types of dividing cells. To gain insight into cell type-specific regulation of PCM proteins, we investigated a gene duplication of the PCM gene *Spd-2* using an evolutionary cell biological approach, reasoning that gene duplication could give rise to centrosome gene duplicates with cell type-specific functions. In *D. melanogaster*, *Spd-2* is a single copy gene, is ubiquitously expressed and functions by organizing PCM in both brain neuroblasts and spermatocytes. In contrast, *D. willistoni* has both *Spd-2A* (ancestral) and *Spd-2B* (derived). To explore expression and function we generated *D. melanogaster* animals with GFP-

tagged *Spd-2A* and *Spd-2B* transgenes, including their *D. willistoni* native regulatory elements. Similar to Spd-2, Spd-2A organizes PCM in neuroblasts, but was insufficient for MTOC function in meiotic spermatocytes. In contrast, Spd-2B was only expressed in spermatogenesis, where it organized PCM during meiosis. Interestingly, driving expression of Spd2-B in the brain rescued neuroblast MTOC, but driving Spd-2A in spermatocytes still failed to rescue meiotic MTOC, indicating an evolutionary change in *Spd-2A* affecting meiotic function. Finally, we used chimeric transgenes to map these evolutionary changes to a ~120 amino acid C-terminal tail domain of Spd-2A which was sufficient to prevent proper MTOC organization in meiosis. Together, these results indicate that somatic and germline cells have different requirements for PCM, and that Spd-2 is differentially regulated at the C-terminal tail to satisfy these requirements. Further, our evolutionary cell biological study points to a general model of Spd-2 function where the C-terminal tail mediates a priming step that precedes PCM recruitment. Our current work aims to use additional chimeras, point mutants, and transgenes to gain further insight into this putative Spd-2 tail priming mechanism.

Site-Specific Phosphorylation of ZYG-1 Regulates ZYG-1 Stability and Centrosome Number

M. Song, J. Medley, J. DiPanni, N. Yim, B. Shaffou, B. Sebou, E. Cramer, C. Wu, M. Kabara; Oakland university, Rochester, MI

Spindle bipolarity is critical for genomic integrity. As centrosome number often dictates mitotic bipolarity, tight control of centrosome number is vital for faithful cell divisions. The kinase Plk4/ZYG-1 plays a conserved role as a master regulator of centrosome assembly. In *Drosophila* and mammalian cells, Plk4 stability is known to be regulated by autophosphorylation-mediated proteasomal destruction. In *C. elegans*, molecular genetic studies have shown that ZYG-1/Plk4 activity is regulated by another kinase, Casein Kinase II (CK2), and phosphatases (PP1, PP2A-B55/SUR-6), while autophosphorylation-mediated regulation of ZYG-1 is yet to be tested in *C. elegans*. Here, we investigated how protein kinase CK2 regulates ZYG-1 stability in *C. elegans*. Given that CK2 kinase activity negatively regulates centrosome duplication by controlling centrosomal ZYG-1 levels, we hypothesized CK2 directly phosphorylates ZYG-1, and CK2-dependent phosphorylation of ZYG-1 triggers proteasomal destruction of ZYG-1, contributing to proper levels of ZYG-1. First, we show that CK2 directly phosphorylates kinase-dead ZYG-1 *in vitro,* and ZYG-1 physically interacts with CK2 in *C. elegans* embryonic protein lysates. Using *in silico* tools, we identified several ZYG-1 serine residues conforming to consensus CK2 target residues and focused on four serine sites within the ZYG-1-Linker-1 domain critical for centrosomal ZYG-1 loading and the ZYG-1-SAS-6 binding. To test the functional impact of site-specific phosphorylation of ZYG-1 *in vivo,* we used CRISPR editing and generated the *C. elegans* strains carrying mutations at the four serine residues replaced with alanine (S-to-A: Non-Phosphorylatable; NP) or aspartic acid (S-to-D: Phospho-Mimetic; PM). Our data illustrate the NP-ZYG-1 mutations result in elevated levels of both cellular and centrosomal ZYG-1, restoring bipolar spindles and embryonic viability to hypomorphic *zyg-1* mutants, suggesting that the NP-ZYG-1 mutation stabilized ZYG-1. As expected for overexpression, extra centrosomes are often observed in the NP-ZYG-1 mutant embryos. By contrast, the PM-ZYG-1 mutations lead to reduced ZYG-1 levels and aggravate *zyg-1* mutant phenotypes. Finally, we show inhibiting 26S proteasome blocks degradation of the unstable PM-ZYG-1 form, whereas the stable NP-ZYG-1 form becomes partially resistant to proteasomal degradation. Collectively, our data support a model where site-specific phosphorylation of ZYG-1 by CK2 regulates ZYG-1 stability via proteasomal degradation. Therefore, CK2-dependent phosphorylation of ZYG-1 provides an additional mechanism to fine-tune

ZYG-1 levels during cell cycle progression, leading to one and only one centrosome duplication during the early *C. elegans* cell division.

The regulation of centriole number by the microtubule-remodeling factor *ssna*-1

J. A. Pfister[1], L. Agostini[2], N. Mizuno[2], K. F. O'Connell[1]; [1]National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, MD, [2]National Heart, Lung, and Blood Institute, Bethesda, MD

The centrosome functions as the primary microtubule-organizing center (MTOC) of the cell and plays important roles in ciliogenesis and assembly of the mitotic spindle. It is composed of an orthogonally oriented pair of barrel-shaped structures known as centrioles surrounded by a dense proteinaceous matrix called the pericentriolar material (PCM). In mitotic cells, centrioles duplicate once per cell cycle in a process that is highly regulated to insure proper centriole number. Improper duplication, resulting in either too few or too many centrioles, disrupts spindle structure and cilia function. Indeed, abnormal centriole number has been linked to cancers, primary microcephaly, and a variety of ciliopathies. Work in *C. elegans* has identified a core group of conserved proteins essential for centriole biogenesis; among these is the master regulatory kinase ZYG-1, a homolog of Plk4, and SAS-6 a key component of the central scaffold. Here we report our molecular and genetical analysis of the *C. elegans* protein SSNA-1, whose human ortholog has been shown to function in neuronal branching and microtubule remodeling. In vitro studies demonstrate that worm SSNA-1 can bind and branch microtubules like its vertebrate counterpart. Using CRISPR-mediated genome editing, we have deleted the *ssna-1* gene and find that this results in a significant decline of embryonic viability and the formation of multipolar spindles. While our analysis indicates that the loss of SSNA-1 results in centriole overduplication, we find that *ssna-1* and *zyg-1* genetically interact in complex manner suggesting that SSNA-1 plays both positive and negative roles in centriole assembly. In particular, we find that loss of SSNA-1 alters centriolar composition such that centrioles have less ZYG-1 and more SAS-6. We have localized SSNA-1 in the embryo and find that during the first cell cycle SSNA-1 is restricted to centrioles; however, during the subsequent divisions, SSNA-1 also localizes to novel satellite-like structures that surround the PCM. Finally, our *in vitro* protein analysis has identified residues that are necessary for function and reveals that high-order oligomerization is essential for SSNA-1 function.

B204/P1198

In Vivo Interactome Profiling of Interferon Regulatory Factor 6 (IRF6) by TurboID-based Proximity Labeling

S. Huang, T. C. Cox[1]; University of Missouri-Kansas City, Kansas City, MO

Mutations in *IRF6* are arguably the most common cause of cleft lip/palate. IRF6 is a member of the interferon regulatory transcription factor (IRF) family which regulate the cell's response during viral infection. However, IRF6 is unique among the family in that it also has a critical developmental role, specifically in embryonic epithelia. Previous data indicate that IRF6 regulates epithelial cell proliferation/differentiation and cell-cell adhesion, although the regulatory networks in which IRF6 functions, and the specific proteins with which it interacts, remain largely unknown. It is notable, though, that IRF6 is predominantly located in the cytosol, with its nuclear import tightly regulated. Proximity-dependent *in vivo* biotin labelling coupled with mass spectrometry provides a sensitive tool by which to identify protein-protein interactions. To better understand IRF6 function within the cell, we

performed IRF6 proteomic profiling based on the promiscuous biotinylase enzyme, TurboID. This analysis identified several known proteins that have been directly implicated in cleft lip/palate, supporting the notion of a distinct cytoplasmic function for this transcription factor. Notably, our analyses also identified many vesicle transport proteins (endocytic adaptor proteins/recycling proteins), suggesting that IRF6 could directly regulate the trafficking of adherens junction proteins by interacting with components of intracellular vesicles. Other labeled proteins of note include several centrosomal proteins such as PCM1 and CEP170, which may support a mechanism whereby IRF6 also impacts cell cycle progression. Further experiments indicated that IRF6 could co-localize with PCM1, and centrosomal enrichment of IRF6 was significantly enhanced by phosphomimetic mutations of key serine residues in its C-terminus. Specific IRF6 interactors are currently being verified by mammalian two-hybrid and co-immunoprecipitation experiments. Taken together, these data will shed light on our understanding of the regulatory mechanisms of IRF6 controlling craniofacial development.

Spindle Assembly 1

B205/P1199

miR-31 regulates cytoskeletal dynamics to impact formation of the mitotic spindle

J. L. Song, C. Remsburg, K. Konrad; Biological Sciences, University of Delaware, Newark, DE.

miR-31 is a highly conserved microRNA that is known to play a role in cell proliferation, migration, and differentiation. Using the sea urchin as a model organism, we observed that miR-31 inhibitor injected embryos are developmentally delayed throughout cleavage stages and have an increased lethality rate at blastula stage. We identified miR-31 to localize at the midzone of the mitotic spindle and perinuclearly in divided blastomeres. miR-31 inhibitor injected embryos display longer astral microtubules and increased interpolar and kinetochore microtubules, as well as increased filamentous actin compared to the control. To understand the mechanism of these cytoskeletal defects, we identified that miR-31 suppresses several actin remodeling transcripts, including *Rab35*, *Gelsolin* and *Fascin*. Interestingly, *Rab35*, *Gelsolin* and *Fascin* transcripts co-localize with miR-31. The 3'UTRs of *Gelsolin* and *Fascin* are sufficient for localization to the mitotic spindle. miR-31 inhibition results in an increase in Fascin protein at the mitotic spindle midzone and perinuclearly in blastomeres in interphase. Our research, as well as previous studies, indicate proper actin dynamics are critical for formation of the mitotic spindle. These findings lead to our hypothesis that miR-31 regulates local translation of transcripts that mediate actin to impact formation of the mitotic spindle. Since proper mitotic spindle formation is a prerequisite for faithful segregation of chromosomes, identifying how miRNAs mediate spindle formation and mitosis is critical for the fundamental understanding of early cell division, birth defects, and predisposition to cancer.

B206/P1200

Differential regulation of sliding microtubule bundles in metaphase and anaphase

S. Forth, E. Tai, A. Alfieri; Biological Sciences, Rensselaer Polytechnic Institute, Troy, NY.

The proper organization of the mitotic spindle is required for successful chromosome segregation during cell division. This highly dynamic network consists of microtubules that are organized, bundled, and transported by motor and non-motor proteins that generate precisely balanced 'active' pushing and 'passive' frictional forces to give the spindle its mechanical robustness. How these mesoscale forces are

produced and regulated by ensembles of mitotic proteins has been unclear. We are addressing this knowledge gap by directly measuring force production across reconstituted micron-scale microtubule bundles and simultaneously observing by single molecule fluorescence microscopy the localization of proteins that build these networks. Here we demonstrate that the essential microtubule crosslinking protein PRC1 performs distinct mechanical tasks in metaphase and anaphase to regulate motor protein activity. In metaphase, when CDK/cyclin-B activity is high, PRC1 is phosphorylated at two threonine residues near its microtubule-binding domain, while in anaphase these marks are removed. Surprisingly, we find that a phosphomimetic PRC1 construct organizes smaller bundles containing fewer filaments than the wildtype protein. In addition, this metaphase PRC1 analog produces significantly less mechanical resistance against motor-driven microtubule sliding than the anaphase analog. These changes are biochemically regulated by phosphorylation of microtubule-adjacent residues within the PRC1 protein, and help explain the functional differences observed in cells between bridging fibers that connect sister kinetochore fibers in metaphase and the central spindle in anaphase that bridges the two separating spindle halves.

B207/P1201

F-actin is essential for the fidelity of bipolar spindle formation in mouse oocytes

E. J. Soto-Moreno, A. Balboula; University of Missouri, Columbia, MO.

The spindle provides the machinery for accurate chromosome segregation. In contrast to somatic mitotic cells, in which centriole-containing centrosomes regulate bipolar spindle formation, mouse oocytes lack centrioles and, therefore, bipolar spindle assembly depends on self-organization of numerous acentriolar microtubule organizing centers (MTOCs) into two poles. Accordingly, following nuclear envelope breakdown, MTOCs undergo two critical steps to assemble a bipolar spindle: 1) MTOC clustering (MTOC-MTOC aggregation) and 2) MTOC sorting (*i.e.,* MTOC distribution towards the poles). The traditional view is that, in mammalian oocytes, microtubules (MTs) and their associated proteins are the only cytoskeletal components responsible for regulating spindle bipolarity. In mammalian oocytes, F-actin localizes to the MT spindle. Interestingly, we found that F-actin also colocalizes and surrounds MTOCs in metaphase I (Met I) oocytes. The biological significance of F-actin localization to the spindle/MTOCs for bipolar spindle assembly is unknown. We found that perturbing global or cytoplasmic, but not cortical, F-actin resulted in MTOC clustering and sorting defects, and decreased bipolar spindle formation at Met I. We investigated the role of spindle/MTOC-localized F-actin in regulating MTOC organization using two different approaches. First, we found that F-actin localization to the spindle depends on unconventional myosin X (MyoX, that links F-actin to MTs by having both MT and F-actin binding domains). siRNA-mediated depletion of MyoX or expressing a dominant negative MyoX mutant (mutation at the MT binding domain) abolished F-actin localization to the spindle, phenocopied MTOC clustering and sorting defects in F-actin-perturbed oocytes and increased the incidence of aneuploidy. Such phenotypes were rescued by forcing F-actin localization to the spindle in MyoX-depleted oocytes using MAP4-UtrCH. Second, we optimized a novel photoswitchable optojasp approach that can manipulate actin dynamics at a µm precision to perturb F-actin selectively at the spindle/MTOCs, following its exposure to 405 nm laser pulses. Perturbing spindle-localized F-actin in oocytes using optojasp approach resulted in clustering and sorting defects compared to laser-exposed untreated or optojasp-treated controls. Importantly, exposing one spindle pole to laser pulses in optojasp- treated Met I oocytes (with already clustered and sorted MTOCs) resulted in MTOC clustering and sorting defects compared to those at the non-laser exposed spindle pole. Taken together, these

findings reveal an unexpected function of F-actin in bipolar spindle assembly in mammalian meiosis, a process that is notoriously prone to mistakes.

B208/P1202

Spindle scaling in cellular differentiation

T. Kletter[1], S. Reusch[1], A. Halavatyi[2], A. Biswas[3], M. Pleitner[4], O. Muñoz[5], B. Neumann[2], V. Zaburdaev[5], S. Reber[1]; [1]IRI Life Sciences, Humboldt-University of Berlin, Berlin, GERMANY, [2]ALMF, European Molecular Biology Laboratory, Heidelberg, GERMANY, [3]Max-Planck-Institute for the Science of Light, Erlangen, GERMANY, [4]University of Applied Sciences, Berlin, GERMANY, [5]Friedrich–Alexander University Erlangen-Nürnberg, Erlangen, GERMANY.

During early metazoan embryogenesis, the mitotic spindle scales with decreasing cell size across successive reductive divisions. However, it is unclear how cells cope with the challenge of organelle scaling when they are differentiating into the various embryonic tissues. The developing brain is notoriously sensitive to mutations in spindle or centrosome-associated genes and here, spindle defects may cause neurodevelopmental disorders. Using adaptive feedback microscopy, we investigated spindle scaling in murine embryonic stem cells driven towards neural progenitor fates. Over the course of differentiation, cells and spindles underwent concerted changes in shape and size. However, from an early timepoint, differentiating cells showed unexpectedly diverging spindle scaling compared to the non-differentiating cells. Spindle mass, and thus spindle scaling, is governed by regulation of microtubule nucleation and dynamics, processes that are highly intertwined with the biophysical properties of the cytoplasm at large. These properties are known to change when cells transition between differentiation states. Using quantitative phase imaging, we found that indeed the differentiating population had altered mitotic cell mass densities. Thus far, with this work we propose that, ultimately, spindle size scales with cellular dry mass rather than with the cell's spatial dimensions.

B209/P1203

Intracellular enrichment of lipid droplets concentrates tubulin to promote microtubule assembly and chromosome segregation errors

G.-Y. Chen, M. Chung, M. A. Lampson; University of Pennsylvania, Philadelphia, PA

Cancer progression is highly associated with chromosome instability arising from mitotic errors, but the underlying mechanisms cannot be entirely explained by mutations in oncogenes or tumor suppressor genes. In addition to genetic defects, physical constraints at the cell and tissue levels can cause mitotic errors. Hepatic cells provide a natural system to study the impacts of intracellular physical constraints on mitosis because they frequently enrich lipid droplets during cancer progression. We show that droplet enrichment increases chromosome segregation errors independent of spindle assembly defects, indicating impaired regulation of kinetochore-microtubule attachments. Furthermore, we find that droplet enrichment increases microtubule polymer by increasing total tubulin concentration. We propose that droplets exclude cytoplasmic volume and promote crowding to increase microtubule polymerization and kinetochore-microtubule attachment errors. Thus, physical constraints generate unstable chromosomes by disturbing cytoskeletal dynamics as a mechanism leading to the genomic variability characteristic of cancer cells.

B210/P1204

ZYG-8 regulates outward sorting forces to achieve proper force balance in*C. elegans*acentrosomal spindles

E. R. Czajkowski, N. Divekar, S. Wignall; Northwestern University, Evanston, IL.

Although centrosomes help organize spindles in most cell types, oocytes lack these structures; we are leveraging *C. elegans* to understand how acentrosomal oocyte spindles form and are stabilized. Using this system, we previously demonstrated that microtubule minus ends are sorted outwards during spindle assembly, where they form multiple poles that coalesce until bipolarity is achieved. Kinesin-12/KLP-18 is the primary outward sorting motor, while kinesin-5/BMK-1 provides a redundant outward force and dynein generates an inward force. However, how these motors are regulated to achieve proper force balance is not known. Now, we have gained insight into this question through studies of ZYG-8, a conserved kinase with a doublecortin-like microtubule binding domain. To study the functions of ZYG-8, we applied the auxin-inducible degron system; this approach enabled both long-term depletion, to investigate a role for ZYG-8 in spindle assembly, and acute removal from pre-formed spindles, to assess a role in maintaining spindle stability. Following long-term ZYG-8 depletion, bipolar spindles formed but were significantly longer, had disrupted pole organization, and were often bent; we observed similar phenotypes upon short-term depletion from pre-formed spindles. These phenotypes suggested that there was excessive outward force on the spindle in the absence of ZYG-8. Notably, when we co-depleted KLP-18 with ZYG-8, we also found evidence for excess outward force. KLP-18 depletion alone results in a failure to sort minus ends outwards during spindle assembly, resulting in a monopolar spindle with all minus ends at the central pole. However, when KLP-18 and ZYG-8 were both depleted prior to spindle assembly, minus ends were not only found at the central pole, but were also located at the periphery of the array. Moreover, when we removed ZYG-8 from pre-formed monopolar spindles, we observed the formation of structures with multiple poles, suggesting that minus ends were being sorted outwards, fragmenting the central pole. These phenotypes suggested that ZYG-8 may normally suppress an activity capable of exerting outward force. Given that KLP-18 was depleted in the monopolar spindle assay, we hypothesized that ZYG-8 may be regulating BMK-1, the redundant outward sorting motor. To test this hypothesis, we acutely removed ZYG-8 from monopolar spindles in a *bmk-1* mutant strain; under these conditions monopolar spindles remained intact and minus ends were not sorted outwards. This result suggests that ZYG-8 functions to dampen the activity of BMK-1, and that this regulation is essential to achieve and maintain proper force balance in the acentrosomal oocyte spindle.

B211/P1205

Regulation of Twist in the Human Anaphase Spindle

L. Neahring, S. Dumont; University of California San Francisco, San Francisco, CA

At each cell division, nanometer-scale motors, crosslinkers, and microtubules give rise to the micron-scale spindle. Although many mitotic motors have been shown to walk in helical paths around microtubules in vitro, the human spindle exhibits only slight global twist. This raises the question of how molecular torques are balanced to build a nearly achiral spindle. Here, we define the mechanisms that generate and resist twist in the anaphase spindle. We find that left-handed twist in RPE1 and MCF10A cells increases at anaphase, and that it is dramatically enhanced by inhibition of NuMA or dynein. We show that KIF4A, a kinesin that regulates microtubule dynamics and sliding in the anaphase midzone, is

required for this left-handed twist. We also uncover a role for the cell cortex, as disrupting actin filaments reduces anaphase twist. Our results suggest a model in which the left-handed torques generated by mitotic kinesins are increased at anaphase by the relocalization of KIF4A and counteracted by NuMA/dynein, either via active right-handed torque generation or by NuMA/dynein-dependent crosslinking that increases the spindle's torsional rigidity. Together, our work sheds light on the spatiotemporal regulation of spindle twist, a recently recognized phenomenon that may have implications for spindle mechanics and function.

B212/P1206

Measuring and modeling the dynamics of mitotic error correction

G. Ha[1], P. Dieterle[1], H. Shen[2], A. Amir[1], D. Needleman[1]; [1]Harvard University, Cambridge, MA, [2]Reverie Labs, Cambridge, MA

The mammalian mitotic spindle normally segregates an equal number of chromosomes to daughter cells with high fidelity. Over the course of spindle assembly, many initially erroneous attachments between kinetochores and microtubules are fixed through a process called error correction. Despite the importance of chromosome segregation errors in cancer and other diseases, we lack methods to characterize the dynamics of error correction and how it can go wrong. We have developed a novel experimental method and analysis framework to quantify chromosome segregation error correction in human tissue culture cells with live cell confocal imaging of spindle assembly, timed premature anaphase, and automated counting of kinetochores after cell division. Our results are consistent with an exponential decrease of errors over time, and an asymmetric initial state of erroneous attachments with high intercellular variability. We have developed a coarse-grained model which can quantitatively explain both the measured error correction dynamics and the distribution of anaphase onset times under different molecular perturbations. Our experimental and analysis frameworks allow us to quantitatively determine the dynamics of error correction for the first time. In order to develop a biophysical model of error correction, we will follow up on these results by characterizing how the regulation of microtubule stability and tension-dependent attachments determines error correction dynamics.

B213/P1207

Morphological growth dynamics, active microtubule mechanics, and mechanical plasticity of the vertebrate meiotic spindle

T. Fukuyama[1], L. Yan[2], M. Tanaka[3], M. Yamaoka[3], K. Saito[3], S.-C. Ti[4], C.-C. Liao[5], K.-C. Hsia[5], Y. T. Maeda[2], **Y. Shimamoto**[3]; [1]National Institute of Natural Sciences, Aichi, Japan, [2]Kyushu University, Fukuoka, Japan, [3]National Institute of Genetics, Shizuoka, Japan, [4]The University of Hong Kong, Hong Kong, Hong Kong, [5]Academia Sinica, Taipei, Taiwan

The spindle is a self-organized subcellular structure built from microtubules and microtubule-associated proteins. The spindle's bipolar shape is essential for the equal partitioning of replicated chromosomes between the two daughter cells. However, multipolar spindles can stochastically arise in a subset of a cell population, leading to chromosome segregation errors. How microtubules occasionally favor non-bipolar self-organization is not known. Here, using a combination of large-field fluorescence imaging, quantitative shape analysis, machine learning-based phenotype sorting, and Xenopus egg cytoplasmic extracts, we find that the microtubule structures growing into bipolar and multipolar shapes exhibit

distinctly different self-organization dynamics. Bipolar spindles are built through a predominant bipolar growth while little exploring other shape morphologies. Multipolar spindles are built while exhibiting a large shape fluctuation, which starts at an early self-organization phase and shows a characteristic temporal pattern. Our high-resolution imaging identifies a local defect in the premature, early microtubule network that can be the source of the multipolar shape growth. We also find that the spindles exhibit substantial shape stability upon maturation but can undergo phenotypic switching in response to a transient force perturbation applied using microneedles. Together with molecular perturbation assays, we discuss the biophysical mechanism of how varied spindle shapes emerge and are stabilized within the dynamic cytoplasm.

B214/P1208

The chromokinesin KLP-19 regulates the microtubule overlap in the central spindle of the C. elegans embryo during mitosis, independently of the microtubule bundling protein SPD-1

S. Redemann, M. Magaj, V. Zimyanin; University of Virginia, School of Medicine, Charlottesville, VA.

The faithful segregation of chromosomes during mitosis is essential for the health and survival of any eukaryotic organisms. Any failure in this process has detrimental consequences such as developmental abnormalities and cancer. During mitosis microtubules assemble into a bipolar spindle that segregates the sister chromatids in anaphase. Recent publications have highlighted the importance of the spindle midzone, the region between the chromosomes, for the process of chromosome segregation. The detailed mechanisms of midzone assembly and function during chromosome segregation has however remained elusive. A number of publications have led to a model of midzone formation and function in mammalian cells that relies on a combination of microtubule organization by bundling of antiparallel microtubules by PRC-1 (*C.elegans* spd-1), regulation of microtubule growth dynamics by KIF4a (*C.elegans* klp-19) and motor driven microtubule sliding by a combination of motors. Combining a detailed 3D structural analysis by electron tomography with state-of-the art light microscopy we have found that the spindle midzone in *C. elegans* is composed of different microtubule subclasses that likely differ in their dynamics. Thus, suggesting a possible differential regulation of microtubule growth during anaphase. Using Fluorescence recovery after photobleaching and second harmonic generation imaging we found that while microtubules within the midzone move pole-wards, the length of the antiparallel microtubule overlap zone in the spindle midzone is constant throughout anaphase, and independent of cortical pulling forces as well as the presence of the microtubule bundling protein SPD-1. Further investigations of the microtubule bundling protein SPD-1 and the chromo-kinesin KLP-19 in *C. elegans*suggest that in contrast to previously reported in mammalian cells, KLP-19 functions independently of SPD-1. Our data suggests that KLP-19 plays an active role in regulating the number of microtubules within the midzone as well as the size of the antiparallel overlap region throughout mitosis.

B215/P1209

Laser Ablation and Fluid Flows Show a Single Force Mechanism Governs Spindle Positioning

H. Wu[1], G. Kabacaoğlu[2], E. Nazockdast[3], H. Chang[4], M. J. Shelley[2,5], D. J. Needleman[1,2]; [1]Harvard University, Cambridge, MA, [2]Flatiron Institute, Simons Foundation, New York, NY, [3]The University of North Carolina, Chapel Hill, NC, [4]Academia Sinica, Taipei, TAIWAN, [5]New York University, New York, NY.

Few techniques are available for elucidating the nature of forces that drive subcellular behaviors. Here we develop two complementary ones: 1) femtosecond stereotactic laser ablation (FESLA), which rapidly creates complex cuts of subcellular structures, thereby allowing precise dissection of when, where, and in what direction forces are generated; and 2) assessment of subcellular fluid flows, by comparing direct flow measurements, using microinjected fluorescent nanodiamonds, to large-scale fluid-structure simulations of different force transduction models. We apply these new techniques to study spindle/centrosome positioning in *Caenorhabditis elegans* early embryos, and probe the contributions of three postulated force mechanisms: *i)* microtubule pushing, *ii)* cytoplasmic pulling, and *iii)* cortical pulling upon centrosomal microtubules. Based on our results, we construct a biophysically-based model to explain the centrosome dynamics. Taken together, we demonstrate that cortical pulling forces provide a general explanation for many behaviors mediated by centrosomes, including pronuclear migration/centration and rotation, metaphase spindle positioning, asymmetric spindle elongation and spindle oscillations. In sum, this work establishes new methodologies for disentangling the forces responsible for cell biological phenomena.

B216/P1210

Mammalian kinetochore-fibers maintain their own lengths, but require poles for spindle coordination

M. Richter; UCSF, San Francisco, CA

At each cell division, nanometer-scale components self-organize to build a micron-scale spindle. In mammalian spindles, microtubule bundles called kinetochore-fibers attach to chromosomes at one end and focus into spindle poles at the other. Despite evidence suggesting poles set length and other spindle properties, their role remains poorly understood. In fact, many species do not have spindle poles. Here, we probe the role of the pole in giving rise to the mammalian spindle's length, dynamics, and function, inhibiting dynein to generate spindles whose kinetochore-fibers do not focus into poles. We find that unfocused kinetochore-fibers have a mean length indistinguishable from control, but a broader length distribution, and reduced length coordination intracellularly and between sisters. Further, we show that unfocused kinetochore-fibers, like control, can grow back if shortened by laser ablation, albeit more slowly, and thus actively recover their length. We find that while control kinetochore-fibers robustly recover their length by increasing plus-end polymerization and suppressing minus-end depolymerization, these dynamics are severely reduced in unfocused ones, slowing length recovery. Finally, we show that spindles with unfocused kinetochore-fibers fail to correctly segregate chromosomes. Thus, while mammalian kinetochore-fibers locally maintain and recover their own lengths without spindle poles, poles globally coordinate them across space and time.

B217/P1211

Myosin 10 supports mitotic spindle bipolarity by promoting PCM integrity and supernumerary centrosome clustering

Y. Yim[1], A. Pedrosa[1], X. Wu[1], R. Cheney[2], J. Hammer[1]; [1]National Institutes of Health, Bethesda, MD, [2]University of North Carolina, Chapel Hill, NC.

Myosin 10 (Myo10) is a member of the MyTH4/FERM domain family of unconventional, actin-based motor proteins. Previous studies have shown that Myo10 supports cell adhesion during interphase via its integrin-binding FERM domain and spindle dynamics during mitosis via its microtubule-binding MyTH4 domain. Here we characterized Myo10's contribution to mitosis using Myo10 knockout HeLa cells and MEFs isolated from a Myo10 knockout mouse. Most notably, both of these knockout cells exhibit a pronounced increase in the frequency of multipolar spindles. Staining of unsynchronized metaphase cells showed that the primary driver of spindle multipolarity in knockout MEFs and knockout HeLa cells lacking supernumerary centrosomes is PCM fragmentation, which creates y-tubulin-positive, centriole-negative microtubule asters that serve as additional spindle poles. For HeLa cells possessing supernumerary centrosomes, Myo10 depletion further accentuates spindle multipolarity by impairing centrosome clustering. These results indicate, therefore, that Myo10 supports spindle bipolarity by maintaining PCM integrity in both normal and cancer cells, and by promoting supernumerary centrosome clustering in cancer cells. Finally, complementation experiments show that Myo10's FERM domain-dependent interaction with integrin is essential for both the clustering of supernumerary centrosomes and the maintenance of spindle pole integrity, and that its MyTH4 domain-dependent interaction with microtubules is primarily required for the maintenance of pole integrity.

PLK-1 is required for establishing and maintaining acentrosomal spindle organization in *C. elegans* oocyte meiosis

J. Narula, S. Wignall; Northwestern University, Evanston, IL

Sexual reproduction relies on meiosis, a specialized cell division program that produces haploid gametes. Female gametes (oocytes) in most organisms lack centrosomes, yet the mechanisms by which acentrosomal spindles are formed and stabilized are poorly understood. Previous work has detailed steps in the spindle assembly pathway in *C. elegans* oocytes and has characterized a layered ring-shaped protein complex ("ring complex") that encircles each chromosome and is required both for spindle assembly and chromosome congression. However, key questions remain regarding how these components work together to ensure the creation of a bipolar spindle, and how these processes are regulated.

Polo-like kinases (PLKs) are critical regulators of chromosome segregation and bipolar spindle formation in mitosis across species. In *C. elegans*, polo-like kinase 1 (PLK-1) plays an essential role in centrosome maturation during mitosis and is required for nuclear envelope breakdown in oocytes. However, whether this kinase performs other functions during meiosis is not known. Here we report that PLK-1 dynamically localizes to several subcellular locations in oocytes including the spindle poles, kinetochore, ring complex, and chromatin, and that the chromosomal passenger complex (CPC) and BUB-1 are required for PLK-1 to target to the ring complex. To investigate the role of PLK-1 further, we utilized auxin-induced degradation (AID) to deplete PLK-1 from oocytes either prior to spindle assembly or after bipolar spindle formation. Depletion of PLK-1 prior to spindle assembly resulted in a failure of nuclear

envelope breakdown, consistent with previous findings. Additionally, we found organizational defects when depleting PLK-1 from fully formed bipolar spindles, indicating that PLK-1 also plays a role in maintaining the spindle after bipolarity has been established. Lastly, we observed the formation of ectopic microtubule asters in these depletion conditions, suggesting a unique role for PLK-1 during acentrosomal meiosis. Taken together, our work identifies PLK-1 as a key player in *C. elegans* meiosis, thus incorporating this protein into a larger model for acentrosomal spindle assembly and chromosome dynamics.

Segregation of the univalent X chromosome in the two striped planthopper *Acanalonia bivittata*

A. Borseth, K. Felt, E. Stowe, L. Paliulis; Bucknell University, Lewisburg, PA

Correct segregation in meiosis I depends on homologous chromosomes pairing to form bivalents. To achieve a successful reduction in ploidy, bivalents align on the metaphase plate and then homologues segregate during anaphase I. While bivalent formation is generally required for correct segregation in meiosis I, many organisms pose an exception to this requirement. Our objective was to study on such exception, the two striped plant hopper *Acanalonia bivittata* (Hemiptera, Auchenorrhyncha), which has a univalent X chromosome. *A. bivittata* were collected and their identification was confirmed through DNA barcoding. Chromosome number was found to be consistent with previously published karyotypes for the species. To observe the behavior of unpaired chromosomes in male primary spermatocytes, live-cell and confocal imaging of stained cells was conducted. The univalent X chromosomes were found to be characterized by independent and delayed segregation that occurred after autosomal segregation during early anaphase I. Delayed segregation of the univalent chromosome was associated with the loss of microtubule connections to one spindle pole, leaving the chromosome aligned on the metaphase plate, often in a position outside the main spindle body. This study characterized the behavior of an unpaired chromosome in an alteration to the traditional meiotic program. This work has translational implications in organisms in which a chromosomal pairing partner is lost, such as the diminution and potential loss of a Y chromosome in mammals.

Mitotic Spindle Remodelling in Response to Severe Metabolic Stress

J. Ng[1], G. Charras[1], S. Banerjee[2]; [1]University College London-41600960, London, United Kingdom, [2]Carnegie Mellon University, Pittsburgh, PA

In response to severe metabolic stress, some organisms enter a reversible state known as suspended animation (SA), in which all observable activities, such as growth and motility, come to a halt. Remarkably, following SA, the organisms can resume their life cycle, unharmed. Upon SA entry, how individual cells switch off their activities and preserve memory of their pre-SA asymmetries are little understood. Here we seek to investigate how cell division, one of the most dynamic cellular processes, is perturbed during SA. We treated mitotic HeLa cells with metabolic inhibitors and paid particular attention to the mitotic spindle. We observed that microtubules (MT) in different parts of the mitotic spindle exhibit differential changes in length under severe metabolic stress, suggesting that their dynamics are spatially controlled by distinct energy-dependent processes. After release from the metabolic stress, most cells were able to resume division. To understand the mechanistic nature of the spindle remodelling, we developed a mathematical model to determine how changes in the mechanical

properties and forces within the spindle during energy depletion may contribute to the observed behaviour. The results suggest that apart from a decrease in motor activities, changes in spindle stiffness, MT polymerization and MT flux are all required to explain spindle remodelling. The model also predicts the lengthening of the overlap regions of the half-spindles and a reduction of tension in the spindle. Overall, they show that the spindle can be viewed as a composite material made up of components with different sensitivities to energy depletion. The size of the spindle is predominantly controlled by the opposing forces generated by these components. These findings raise new questions about what energy-dependent processes are connected to the physical properties of the spindle and how the remodelling preserves the memory for division.

Cancer Therapy - Inhibitor Activity 1

B222/P1215

The Antitumor Activity ofcannabis sativa/CBD in prostate cancer pc3 cells

L. R. Motadi; University of Johannesburg APK, Johannesburg, SOUTH AFRICA.

Prostate cancer is the second most frequently occurring carcinoma in males worldwide and one of the leading causes of death in men around the world. Recent studies estimate that over 1.4 million males are diagnosed with prostate cancer on an annual basis, with approximately 375 000 succumbing to the disease annually. With current treatments continuing to show severe side effects, there is a need for new treatments. In this study we looked at the effect of cannabis sativa extract, cannabidiol and cisplatin on prostate cancer cells, PC3. Methods In addressing the above questions, we employed the MTT assay to measure the antiproliferative effect on PC3 cells following treatment with varying concentrations of Cannabis sativa extract, cisplatin and cannabidiol. xCELLigence was also used to confirm the IC50 activity in which cells were grown in a 16 well plate coated with gold and monitor cell attachment. Caspase 3/7 activity was also measured using 96 wellplate following treatment. Western-blot and qRT-PCR was also used to measure the gene expression of tumour suppressor genes, p53, Bax and Bcl2. Animal studies were employed to measure the growth of PC3-mouse derived cancer to evaluate the effect of compounds in vivo. Results From the treatment with varying concentrations of Cannabis sativa extract, cannabidiol and cisplatin, we have observed that the three compounds induced antiproliferation of PC3 cancer cell lines through the activation of caspase 3/7 activity. We also observed induction of apoptosis in these cells following silencing of retinoblastoma binding protein 6 (RBBP6), with upregulation of p53 and bax mRNA expression, and a reduction in Bcl2 gene expression. The growth of tumours in the mouse models were reduced following treatment with cisplatin and cannabidiol.

B223/P1216

Analysis of off-target effects on cardiac muscle by drugs used to treat multiple myeloma and breast cancer

J. Wang; Cell and Developmental Biology, SUNY Upstate Medical University, syracuse, NY.

We have previously demonstrated that myofibril assembly occurs in three steps (premyofibrils to nascent myofibrils to mature myofibrils) representing increased complexity of protein arrangements (Rhee et al., 1994; White et al., 2018). Our discovery that inhibitors of the Ubiquitin Proteasome System (UPS) prevent nascent myofibrils from progressing to mature myofibrils in cultured embryonic quail

muscle supports the three-step model, and indicates some proteins in nascent myofibrils in skeletal muscles must be proteolyzed to permit the maturation of mature myofibrils. These UPS inhibitors have no effects on the formation of premyofibrils and nascent myofibrils, and no effects on existing mature myofibrils. Similar UPS inhibitors treatments on cardiomyocytes isolated from embryonic chick embryos, and on hiPSC-derived cardiomyocytes also led to the halt in nascent myofibrils progressing to mature myofibrils. Our experiments using UPS drugs on skeletal and cardiac muscled cells suggest possible explanations for the off-target cardiac and skeletal muscle effects of UPS inhibitors that are also used on multiple myeloma patients. We suggest that analyses of cultured embryonic heart cells and human cultured muscle cells will provide a preclinical assay for testing of novel cancer drugs with improved outcomes for patients., an important "…goal of the emerging field of cardio-oncology…" (Narezkina and Nasim, 2019). As a test of our suggestion, we have used a new UPS drug suggested for cancer patients that is a ligase inhibitor. This compound did inhibit myofibrillogenesis in embryonic quail skeletal muscle cells. However, it had no effect on myofibrillogenesis in embryonic chick heart cells at the same concentration. In support of our suggested assay, the ligase that the new UPS inhibitor binds to is not present in cardiac muscle cells, but is present in skeletal muscle cells. Use of doxorubicin to treat breast cancer patients has a serious effect on the hearts, and skeletal muscles. Our experiments indicates that this compound inhibits the assembly of myofibrils, and in contrast to UPS inhibitors lack of effects on mature myofibrils, doxorubicin induces the disassembly of mature myofibrils. The idea that doxorubicin interferes with the assembly and/or maintenance of mature myofibrils may explain its cardiotoxic effects on breast cancer patients.

Podoplanin Expression and Ex Vivo Lectin Effects on OSCC Cells from Clinical Trial Subjects

T. J. Hellmig[1], E. J. Brace[1], S. Parikh[1], S. Basu[1], A. J. Shienbaum[2], D. I. Suster[3], E. M. Capitle[3], E. Kalyoussef[3], D. Roden[3], S. Baredes[3], M. Fatahzadeh[4], G. S. Goldberg[1]; [1]Rowan University, Stratford, NJ, [2]Keystone Medical Laboratories, Throop, PA, [3]Rutgers New Jersey Medical School, Newark, NJ, [4]Rutgers School of Dental Medicine, Newark, NJ.

Oral cancer kills over 13,000 people in the USA and over 145,000 people worldwide each year. Current treatments include surgical procedures that can leave patients with permanent sequalae and decrease their quality of life. Novel therapies are needed to treat oral cancer. Maackia amurensis seed lectin (MASL) can target the podoplanin (PDPN) receptor which is expressed on OSCC cells that cause over 90% of oral cancers. These findings prompted the investigation of MASL as a novel agent in an ongoing clinical trial (NCT04188665) aimed at oral cancer. Here, we examined PDPN expression and the effects of MASL on OSCC cells derived from patients enrolled in this trial. IHC detected robust levels of PDPN expression on OSCC cells in oral lesions from these patients. Western blot analysis confirmed PDPN expression by these cells adapted to culture. Submicromolar (770 nM) MASL concentrations decreased the motility and viability of these OSCC cells by over 70% and 10%, respectively. Moreover, higher (2880 nM) MASL concentrations completely inhibited the motility of these cells, and decreased their viability by over 50%. These results support the consideration of MASL as a potential OSCC anticancer agent.

B225/P1218

Antiproliferative Activity of Male and Female *Maclura pomifera* Extracts in ER-positive Breast Cancer Cell Lines

M. Rumpa, C. Maier; Biology, Texas Woman's University, Denton, TX.

Breast cancer is one of the most diagnosed cancers in women around the world. Natural products of plant origin have been recognized as prominent sources of anti-cancer drugs. *M. pomifera* is a dioecious (separate male and female plants) tree native to the south-central USA, reported to have anti-inflammatory, antinociceptive, and antiproliferative properties. Native Americans have used plant parts for cancer treatment, but few cancer research studies have focused on *M. pomifera*, limiting our understanding of its medicinal properties. The goal of this research is to identify capsaicin-like compounds in *M. pomifera* plant extracts and determine their antiproliferative activities in the ER-positive breast cancer MCF-7 and T47D cell lines. Capsaicin, a bioactive phytochemical abundantly present in chili peppers, is known as a potent transient receptor potential vanilloid type 1 (TRPV1) calcium-permeable ion *channel* agonist. Other plants synthesizing capsaicin-like compounds could provide new therapeutic agents for cancer treatments. To identify capsaicin-like phytochemicals, stem and leaves of male and female *M. pomifera* were sequentially extracted with hexane, ethyl acetate, ethanol, and methanol. *M. pomifera* contains capsaicin-like compounds based on a colorimetric assay, TLC, and UPLC-ESIMS/MS. Antiproliferative activities evaluated using MTS assays revealed that *M. pomifera* plant extracts possess antiproliferative properties. Both male and female *M. pomifera* plant extracts inhibited growth of MCF-7 and T47D cells. Male extract at 500 µg/ml concentration inhibited both MCF-7 and T47D cells by 80% compared to female extract (45%). Blocking of TRPV1 with capsazepine significantly increased cell viability suggesting that *M. pomifera* phytochemicals works through TRPV1 in inducing cell death. We hypothesize that *M. pomifera* capsaicin-like compounds trigger apoptosis through the mitochondrial apoptotic pathway due to intracellular calcium overload *via* TRPV1. To find out whether plant extracts increase the calcium concentration in the cell, cells were pretreated with the calcium chelator BAPTA-AM and then treated with plant extracts. Chelation of calcium ions significantly increased cell viability, revealing that *M. pomifera* phytochemicals activate TRPV1 thus overloading cells with calcium ions and triggering cell death. Future work will focus on chemically characterizing capsaicin-like phytochemicals in *M. pomifera* extracts and elucidating their mechanism of action in inducing apoptosis in cancer cell lines *via* the TRPV1 ion channel. The findings could lead to the discovery of natural products for the development of new cancer treatment drugs.

MiR92b-targeted miRNA inhibitor-containing Gold Liposomal Formulation Reduces Cell Growth in Glioblastoma Cells

A. O. Sanchez Alvarez[1], N. Grafals-Ruiz[1], F. Valiyeva[1], R. Rabelo[2], P. E. Vivas-Mejía[1,3]; [1]Comprehensive Cancer Center UPR, San Juan, PR, [2]University of Puerto Rico Rio Piedras Campus, San Juan, PR, [3]Department of Biochemistry, University of Puerto Rico Medical Science Campus, San Juan, PR.

MicroRNA (miRNA) dysregulation plays a central role in the initiation, progression, and drug resistance of most malignancies. MiRNA-based therapies are designed to target upregulated or downregulated miRNAs with oligonucleotide miRNA inhibitors (OMIs) or oligonucleotide miRNA mimics (OMMs), respectively. Although OMIs and OMMs are promising therapies for cancer treatment, their significance has been hindered as these molecules are quickly degraded when systemically administered. MicroRNA-

92b (miR92b) is aberrantly abundant in glioblastoma (GBM), the most aggressive of the primary brain tumors. Brain-targeted drug delivery systems have the extra challenge of overcoming the blood-brain barrier (BBB). Apolipoprotein E (ApoE) is under study for its role as a lipid transport protein in the brain, making it suitable for brain targeting. The internalization of nanocarriers is increased with ApoE peptide functionalization compared to empty liposomal formulation in U87 cells. Our lab recently published successful systemic delivery of miR92b-OMIs containing gold-liposomal formulation into the brain of a GBM syngeneic mouse model. However, this formulation was prepared with 15 nm gold nanoparticles ($AuNPs_{15}$), and very low OMI conjugation and high AuNP agglomeration were observed. Therefore, optimization and standardization of this procedure are necessary to obtain a formulation with potential clinical use. The herein project furtherly explores the role of miR92b in the U87 human GBM cell line while addressing the above-described challenges. We used AuNPs of different sizes and observed that 5 nm AuNPs ($AuNPs_5$) increased the AuNP-OMI conjugation, reduced the AUNP aggregation, reduced the size of the nanocarrier system (liposomes), and increased the homogeneity of the liposomal formulation. These traits also result in enhanced cost efficiency due to less waste of raw material. The liposomal nanocarrier system using $AuNPs_5$ results in a 22% size reduction from the previously reported value with a 50% increase in homogeneity. Using $AuNPs_5$ gold-liposomal formulation the previously observed tendency was intensified, achieving better internalization compared to empty liposomes and $AuNPs_5$ gold-liposomal formulation without ApoE. In vitro administration of miR92b-OMI to U87 cells resulted in decreased proliferation and a reduction in the ability to migrate. Quantitative PCR confirmed complete inhibition of miR92b after transfection. A caspase 3 assay suggests apoptosis after miR92b inhibition. These findings help elucidate the role of miR92b in GBM for future therapy designs.

B227/P1220

Anti-Cancer Ruthenium Complex KP1019 Causes Ribosomal Biogenesis Stress in Yeast

J. S. Blackman, P. K. Hanson, S. L. Gary; Biology, Furman University, Greenville, SC.

Platinum-based drugs (cisplatin, carboplatin etc.) are used to treat many cancers, but limitations include harsh side effects and evolution of drug resistance. The ruthenium based complex indazole *trans*-[tetrachlorobis(1*H*-indazole) ruthenate(III)], also known as KP1019, may overcome these limitations and appeared promising in an early clinical trial. Prior studies demonstrated KP1019's ability to cause DNA damage and alter the cell cycle, however the drug's impact on cells is not fully understood. More recently, the ribosome has been implicated as a potential target of KP1019 in both cancer cells and the model organism *Saccharomyces cerevisiae*. For example, in a previous proteomic analysis in yeast, KP1019 increased expression of translation and ribosome related genes. To understand KP1019's impact(s) on ribosomes, here we examine KP1019 sensitivity of yeast lacking genes that encode ribosomal structural proteins or proteins involved in ribosome biogenesis. In the presence of KP1019 these deletion strains appeared drug resistant, displaying a higher growth rate than wildtype yeast. To determine whether the altered gene expression and mutant growth kinetics might be due to KP1019's effect on ribosomal biogenesis, we used fluorescence microscopy to monitor the localization of GFP-tagged large ribosomal protein Rpl7a. We discovered that KP1019 treatment causes a dose-dependent increase in the proportion of cells with a single focus of Rpl7a-GFP, as opposed to a diffuse cytoplasmic distribution. Additionally, we used Sik1-RFP and Elo3-BFP proteins to visualize the nucleolus and endoplasmic reticulum respectively to refine the drug-induced localization of Rpl7a-GFP localization as being nucleolar, a result that suggests KP1019 does indeed interfere with ribosomal biogenesis.

Identification of this process as a target of KP1019 opens new opportunities for rational design of combination drug therapies.

Chromatin remodeling in sodium valproate-treated U251MG glioblastoma cells as assessed by image analysis

C. B. M. Oliveira, M. A. Rocha, M. L. S. Mello; Department of Cell Biology, University of Campinas - UNICAMP, Campinas SP, BRAZIL.

Sodium valproate (VPA), a drug widely prescribed as an anticonvulsant, is a well-known class I histone deacetylase inhibitor (HDACi), a DNA demethylation inductor and a promising antitumor agent. Cells of glioblastoma, a very aggressive tumor of the central nervous system, have been reported to contain increased levels of DNA methylation in several of their gene promoters. When cultivated in the presence of VPA, glioblastoma cells not only undergo histone H4 hyperacetylation but also exhibit decrease in their DNA methylation profile. In this work, we investigated whether these VPA-induced epigenetic changes are accompanied by chromatin remodeling characteristics in Feulgen-stained U251MG glioblastoma cells that could be revealed using image analysis. Such an analysis was performed in an Axiophot 2 microscope equipped with AxioCam HRc video camera and Kontron KS-400-3 software (Carl Zeiss, Oberkochen/Munich, Germany). U251MG cells cultivated in the presence of 1 mM and 10 mM VPA for 4 and 24 h and of 5 µM 5-aza-CdR for 28 h (a control of DNA demethylation) were used. Increase in the acetylation levels of histone H3 was demonstrated with the VPA treatments but not with the 5-aza-CdR assay, whereas decrease in the global levels of 5-methylcytosine followed treatments with both drugs. A decreased variability in the degree of chromatin packing per nucleus and in nuclear entropy, defined in terms of number of bits needed to store densitometric values per nuclear image, in the cells treated with the longer VPA treatment especially at the 10 mM concentration, but not with the 5-aza-CdR assay, revealed chromatin decondensation. These results suggest that the chromatin remodeling induced by VPA in U251MG cells, that may favor gene expression, is more involved with histone acetylation than with DNA demethylation.

Assessment of NK Cell-based Immunotherapies Using an Optimized Multiplexed Assay and Advanced Flow Cytometry

J. Lovchik, M. Carter; Sartorius Bioanalytical Instruments, Inc., Albuquerque, NM

NK cells are potent cytotoxic effector cells that offer great promise for clinical utilization in treating cancers without the adverse side-effects associated with T cell-based cytotherapies. Hence, there is currently a focus on the development of NK cell-based cancer immunotherapies, including chimeric antigen receptor-engineered NK (CAR-NK) cells and tumor-specific monoclonal, bi-specific and tri-specific NK cell engaging antibodies (mAbs, BIKES, and TRIKES) that can induce NK cell-mediated antibody dependent cellular cytotoxicity (ADCC). In this study, we utilized a Burkitt lymphoma cell model to examine the effect of cytokine activation on NK cell-mediated killing, and the potency of different anti-hCD20 mAbs in NK cell-mediated ADCC across multiple donors. Assessing tumor cell killing is critical in evaluating the efficacy of new NK cell-based immunotherapies. However, full characterization

requires concurrent analysis of multiple factors, including expression of activation markers and cytokine production which involve performing multiple assays requiring a high number of effector cells. For this reason, we utilized a rapid, high throughput, multiplexed, flow cytometry assay that not only measures target cell killing, but also determines expression of NK cell activation markers and cytokine production using 10 µL of sample in either 96 or 384-well plate format. The results showed that direct tumor cell killing was induced upon cytokine activation and corresponded to increased production of several cytokines, plus expression of CD25 and CD69 activation markers. Tumor cell killing was also induced upon addition of certain anti-CD20 mAbs to unactivated NK cells, although the level of ADCC depended on which mAb was used. Corresponding increases in Granzyme B, CD178 (Fas Ligand), IFNγ, TNF, and RANTES secretion were also observed. In general, higher levels of ADCC and effector protein secretion were seen using a non-fucosylated mAb. However, differences were observed in both the degree of ADCC and cytokine expression between donors that corresponded to differences in their CD16 genotype. Overall, use of this multiplexed assay revealed tumor cell killing by NK cells was effectively enhanced by cytokine activation or addition of anti-tumor mAbs, and simultaneously provided characterization of the NK cells in relation to tumor target killing.

A Novel PSMA Targeting Small Molecule Drug Conjugate Can Successfully Enter PSMA-Positive Prostate Cancer Cells Through Receptor Mediated Endocytosis

B. McAllister[1], L. Caromile[1], C. Berkman[2]; [1]UConn Health, Farmington, CT, [2]Washington State University, Pullman, WA

A common roadblock in cancer research is drug delivery. The primary tumor microenvironment can prevent a drug from reaching its target, which can cause off-target effects if not tumor specific. Prostate specific membrane antigen (PSMA) is a transmembrane protein with high therapeutic potential due to its specific overexpression in prostate cancer. Targeting PSMA for drug delivery is already being implemented; however, many designs struggle with efficacy and durability. This study aims to investigate a PSMA targeting small molecule drug conjugate's (SMDC) ability to target PSMA-positive prostate cancer cells, with the goal of improving delivery, uptake, and efficiency of treatment moieties such as radioligand therapy. The SMDC, 5FAM-X-FPO-42 (5FAM) contains a specific, irreversible PSMA targeting region and is conjugated to a 488 fluorophore. To demonstrate that PSMA SMDC was specific, we treated C42B PSMA-positive and C42B$^{PSMA\text{-}KO}$ cells with the SMDC and found that 5FAM specifically interacted with cell surface PSMA of the C42B PSMA-positive cells, not the C42B$^{PSMA\text{-}KO}$, and was subsequently internalized into the cell. It is known that PSMA is internalized into the cell by receptor mediated endocytosis of clathrin coated pits. To further characterize the SMDC's trafficking through the cell, we found that PSMA and 5FAM both colocalized in the endosome (EEA1) and lysosome (LAMP1) but only low levels of PSMA was visible in the endoplasmic reticulum (PDI) and Golgi (RCAS1). The SMDC was not detected hinting that the 5FAM might have been cleaved off the linker by low pH. Cell fractionation and a western blot verified that PSMA was in the membrane/organelle fraction of C42B PSMA-positive cells. These results provide evidence that the PSMA targeting SMDC is effectively and exclusively targeting PSMA-positive cells *in vitro*. To further investigate the trafficking of the PSMA SMDC, this study aims to follow the movement of PSMA undergoing endocytosis while interacting with the SMDC to investigate if PSMA is recycling back to the cell membrane. PSMA recycling is essential for treatment of PSMA positive prostate cancer as it continuously provides a therapeutic target. Therefore,

this research will provide a better understanding of the trafficking of the SMDC, its interaction with PSMA during receptor mediated endocytosis and its potential clinical utility.

Differential Radiation Responses in alt-NHEJ Pathway in Human Neuroblastoma Cells and Human Glioblastoma Cells

Q. Randle, G. Regisford, P. Saganti, H. Wang; Biology, Prairie View A&M University - Prairie View, TX, Prairie View, TX.

Radiation DNA double-strand breaks are repaired by homologous recombination(HR) and non-homologous end-joining (NHEJ). Poly(ADP-ribose) polymerase I (PARP-1) is involved in the alternative NHEJ pathway (alt-NHEJ). To improve radiotherapy efficacy in human malignant glioblastoma tumors and to decrease toxicity in human neurons, we investigated the radiation response in human neuroblastoma cells (SH-SY5Y) and human malignant glioblastoma cells (U251 MG) and the regulation of poly(ADP-ribose)polymerase I (PARP-1), Ataxia telangiectasia-mutated (ATM) and Nicotinamide adenine dinucleotide (NAD) on radiation sensitivity, DNA damage, and repair, apoptosis, and autophagy. Cell survival fractions of radiation dose were determined by clonogenic assays in U251 MG and SH-SY5Y cells, pretreated with a triple-component complex consisting of PARP inhibitor, ATM inhibitor, and NAD supplements. Necrosis and apoptotic cells were detected by a combination of propidium iodide and Hoechst 333342staining and analyzed using Flow Cytometry and confocal microscopy. DNA damage was detected by immunostaining gamma-H2AX and 53BP1 and DNA damage foci were observed under confocal microscopy and quantified by Image J. Radiation-induced autophagy was detected by fluorescent Live Cell Imaging of GFP-LC3 MediatedAutophagy under confocal microscopy. Our results demonstrated that the triple-component complex significantly increased the radiation sensitivity of U251 MG, but notSH-SY5Y cells. The synergistic interaction of the triple complex inhibitors on DNA damage and repair is under investigation. Our study suggests that modulation of the alt-NHEJ pathway may enhance radiotherapy efficacy in human malignant glioblastoma tumors.Differential Radiation Responses in alt-NHEJ Pathway in Human NeuroblastomaCells and Human Glioblastoma Cell

Cancer Therapy-3D Culture Models

AI-enabled Novel Workflow to Evaluate Cell Therapy Using 3D Spheroid Models

Z. Tong, A. Lim, A. Katiyar, T. Baranowski, J. Baade, O. Sirenko; Molecular Devices, LLC, San Jose, CA.

T-cell therapies are designed to help our immune system fight cancer cells, including CAR T cells, tumor infiltrating lymphocytes (TIL), and other genetically modified T cells. In recent years, the field of cell therapy has started to expand, among which, the launch of the first CAR T-cell therapies to treat blood cancer in 2017 was a critical milestone in this field. Despite its boom, the discovery of novel immunotherapies that specifically enhance T-cell response against cancer cells remains a challenge task, especially when trying to find robust in vitro models to evaluate these immunotherapies throughout their development. In the past, the models have been limited to the use of suspension cells and 2D cell monolayers, which lack the key features of 3D extra-cellular microenvironment. In recent studies, 3D advanced tumor models, such as multicellular spheroids, are believed to bring a closer resemblance to the in vivo clinical scenario because it has more complex cell-cell interactions, optional extracellular

matrix proteins, and a layered structure. In addition, these models have the added requirements for immune cells to penetrate the layered structure during killing. Moreover, the information associated with how the phenotype of the 3D model evolves and how the penetration of T cell into the 3D model can be measured has not been fully explored and exploited to evaluate the cell therapy.
To address some of the obstacles mentioned above, we used multi-cellular spheroids cultivated from Hela cell line in 96-well round bottom plate as our 3D model. In this study, we stained and activated the human peripheral blood mononuclear (PBMC) cells with PMA/ionomycin for 6 hrs, treated the spheroids with stimulated PBMC for 3 days, and imaged the whole plate with a high-content confocal imager every 2hrs. For the evolution of the phenotypic change of the spheroids analysis, a deep learning-based segmentation model was generated to mask the whole spheroid and the edge of the spheroid. The resulting masks were then used to classify the spheroids using machine learning, where the clear distinct phenotypic changes of the spheroids were observed compared to controls, allowing for live monitoring of the T cell efficacy. To analyze how T cells penetrated inside the spheroids, we calculated the coordinates of the penetrated T cells and the distance of cell movement from the nearest edge of the spheroid mask. By collecting the statistics of the distances and the time, we measured the speed of the T cell penetration into spheroids. Overall, our results show that the 3D spheroid models and the high-content analysis workflow may potentially be used as a metric to evaluate the efficacy of cell therapy in vitro.

B233/P1226

The Identification and Characterization of FOLFOX Resistance in Colorectal Cancer Patient Derived Organoids

J. Morris; Cellular and Molecular Medicine, University of Arizona, Tucson, AZ.

Resistance to chemotherapy drugs is a well-documented issue inhibiting the treatment of a wide variety of cancers. Colorectal cancer (CRC) is the third most common neoplasm worldwide and has the third highest mortality rate. However, the longtime gold-standard FOLFOX chemotherapy regimen, consisting of 5-FU and Oxaliplatin, results in only 70% survival rates in Stage 3 CRC patients, worse in Stage 4. More recent targeted therapies have marginally improved on this number, but the fact remains that CRC represents a highly heterogeneous neoplasm and resistance to standard chemotherapeutic regimens poses a significant barrier in treating this devastating disease. There is an immediate need to better understand how this resistance arises. We hypothesize that a small number of cells with high phenotypic plasticity (HPP) are able to remain dormant during the initial chemotherapy treatment then reenter the cell cycle to cause recurrence and metastasis months or even years after treatment has concluded. Patient-derived organoids (PDOs) are a recently developed *ex vivo* model that allows for the study and extensive characterization of such HPP cell populations that may be found in patient tumors. We are developing and expanding various PDO populations to examine them genotypically and phenotypically on the single-cell level through RNA sequencing and high throughput imaging, respectively. By identifying these HPP cell populations, we then discover drugs that prevent the development of drug-resistant subpopulations. In the long term, we use our tumor phenotype profile to develop models that predict the responsiveness of tumors, including their drug-resistant HPP subpopulations, to well-documented and clinically used oncology drugs, streamlining treatment and improving survival outcomes. Thus far we have characterized the phenotypes of five different tumor PDO lines as well as a polyp control. We observe that each tumor has a vastly different morphological and phenotypic profile

and as such are susceptible to different drugs. However, some drugs appear to target the stem cell compartment and thus slow or stop the growth of all lines examined so far.

Evaluating drug response in 3D triple negative breast cancer organoids with high content imaging and analysis

O. Sirenko; Molecular Devices, San Jose, CA.

Triple negative breast cancer is a clinically aggressive subtype, with high rates of metastasis, recurrence, and drug resistance and few clinically approved small molecule targeted therapies. There is a critical need to develop methods for efficient testing drug efficacy in patient-derived tumor samples to discover new therapeutic targets. Additionally, most potential oncology drugs fail the drug development pipeline despite having promising data for their efficacy *in vitro*, further reflecting the need for research models that more accurately model tumor biology. Two-dimensional (2D) cell culture remains the primary method of drug screening, despite being considered less physiologically relevant than three-dimensional (3D) culture. Challenges with 3D culturing methods, such as increased complexity and technical issues in performing and analyzing experiments, have prevented its widespread adoption as a primary screening method during drug studies. However, these challenges can be addressed by using automated high content imaging and analysis systems. In the present study, we describe automation of imaging and cell culture methods which enables scaling up complex 3D cell-based assays and compound screening. In addition, we show advanced analysis approaches and descriptors that allow scientists to gain more information about complex cellular systems, disease phenotypes, and compound effects. Using these methods, we measured responses to drug treatment in 3D mammospheres, including cytotoxicity, metabolism, and altered cell morphology. Tumoroids were formed from primary cells isolated from a patient-derived tumor explant, TU-BcX-4IC, that represents metaplastic breast cancer with a triple-negative breast cancer subtype and treated with 165 compounds of approved cancer drugs at multiple concentrations. We characterize multiple quantitative descriptors for tumor phenotypes and compound effects including characterization of tumoroid size, integrity, cell morphology and viability. In addition, the Cell Painting method was used for 3D tumoroids for evaluation of phenotypic effects. Principal component analysis was used to identify hits and cluster them based on similarity of phenotypes. Eight compounds were detected that demonstrated effects at low concentrations (10 nM), including romidepsin, trametinib, bortezomib, carfilzomib, panobinostat, that will be further investigated as potential drug candidates. 33 additional compounds were identified as effective at higher concentrations. In this study, we demonstrate methods for increased throughput and automation in 3D cancer assays that are suitable for compound screening using patient-derived samples.

B235/P1228

Genomic heterogeneity in pancreatic cancer organoids and its stability with culture

O. Usman[1], L. Zhang[2], G. Xie[1], H. M. Kocher[3], C. Hwang[4], Y. Wang[1], X. Mallory[2], **J. Irianto**[1]; [1]Department of Biomedical Sciences, Florida State University, Tallahassee, FL, [2]Department of Computer Science, Florida State University, Tallahassee, FL, [3]Barts Cancer Insitute, London, UNITED KINGDOM, [4]University of California Davis, Davis, CA.

The establishment of patient-derived pancreatic cancer organoid culture in recent years creates an exciting opportunity for researchers to perform a wide range of *in vitro* studies on a model that closely

recapitulates the tumor. Among the outstanding questions in pancreatic cancer biology are the causes and consequences of genomic heterogeneity observed in the disease. However, to use pancreatic cancer organoids as a model to study genomic variations, we need to first understand the degree of genomic heterogeneity and its stability within organoids. Here, we used single-cell whole-genome sequencing to investigate the genomic heterogeneity of two independent pancreatic cancer organoids, as well as their genomic stability with extended culture. Clonal populations with similar copy number profiles were observed within the organoids, and the proportion of these clones was shifted with extended culture, suggesting the growth advantage of some clones. However, sub-clonal genomic heterogeneity was also observed within each clonal population, indicating the genomic instability of the pancreatic cancer cells themselves. Furthermore, our transcriptomic analysis also revealed a positive correlation between copy number alterations and gene expression regulation, suggesting the functionality of these copy number alterations.

B236/P1229

Novel patient derived colorectal cancer organoid platform for automated high throughput drug discovery applications.

A. Lim[1], Z. Tong[1], E. Fraser[2], V. Durban[2], P. Macha[1], O. Buddhikot[1], T. Baranowski[1], j. Baade[1], A. Katiyar[1], H. Amijee[2], O. Sirenko[1]; [1]Molecular Devices, San Jose, CA, [2]Cellesce Biotechnology, Cardiff, UNITED KINGDOM.

There is a critical need to develop methods for efficient testing of drug efficacy using patient-centric models, to discover new therapeutic targets. Most potential oncology drugs fail at the later stages of the drug development pipeline and in clinical trials, despite having promising data for their efficacy in vitro. This high failure rate is partly due to insufficient predictive models being used to screen drug candidates in the early stages of drug discovery.

3D cell models, specifically patient-derived organoids (PDOs), offer a promising solution to this problem. Cells grown in 3D can better mimic cell-cell interactions and the tissue microenvironment, including cancer stem cell niches. Studies show that patients and their derived organoids respond similarly to drugs, suggesting the therapeutic value of using PDOs to improve therapeutic outcomes. However, challenges commonly associated with using these organoids, such as assay reproducibility, ability to scale up, and cost have limited their widespread adoption as a primary screening method in drug discovery.

To address some of the hurdles associated with the use of PDOs in large scale screens, a semi-automated bioprocess has been developed for the controlled production of standardized PDOs at scale. They are of a uniform size, high viability and are produced in repeatable batches in an assay-ready format.

In this study, patient-derived colorectal cancer organoids were seeded in 384 or 96-well microtiter plates manually, or with an automated cell bioprinter and dispenser. These PDOs were treated with selected anti-cancer compounds at various concentrations. Compound effects were monitored over time using transmitted light imaging. For the analysis of organoid growth and development, a deep learning-based image segmentation model was developed to automate the segmentation of the organoids. Using this approach, we tracked the effects of the compounds on colorectal organoid size, morphology, texture, and additional morphological and phenotypic readouts. A viability assay was carried out using live/dead cell dyes and the PDOs were imaged in 3D on a high-content confocal imager. Out of the tested panel of known anti-cancer drugs, we found that PDOs treated with

romidepsin and trametinib showed the most significant reduction in size, with a greater number of dead cells compared to the other compounds and controls. Overall, our results show the potential for the utility of PDOs in both precision medicine and high throughput drug discovery applications, when using automation with high-content imaging.

Probing tumor spheroid hypoxia using red/near-infrared ratiometric O_2-sensitive nanoparticles

A. C. Debruyne[1], I. A. Okkelman[1], S. M. Borisov[2], R. I. Dmitriev[1]; [1]Human Structure and Repair, University of Ghent, Gent, BELGIUM, [2]Institute of Analytical Chemistry and Food Chemistry, Graz University of Technology, Graz, AUSTRIA.

The role of the tumor microenvironment is paramount in supporting cell survival, promoting local invasion and metastatic dissemination. While the limited nutrient availability and hypoxia are known to be important contributors to the 'niche' environment and lead to metabolic cell heterogeneity, their quantitative non-destructive analysis is rather difficult. For instance, analysis of real-time oxygenation in such 3D cell cultures as spheroids and organoids, is rarely performed. To address this, we produced cell-penetrating O_2-sensitive nanoparticle probes, which can enable measurements of spheroid oxygenation and consumption rate on a conventional fluorescence microscope. We used near-infrared O_2-sensitive (PtTPTBPF) metalloporphyrin and red aza-BODIPY reference dyes to increase the light penetration depth and used well-known biocompatible polymer nanoparticles (Eudragit RL100 and PMMA-AA) to achieve efficient cell staining. The resulting probe, termed 'MMIR' (multi-modal infrared) enables measuring oxygenation gradients via fluorescence emission ratiometric measurements or the phosphorescence lifetime imaging microscopy (PLIM).To test the brightness, photostability, phototoxicity, and reproducibility of MMIR, we evaluated different reference:sensing dye (1:1, 1:0,5 and 0,5:0,5) ratio and the presence of nanoparticle charge groups. We examined multiple cell lines including HCT116, PANC-1, dental pulp stem cells, HUVEC, MCF-7, and SKOV-3. Preliminary results showed cell line-dependent staining and lower aggregation in case of negatively charged probe. No significant toxicity was found and after optimizations of the staining protocol, nanoparticle probes were used for staining 3D spheroid cultures and subsequent analysis of O_2 gradients. Surprisingly, the human colon cancer HCT116 spheroids displayed an "inverted" oxygenation gradient, with elevated oxygenation at the spheroid core, compared to the cells located at the periphery. This can be explained by the presence of necrotic core and the large size of spheroids (~700 µm), which cannot consume O_2. In addition, using the MMIR probe we studied how the growth medium composition can influence the oxygenation gradients. Collectively, presented ratiometric O_2-sensing nanoparticle probes provide means for multi-parameter quantitative oxygenation measurements and characterization of 3D cultures. Funding: supported by the Special Research Fund (BOF) grant of Ghent University (BOF/STA/202009/003).

Investigating the effects of confined cell migration on chromatin organization

J. McAllister[1], C.-R. Hsia[2], O. Hasan[1], J. Judd[1], S. Lee[1], R. Agrawal[1], C.-Y. Chang[1], P. Soloway[1], J. Lammerding[1]; [1]Cornell University, Ithaca, NY, [2]National Institutes of Health, Bethesda, MD

Cancer cells must migrate through small interstitial spaces during metastasis. These invasion events require extensive deformation of the cell body and nucleus, which can result in changes in chromatin organization. Previous studies have shown that 2D migration can induce heterochromatin formation in

cells, but this effect has not yet been investigated in 3D environments. In my research, we use polydimethylsiloxane (PDMS) microfluidic devices that mimic 3D interstitial spaces to study the effect of confined migration on chromatin organization. We demonstrate that confined 3D migration induces significantly more heterochromatin formation in human fibrosarcoma cells than unconfined 3D migration, and that histone-modifying enzyme HDAC3 is involved in this process. We have also shown that confined migration leads to changes in chromatin accessibility, which may alter gene expression to confer cells migratory advantages during confined migration. Whereas previous studies found that mechanical compression can induce heterochromatin formation via nuclear translocation of HDAC3, we found that HDAC3-dependent increases in heterochromatin during confined migrations are due to an activating change in its phosphorylation status. Previous studies have also shown that mechanical stimuli (stretch) can activate mechanosensitive ion channels and lead to changes in chromatin organization. Thus, we hypothesize that confined migration activates mechanosensitive Ca^{2+} channels, which contribute to heterochromatin formation. Indeed, preliminary experiments suggest that inhibition of stretch-sensitive Ca^{2+} channels and Ca^{2+} chelation reduces heterochromatin formation during confined migration in fibrosarcoma cells. These findings are an important first step to understanding how confined migration influences chromatin modifications and may provide insights into future therapies for invasive cancers.

Exploring the role of fibroblast-shed syndecan-1 ecto domain molecules in the promotion of mammary tumor formation

R. Bellin, G. Aucello, A. Maher, C. McCutcheon, M. Slanetz, J. Kelly, B. Lawton; College of the Holy Cross, Worcester, MA

It has been shown that chemical cross-talk between ductal epithelial cells and stromal fibroblasts in mammary gland tissue can play a role in promoting the development of breast cancer, specifically the formation of ductal carcinomas. Studies have suggested that the ecto domain of syndecan-1 (sdc-1), a transmembrane heparan sulfate proteoglycan, is one possible molecular basis for this cross-talk as it can serve as driver of epithelial cell division by acting as a growth factor co-receptor. In addition, clinical studies have linked the aberrant expression of sdc-1 in tumor proximal fibroblasts to poor breast cancer prognosis. In our current study, using a combination of conventional 2D tissue culture approaches and a 3D mammary duct-on-a-chip model system, we are testing the hypothesis that sdc-1 ecto domain molecules shed from stromal fibroblasts can serve as co-receptors for epithelial cell FGF receptors, thereby stabilizing the growth factor-receptor complex and driving elevated levels of epithelial cell division. In 2D dish-based studies, we have demonstrated that NIH-3T3 fibroblast cells actively express and shed sdc-1 ectodomain molecules when grown in culture, an expression pattern that not typical of most fibroblasts present in tissues. When epithelial cells were co-cultured with NIH-3T3 cells using a 2D Boyden chamber system, FGF-driven mammary epithelial cell proliferation was significantly increased in comparison to epithelial cells grown in the absence of fibroblasts. To expand the physiological relevance of these findings, we have adapted an existing 3D mammary duct-on-a-chip model system to allow the inclusion of stromal fibroblasts and used CRISPR/Cas9 to generate a paired fibroblast line unable of expressing sdc-1. We are using a combination of qualitative ductal atypia formation assays and quantitative in-chip proliferation assays to test if our 2D culture findings can be replicated in a culture system with a more tissue-relevant 3D structure.

Simple 3-D *in-vitro* Solid Tumor Gliospheres Advance the Study of Cellular Interactions Between CAR T-cells and Solid Brain Tumor Cells

I. I. Torres-Vazquez, E. Rosa-Molinar; The University of Kansas, Lawrence, KS

Chimeric antigen receptor (CAR T)-cells are developed by genetically modifying patients' T cells to express an artificial T cell receptor designed to be specific against the patient's tumor associated antigen, and they are used in CAR T-cell therapy to treat non-solid and solid brain tumors. Despite CAR T-cell therapy's effectiveness against non-solid brain tumors, Car T-cells' penetration and efficacy in treating solid brain tumors such as glioblastoma multiforme (GBM) are significantly limited.
To overcome this barrier, we developed a simple 3-D *in-vitro* solid tumor gliospheres to study the cellular interactions between CAR T-cells and solid brain tumor cells. We generated 3-D gliospheres from low-passage, serum-free cell lines derived from GBM patient tumors, GBM-39 (MC PDX NR, GMB 39); as a control we generated 3-D gliospheres using a commercially available cell line, LN-18 (ATCC, CRL-2610). Multi-modal widefield fluorescence imaging combined with whole-mount immunostaining for glial, neuronal, glioma stem cell markers, as well as EGFR permitted us to determine the cellular phenotype present as well as the presence of EGFR within GBM-39 and LN-18 gliospheres. To study the cellular interactions between the cellular phenotypes, present in the GBM-39 and LN-18 gliospheres and Car T-cells, both GBM-39 and LN-18 gliospheres were exposed to Jurkat epidermal growth factor receptor (EGFR) CAR T-cells. We imaged the GBM-39 and LN-18 gliospheres exposed to EGFR CAR T-cells at 24, 48, and 72 hours. In GMB-39 gliospheres, the effects of EGFR CAR T-cells were observable five (5) days post exposure. In contrast, in LN-18 gliospheres, EGFR CAR T-cells effects were observable 24 hours post exposure.
In the GBM 39 type, EGFR CAR T-cells were not found throughout the gliospheres; rather they were restricted to the outer layer. In the LN-18 gliospheres, EGFR CAR T- cells rapidly penetrated and freely distributed themselves throughout the gliospheres. In addition, LN-18 gliospheres were reduced in size. These differences suggest something is limiting EGFR CAR T-cells' penetration of GBM-39 gliospheres which is the focus of ongoing research effort.

Mechanism and Targeting of Adaptive Resistance to Anchorage Independent Cell Death in Cancer

M. Monavarian[1], E. F. Page[1], A. Kumari[1], R. Rajkarnikar[1], L. Quintero-Macias[1], S. Sathoo[2], L. Lanov[3], F. Massicano[3], E. A. Worthey[3], M. K. Jolly[2], E. V. Broude[4], A. Singh[5], K. Mythreye[1]; [1]Division of Molecular Cellular Pathology, Department of Pathology, O'Neal Comprehensive Cancer Center, University of Alabama at Birmingham Heersink School of Medicine, Birmingham, AL, [2]Centre for BioSystems Science and Engineering, Indian Institute of Science, Bangalore, INDIA, [3]Center for Computational Genomics and Data Sciences, University of Alabama at Birmingham, Birmingham, AL, [4]Department of Drug Discovery and Biomedical Sciences, University of South Carolina College of Pharmacy, Columbia, SC, [5]Electrical and Computer Engineering, University of Delaware, Newark, DE.

Intraperitoneal metastasis in cancer such as ovarian (OC) is characterized by accumulation of malignant ascites containing tumor cells that evade cell death in suspension contributing to poor patient outcomes

including distant metastasis and enhanced chemoresistance. We find that development of resistance to cell death under anchorage independence or anoikis resistance can occur in an oncogene agnostic but transcriptional reprogramming manner. Adapted cells are significantly more invasive and chemo resistant in vitro and promote distant metastasis to the lungs in vivo. Bulk transcriptomics and kinome analysis reveals strong MYC dependent repression programs and increased JAK STAT activities, with resistant cells characterized by hybrid epithelial/mesenchymal phenotypes and reduced apoptosis. In testing models for development of resistance we find that difference in proliferation rates, does not explain the outcomes in the longitudinal data. Thus using a modified Luria-Delbrück's "fluctuation analysis' we find a transiently primed stress-tolerant state where single cells reversibly switch back to being stress sensitive after being tolerant for several generations. This transient memory as estimated from the extent of clone-to-clone fluctuations in survival under stress is consistent with experimental loss of the tolerant state. Notably, inhibition of transcriptional reprogramming globally early in the process using specific CDK8/19 inhibitors abrogates development of resistance and concomitantly suppresses metastasis in vivo. These and additional characteristics of resistant cells will be presented.

B242/P1235

microRNA-18a regulates the metastatic properties of oral squamous cell carcinoma cells via HIF-1α expression

S. Kim[1], J. Oh[2], J. Choi[1]; [1]Oral Pathology, Gangneung-Wonju National University, Gangneung-si, KOREA, REPUBLIC OF, [2]Oral and Maxillofacial Surgery, Gangneung-Wonju National University, Gangneung-si, KOREA, REPUBLIC OF.

Rapid metastasis of oral squamous cell carcinoma (OSCC) is associated with a poor prognosis and a high mortality rate. However, the molecular mechanisms underlying OSCC metastasis have not been fully elucidated. Although deregulated expression of microRNA (miRNA) has a crucial role in malignant cancer progression, the biological function of miRNA in OSCC progression remains unclear. This study aimed to investigate the function of miRNA-18a in OSCC metastatic regulation via hypoxia-inducible factor 1α (HIF-1α). miRNA-18a expressions in patients with OSCC (n = 39) and in OSCC cell lines (e.g., YD-10B and HSC-2 cells) were analyzed using quantitative real-time polymerase chain reaction. HIF-1α protein expressions in OSCC cells treated with miRNA-18a mimics or combined with cobalt chloride were analyzed using western blotting. The miRNA-18a expression-dependent proliferation and invasion abilities of OSCC cells were analyzed using MTT assay, EdU assay, and a Transwell® insert system. miRNA-18a expression was significantly lower in OSCC tissue than in the adjacent normal tissue. In OSCC cell lines, HIF-1α expression was significantly decreased by miRNA-18a mimic treatment. Furthermore, the migration and invasion abilities of OSCC cells were significantly decreased by miRNA-18a mimics and significantly increased by the overexpression of HIF-1α under hypoxic conditions relative to those abilities in cells treated only with miRNA-18a mimics. miRNA-18a negatively affects HIF-1α expression and inhibits the metastasis of OSCC, thereby suggesting its potential as a therapeutic target for antimetastatic strategies in OSCC.

B243/P1236

Excess cholesterol synthesis driven by upregulation of lamin B receptor causes nuclear envelope fragility in metastatic melanoma

M. A. Baird[1], A. Cartagena-Rivera[2], C. Jewett[3], M. Pirooznia[1], R. Fischer[1], C. Waterman[1]; [1]National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, [2]National Institute of Biomedical Imaging and Bioengineering (NIBIB), NIH, Bethesda, MD, [3]Johns Hopkins University, Baltimore, MD.

Malignant melanoma (MM) is characterized by its mutational heterogeneity and aggressive metastatic spread. During metastasis, MM cells migrate through diverse microenvironments, including regions of dense tissue confinement to reach the vasculature. Microenvironmental confinement of tumor cells causes nuclear deformation, resulting in loss of nuclear envelope (NE) integrity and DNA damage, improper repair of which leads to genomic aberrations and genetic heterogeneity in the population. We hypothesize during metastatic progression, expression of NE genes is altered, increasing nuclear deformability and fragility, thus leading to increased genetic heterogeneity within the population. To test this hypothesis, we used a PDMS confinement device to assay for NE fragility in a range of metastatic and benign cancer cell types, revealing that metastatic cells displayed increased susceptibility to NE rupture. We then performed bioinformatic analysis of RNA-seq data sets from patient samples of MM and benign nevi, revealing potential NE proteins upregulated in metastatic disease. A targeted siRNA-based screen of upregulated NE genes showed knockdown of lamin B receptor (LBR) strongly reduced NE fragility in MM cells, and ectopic overexpression of LBR was sufficient to increase NE fragility in benign melanocytes. Similarly, atomic force microscopy showed knockdown of LBR in MM cells caused decreased nuclear deformability, while overexpression of LBR in benign melanocytes was sufficient to increase nuclear deformability. siRNA rescue experiments utilizing protein domain truncations and human disease-related point mutations in LBR demonstrated that the cholesterol synthase activity of LBR was required for increased NE fragility and deformability, independent of LBR's additional roles tethering heterochromatin and lamin B to the NE. Furthermore, reduction of LBR decreased cellular cholesterol and caused altered cholesterol distribution in the NE, potentially creating local membrane defects for NE rupture. These results show that upregulation of LBR in MM plays dual roles in reducing nuclear deformability and increasing NE rupture through alterations in cholesterol distribution in the NE. Utilizing whole genome sequencing, mouse tumor models and in vitro tumor spheroids, current work focuses on LBRs potential role in generating chromothripsis and genetic diversity in MM tumors.

B244/P1237

A link between size and phenotype in tetraploid cancer cells

M. Bloomfield, T. Chau, S. Huth, D. McCausland, A. McCaffrey, K. Fluet, D. Cimini; Virginia Tech, Blacksburg, VA.

Changes in DNA content can affect cell and nuclear size, and both tetraploidy and cell/nuclear size alterations have been linked to tumorigenesis. To investigate a potential link between tetraploidy and cell/nuclear size in tumorigenesis, we experimentally induced whole genome doubling (WGD) in diploid (2N) breast and colorectal cancer cells and generated single-cell tetraploid (4N) clones. We found that cell and nuclear volume do not always scale with DNA content after WGD and identified 4N clones that were classified as small and large based on their cell and nuclear size. While cell and nuclear volume doubled in the large 4N clones, they only increased by ~50% in the small 4N clones compared to 2N

counterparts. Both the small and large 4N clones maintained near-4N genomes, confirming that the size variations are not caused by a difference in chromosome number. Analysis of tumor histology images from The Cancer Genome Atlas (TCGA) also revealed that nuclear size of cancer cells increased in WGD+ compared to WGD- tumors. Interestingly, cancer cell nuclear area varied among WGD+ tumors, consistent with our small and large 4N clones, indicating that size variations also occur following WGD *in vivo*. Further characterization of our 4N clones showed that the small and large 4N clones displayed distinct mitotic phenotypes and tumor-like behavior. The large 4N clones had a higher incidence of unaligned chromosomes, multipolar spindles, and anaphase lagging chromosomes compared to the small 4N clones and the 2N cells. Moreover, we found that the small 4N clones outperformed the large 4N clones and 2N parental cells in several phenotypic assays, including cell migration and soft agar colony formation. These findings suggest that the small 4N clones may have increased tumorigenic potential relative to the large 4N clones. We are currently testing the hypotheses that cancer cell nuclear area is predictive of clinical outcome in WGD+ tumors, and that the mechanism(s) restricting cell and nuclear size scaling after WGD are responsible for the phenotypic differences in the 4N cells. Overall, our findings suggest that cell/nuclear size could be an important factor for the prognosis of WGD+ tumors.

B245/P1238

CanCel TatToo: receptor-mediated ablation of cancer cells and beyond

V. Purde[1], R. Shakya[1], E. Kudryashova[1], T. Cripe[2], **D. Kudryashov**[1]; [1]Ohio State University, COLUMBUS, OH, [2]Nationwide Childrens' Hospital, COLUMBUS, OH.

The application of protein toxins for therapeutic cell ablation is limited by their severe side effects due to high on- and off-target toxicity. We propose that the selectivity of targeting can be enhanced by intein-based toxin reconstitution from two dysfunctional fragments delivered to the cytoplasm via selective independent pathways. We designed a robust splitting algorithm and achieved reliable cytoplasmic reconstitution of functional Diphtheria toxin from engineered intein-flanked fragments upon receptor-mediated delivery of one of them to the cells expressing the remaining part. Retargeting the delivery machinery towards different receptors overexpressed in cancer cells enables selective ablation of specific sub-populations in mixed cell cultures. In a mouse model, the transmembrane delivery of a split-toxin construct potently inhibits the growth of subcutaneous xenograft tumors expressing the split-counterpart. Interestingly, delivery of a split part to the cells infected by a virus encoding the second part, clears the virus, allowing the cells to survive even high MOI doses of the virus in cell culture. Receptor-mediated delivery of engineered split-proteins provides a platform for precise therapeutic and experimental ablation of tumors or desired cell populations while also expanding the applicability of the intein-based protein trans-splicing for various applications.

B246/P1239

Role of Aging Associated Vascular Senescence on Ovarian Cancer Burden

A. Kumari[1], M. Monavarian[1], L. Macias[1], B. Horst[1], R. Arend[2], K. Mythreye[1]; [1]Department of Pathology and O'Neal Comprehensive Cancer Center, Heersink School of Medicine, University of Alabama at Birmingham, Birmingham, AL, [2]Department of Obstetrics and Gynecology-Gynecologic Oncology, University of Alabama at Birmingham, Birmingham, AL.

Ovarian cancer is the most lethal gynecological cancer, typically diagnosed at advanced stages post-menopausally. The ovaries, which are a primary site of tumor growth for all ovarian cancers, are subjected to rapid changes in the vasculature upon the onset of menopause. In a corollary manner, the vasculature is a primary therapeutic target for the management of advanced ovarian cancers indicating the significance of tumor angiogenesis in diseases progression and metastasis. Given the association between aging endothelial senescence and angiogenesis, we hypothesized that pre-existing senescent endothelial cells in aged and/or menopausal ovaries could contribute to ovarian cancer growth and invasion in the ovaries. To first distinguish the effects of follicular changes associated with the onset of menopause versus the effect of age we used 4-vinylcyclohexene diepoxide (VCD) for inducing menopause in young mice and a physiologically aged model. Menopausal changes of the ovary in both models were confirmed by follicle count and hormonal profile. Intrabursal implantation and assessment of tumor growth kinetics of mouse ovarian cancer cells (MOVCs) (ID8p53-/-) into the bursa of the ovaries from both these models revealed that physiologically aged mice had high tumour growth kinetics as compared to young (6 week old) mice. However, tumour burden in VCD induced mice was not significantly altered as compared to age-matched control mice suggesting that age-associated changes in ovaries contribute to tumor growth. We next assessed whether ovarian endothelial cells contribute to tumour growth, invasion into the ovary, by implanting MOVCs mixed with primary mouse ovarian endothelial cells (MOECs) intrabursally, and comparing to MOVCs alone. We find that mice implanted with MOVCs and MOECs together had significantly higher tumour burden as compared to MOVCs alone. Examining MOECs from aged mice indicate strong senescence features as evident by β-galactosidase staining, γH2Ax immunofluorescences, p16, TRF-1 (Telomeric repeat factor-1) and PAI-1 (Plasminogen activator inhibitor-1) levels. We find that condition media from senescent MOECs from older mice promoted invasion of cancer cells *in vitro*. These findings suggest a potential direct contribution of the aged and senescent vasculature to tumour growth and invasion into the ovary. These findings and ongoing studies will be presented.

Engineering antibody-based fragments to HPV oncoproteins

T. Smalley, A. Nicolaci, S. Pilon-Thomas, J. Binning; Moffitt Cancer Center, Tampa, FL.

BACKGROUND: Antibodies and their derivatives have revolutionized therapies and research and continue to expand science's biological toolkit. Specifically, the single domain antibody fragment (nanobody) has been a focus of researchers due to its advantageous characteristics such as small size, affinity, specificity, and solubility in the cytosol. In line with these advancements, we developed nanobodies specific to the early oncoprotein E6 found in the Human papillomavirus (HPV) genome. HPV infections are the most common sexually transmitted disease and are linked to ~ 4.5% of the total cancer incidence worldwide; however, there are no targeted therapies for HPV-related diseases and some HPV pathology remains elusive. We hypothesize that the nanobody's engagement of the viral E6

oncoproteins will suppress tumor growth and induce apoptosis in HPV(+) tumor cells, while having no off-target effects in non-infected cells. To test this hypothesis, we will use a DNA-based delivery system to induce intracellular expression of E6 nanobody antagonists in tumors.METHODS: Nanobodies against HPV E6 were selected using a yeast surface display platform. To determine the inhibitory effects of the nanobodies on the HPV(+) cell line CaSki, a colony formation assay (ability to form colonies) and Annexin V-APC/PI assay (apoptosis) were utilized. Further, we derivatized our nanobodies into nanobody-PROTACs. To assess the potential of our PROTACs to promote the proteasomal degradation of E6, a E6-GFP probe was transfected into HEK293T cells alone and in combination with the PROTAC. Levels of GFP were monitored using flow cytometry and microscopy.RESULTS: The colony formation assay showed the significant inhibitory effects of the A2 (n=6, $p < 0.05$) and C11 (n=6, $p < 0.05$) nanobodies. Further analysis of the inhibitory nanobodies showed 2-fold increases in late apoptosis, illustrating neutralizing candidates to move *in vivo*. Nanobody-PROTACs were also shown to promote E6 degradation. Expression of E6-GFP decreased when co-expressed with the nanobody-PROTAC (n=3, $p <0.05$), suggesting the bifunctional nanobody-PROTAC is recruiting E6 to a functional E3 ligase and marking it for proteasomal degradation.CONCLUSION: The summation of these current screens has allowed us to determine the most promising nanobody candidates for inhibition of endogenous E6 in HPV(+) cells. In addition, the results from our preliminary nanobody-PROTAC assay warrants further exploration of this orthogonal approach. Further studies involving the HPV(-) cervical cancer cell line C33A will be used to determine any off target or cytotoxic effects.

B248/P1241

Haploinsufficient tumor suppressor PRP4K is negatively regulated during epithelial-to-mesenchymal transition

L. E. Clarke, A. Cook, S. Mathavarajah, A. Bera, J. Salsman, **E. Habib**, C. V. Iderstine, M. Bydoun, S. M. Lewis, G. Dellaire; Dalhousie University, Halifax, NS, Canada

The pre-mRNA processing factor 4 kinase (PRP4K, also known as PRPF4B) is an essential gene in mammals. However, PRP4K is considered a haploinsufficient tumor suppressor, as partial loss of PRP4K expression in breast and ovarian cancer is associated with aggressive tumour phenotypes including taxane chemotherapy resistance, increased cell migration and invasion *in vitro*, and cancer metastasis in mice. Increased cell migration and invasion is associated with epithelial-to-mesenchymal transition (EMT) during cancer development. Therefore, we examined how partial depletion of PRP4K expression in the mammary epithelial cell lines HMLE and MCF10A affected cell migration the relationship of PRP4K protein expression to the process of EMT. Reduction of PRP4K expression by small hairpin RNA (shRNA) in these epithelial cell lines induced partial EMT marked by the upregulation of mesenchymal markers, such as fibronectin and Zeb1. In addition, depletion of PRP4K reduced or had no effect on 2D migration in the scratch assay but resulted in greater invasive potential in 3D transwell assays. In comparison, depletion of PRP4K in mesenchymal triple-negative breast cancer cells (MDA-MB-231) resulted in both enhanced 2D migration and 3D invasion, with 3D invasion correlated with higher fibronectin levels in both MDA-MB-231 and MCF10A cells. Surprisingly, these cellular changes occurred without changes in E-cadherin as would be expected for induction of full EMT. Induction of complete EMT in MCF10A cells, by treatment with WNT-5a and TGF-β1, or depletion of eukaryotic translation initiation factor 3e (eIF3e) by shRNA, resulted in significantly reduced PRP4K expression. Mechanistically, induction of EMT by WNT-5a/TGF-β1 reduced PRP4K transcript levels, whereas eIF3e depletion led to reduced PRP4K translation. Finally, reduced PRP4K levels after eIF3e depletion correlated with increased YAP activity

and nuclear localization, both of which are reversed by overexpression of exogenous PRP4K. Thus, PRP4K is a haploinsufficient tumor suppressor negatively regulated by EMT, that when depleted in normal mammary cells can increase cell invasion without inducing full EMT.

Localization of phosphofructokinase-1 to the plasma membrane through a novel interaction with the sodium/hydrogen exchanger NHE1

H. L. Hansen, B. A. Webb; West Virginia University, Morgantown, WV

Dysregulation of glycolysis and increased cell migration are hallmarks of cancer. Cancer cells are polarized, suggesting that glycolytic enzymes may be spatially regulated. We found that the first rate limiting enzyme of glycolysis phosphofructokinase-1 (PFK1) is enriched to the lamellipodia of migrating human and rat breast cancer cells. We hypothesize PFK1 is recruited to lamellipodia to locally generate ATP for cell migration; however the mechanism of recruitment is unknown. Glycolytic enzymes, including PFK1, pyruvate kinase M2, and lactate dehydrogenase A, have been shown to localize to the plasma membrane through interactions with transmembrane ion transport proteins, suggesting the formation of a glycolytic metabolon. We previously identified a novel interaction between the liver isoform of PFK1 (PFKL) and the ubiquitously expressed sodium/hydrogen exchanger NHE1, which is essential for pH homeostasis and directed cell migration and asked if this interaction could localize PFKL to lamellipodia. First, we asked if PFKL and NHE1 colocalize by immunofluorescent labelling. We found that PFKL and NHE1 colocalize in membrane ruffles of CCL39 Chinese hamster ovary fibroblasts but not NHE1-deficient CCL39 cells. To determine the affinity and identify the regions of interaction we generated GST-tagged chimeras of regions of the NHE1 cytoplasmic tail. Using sedimentation binding assays, we found that PFKL binds to a 70 amino acid region (637-707) of NHE1 with high affinity (695±162nM). Next, we asked if the NHE1-PFK1 interaction was isoform specific and determined that PFKL and the muscle isoform PFKM bind to this region; however, the platelet isoform PFKP does not. Next, we asked if the NHE1-PFKL interaction was evolutionarily conserved and found that mouse PFKL and zebrafish PFKLA and PFKLB were able to bind. To identify the residues of PFKL that bind to NHE1, we compared surface residues conserved between the isoforms and species. We have identified 21 potential amino acids on PFKL that participate in this interaction. Future studies will generate binding incompetent mutants of PFKL to determine if the interaction with NHE1 is required to locally produce ATP. Identifying the mechanism of PFKL recruitment to the plasma membrane will provide insight into the spatiotemporal dynamics of glucose metabolism and organization of glycolytic enzymes in cells.

Single-cell spatial molecular profiling of an *in vitro* 4T1 model of tumorigenesis

G. Abbott[1], S. Forward[1], M. Fahlberg[1], Y.-C. Lin[1], S. Anmalsetty[2], D. A. Wink[2], S. J. Lockett[2], W. F. Heinz[2], S. J. Kwok[1]; [1]LASE Innovation, Woburn, MA, [2]National Institute of Health, Frederick, MD

Probing the spatial context and dynamic behaviors of individual cancer cells is critical for understanding tumorigenesis, metastasis and treatment resistance. However, single-cell spatial information that is obtained from microscopy cannot easily be connected to molecular profiling methods such as flow cytometry and single cell sequencing. Here, we develop an approach using novel laser particles (LPs) to optically barcode individual cells and connect imaging to proteomic characterization with flow cytometry. LPs are micron-sized, semiconductor-based probes that emit narrowband laser light (<0.3

nm) and have been developed for massively multiplexed cell tracking. We employ an *in vitro* 4T1 murine breast cancer model of tumorigenesis, in which cells are grown in a restricted exchange environment chamber to form a 2D "disk" that recapitulates oxygen and nutrient gradients in a tumor. The disk is tagged with the LPs and imaged to record the spatial location of each barcode. The disk is then dissociated and stained for surface and intracellular markers and measured on a flow cytometer that reads out both fluorescence and LP barcodes. The barcodes read out during imaging and cytometry are matched and the data are combined for each barcoded cell. A key challenge was ensuring LPs found on cells during imaging were retained through the cell processing steps and the cytometry acquisition. We developed and optimized methods for tagging the disk using a biotin-streptavdin binding. We found that cells need to have 3LPs to be uniquely identifiable. To maximize the tagging and recovery of cells we tested several different fixation and dissociation methods for the cell disk. We found that fixation with PFA and dissociation with Accutase provided the most stable recovery and results of tagged cells. Overall, we were able to tag ~30% of the cells in a 2D disk (~1,000 cells) with 3+ LPs and measure them using flow cytometry. We are validating our method by comparing to previously published fluorescence microscopy data, reproducing spatial gradients of surface and intracellular markers (PMID: 33859337). Our results establish LPs as a novel method for cellular barcoding and connecting single-cell information from different platforms, from imaging to cytometry, cytometry to imaging, and imaging/cytometry to sequencing. Nickel Sulfide Nanoparticles Conjugated with Graphene and their Use as Photothermal Therapeutic Agents in Breast and Ovarian Cancer Models

G. Ray[1], G. Neelgund[1], H. Wang[2], G. Regisford[3]; [1]Chemistry, Prairie View A&M University, Prairie View, TX, [2]Physics, Prairie View A&M University, Prairie View, TX, [3]Biology, Prairie View A&M University, Prairie View, TX.

Nickel sulfide (NiS) nanoparticles are important transitional metal chalcogenides and are explored for their possible applications. NiS nanoparticles have high absorption in the near-infrared (NIR) region, which is a basic need for application in the photothermal therapy (PTT) of cancer. PTT relies on the NIR absorption ability of the photothermal agent employed. The NIR absorption of NiS nanoparticles is improved by its conjugation with graphene oxide (GO) and graphene (GR) nanosheets. The objective of this study was to design and synthesize robust near-infrared (NIR) active photothermal agents comprised of nickel sulfide nanoparticles with graphene oxide and graphene nanosheets for the advancement of PTT. Two NIR responsive nanomaterials *viz.,* GO-NiS and GR-NiS were prepared by hydrothermal method. Before deposition of NiS nanoparticles, GO nanosheets were prepared by modified Hummers and Offeman method, and thus produced GO nanosheets that were modified to GR nanosheets through conjugation with ethylene diamine. The successful formation of GO-NiS and GR-NiS in the nano regime was characterized using UV-vis spectroscopy, ATR-FTIR spectroscopy, powder XRD, and thermogravimetric analysis (TGA). The response of GO-NiS and GR-NiS towards the absorption of NIR radiations was estimated by the illumination of aqueous dispersions of GO-NiS and GR-NiS to 980 nm laser. We investigated the biological effect of GO-Nis and GR-Nis nanoparticle breast cancer cells (MCF7) and ovarian cancer cells (UWB1.289) combined with 980 nm laser irradiation. Cell toxicity was determined using MTT assay and Trypan blue staining. Necrosis and apoptotic cells were detected by a combination of propidium iodide and Hoechst 333342 staining and analyzed using Flow Cytometry and confocal microscopy. DNA damage was detected by immunostaining gamma-H2AX and 53BP1 and DNA

damage foci were observed under confocal microscopy and quantified by Image J. Our results demonstrated that laser radiation induces cell death in both cancer cells and GO-Nis and GR-Nis in a dose- and concentration-dependent manner. In conclusion, the GO-NiS and GR-NiS have demonstrated a significant photothermal effect under irradiation to NIR laser. The use of nickel sulfide nanoparticles with graphene and graphene oxide sheets for treatment in killing cancer cells will allow for a more cost-efficient treatment with no harmful side effects.

Prostate Specific Membrane Antigen (PSMA) in Prostate Cancer CellsParticipates in Prostate Cancer Bone Metastasis

R. Sohan, L. Caromile; University of Connecticut Health Center, Farmington, CT

Metastasis to bone affects 80% of advanced prostate cancer (PCa) patients. Once bone metastasis forms, the 5-year survival rate drops to <60%. Prostate-specific membrane antigen (PSMA) is found on the surface of prostate epithelial cells and is a prognostic biomarker of PCa progression both in the primary and metastatic bone tumors. However, PSMA's interaction within the metastatic bone microenvironment via the "vicious cycle" of bone metastasis is not well understood. Therefore, this study aims to elucidate if PSMA's status within the immortalized human PC cells C42B can affect bone formation in the permissive human osteoblast cell line (hFOB 1.19) through the recreation of the bone microenvironment. To ensure that PCa cell lines can form bone-like mineral, we treated the C42B cell lines with osteogenic growth media containing 50 µg/mL L-ascorbic acid and 10 mM β-glycerophosphate for 0-10 days. Alizarin Red staining (ARS) verified that PSMA positive C42B could form calcium based mineral deposits and alter known bone biomarkers transcript levels (DKK1, RANKL, VIM, BMP2, ALPL). Additionally, the bone biomarker transcript BMP2 was upregulated in C42B$^{PSMA\ KO}$ but not in the PSMA positive C42B which is associated with increased PCa reoccurrence in this cell type. Overall, knocking out PSMA of our C42B PCa cell line resulted in a less aggressive phenotype as measured by decreased ability to mineralize and a change in the profile of known bone biomarkers. Future directions include trans-well experiments to mimic the PCa bone microenvironment's vicious cycle and exosome isolation.

A Copper Sulphate Nanoparticle Complex Sensitizes Radiation and PARP Inhibitors in Human Cancer Cells

G. C. Regisford[1], H. Wang[2], G. Neelgund[2], F. Guice[1], D. Ruiz[3], P. Saganti[2]; [1]Biology, Prairie View A&M University, Prairie View, TX, [2]Chemistry and Physics, Prairie View A&M University, Prairie View, TX, [3]Genetics and Genomics, Texas A&M University, Prairie View, TX.

To improve therapeutic efficacy and decreased toxicity in the nanosized mediated drug delivery model, we examined the effects of a copper sulfate nanoparticle coupled with heparin and folic acid (HP-CuS-FA), combined with radiation and a PARP inhibitor on the proliferation of Human cervical carcinoma (HeLa) cells and normal human skin fibroblast cells (AG1522). An MTT assay was used to assess the toxicity of the chemically synthesized and fully characterized HP-CuS-FA nanoparticles on HeLa and AG1522 cells. Clonogenic assays were used to determine the radio-sensitizing effects of HP-CuS-FA nanoparticles. Necrosis and apoptotic cells were detected by a combination of propidium iodide and Hoechst 333342 staining and were analyzed using Flow Cytometry and confocal microscopy. DNA damage was detected by immunostaining gamma-H2AX and 53BP1 and DNA damage foci were

observed under confocal microscopy and quantified by Image J. Our results indicated that HP-CUS-FA nanoparticles induced significantly more cell death in Hela cells than in AG1522 cells. Treatment of HeLa and AG1522 cells with HP-CuS-FA resulted in apoptosis, necrosis, and the generation of reactive oxygen species in mitochondria. Treatment of HeLa and AG1522 cells with HP-CUS-FA nanoparticles and a PARP inhibitor (ABT888) led to an increase in cytotoxicity, DNA damage, and apoptosis. While colony formation was reduced with increasing radiation dose, the pretreatment of cells with HP-CUS-FA NP and PARP inhibitor (ABT888) significantly reduced the colony formation following radiation exposure. Our data show that the combination treatment of CuS-FA nanoparticles and a PARP inhibitor enhances the efficacy of radiation therapy by increasing the reactive oxygen species, inducing apoptosis and DNA damage. This study suggests that HP-CuS-FA nanoparticles and a PARP inhibitor have a synergistic effect on cancer cell death and are potential nano radio-sensitizing agents for the treatment of cancer.

Immunomodulation and the Tumor Microenvironment

Anti-tumor macrophages increase intracellular iron in cancer cells and inhibit proliferation.

D. Greiner, S. Varady, M. Roh-Johnson; University of Utah, Salt Lake City, UT.

Different immune landscapes can promote or inhibit tumor progression. Interactions between tumors and immune cells alter how tumors maintain and use vital metabolites such as iron. In mammals, iron is a primary cofactor in many cellular activities, including proliferation. Tumors require sufficiently high levels of iron for sustained proliferation; however, too much iron can be toxic to cells, thus cells have developed mechanisms to tightly regulate their iron levels. Macrophages are a key immune cell type in solid tumors with differing cell fates that can either promote or inhibit tumor growth. Macrophages also regulate environmental iron: Anti-tumor macrophages are thought to act as an iron sink, sequestering iron from cancer cells and preventing cancer cell growth, while pro-tumor macrophages are thought to act as an iron source for cancer cells, promoting cancer cell growth. These hypotheses are primarily generated from measuring iron influx and efflux in macrophages, independently of how these processes affect cancer cell iron levels. Contrary to this model, our data suggest that anti-tumor macrophages cause elevated levels of available iron in cancer cells. Furthermore, we found that cancer cells exhibit increased levels of an iron import protein and reduced levels of an iron export protein in the presence of anti-tumor macrophages. These results suggest that anti-tumor macrophages cause cancer cells to have aberrantly high levels of iron, potentially due to dysregulation of iron homeostasis. Thus, we will test the hypothesis that anti-tumor macrophages inhibit cancer cell growth by increasing intracellular levels of available iron to drive ferroptosis, iron-mediated-cell death. This work may suggest the potential for the use of ferroptosis agonists in conjunction with potential anti-cancer treatments that aim to reprogram the molecular immune landscape.

Macrophages Promote Tumor Cell Extravasation across an Endothelial Barrier through Thin Membranous Connections

A. Genna, C. Duran, D. Entenberg, J. Condeelis, **D. Cox**; Albert Einstein College Med-Jack & Pearl Resnick Campus, New York, NY

Macrophages are important players involved in the progression of breast cancer, including in seeding the metastatic niche. However, the mechanism by which macrophages promote tumor cell extravasation at metastatic sites is not clear. Examining time-lapse intravital-imaging (IVI) data sets of breast cancer cell extravasation in the lung, we detected the presence of Thin Membranous Connections (TMCs) between macrophages in lung parenchyma and tumor cells in the vasculature. These TMCs resembled similar structures formed between macrophages and tumor cells called tunneling nanotubes that we previously demonstrated to be important in tumor cell invasion *in vitro* and *in vivo* (Hanna 2019). We used an *in vitro* assay to mimic macrophage-driven tumor cell extravasation, in which an endothelial monolayer and a matrigel-coated filter separated tumor cells and macrophages from each other. We observed TMCs formed between macrophages and tumor cells through the endothelial layer on top of the porous filter. Furthermore, tumor cells are more frequently found to associate with pores that contain macrophage protrusions. Macrophage conditioned media was insufficient to stimulate tumor cell extravasation *in vitro*, consistent with a requirement for contact between macrophages and tumor cells. To determine if TMCs were important for tumor cell extravasation we used macrophages with reduced levels of endogenous M-Sec (TNFAIP2), which causes a defect in tunneling nanotube formation. As predicted, these macrophages showed reduced macrophage-tumor cell TMCs. There was also a concomitant reduction in tumor cell extravasation *in vitro* with M-Sec deficient macrophages compared to control macrophages, using either a human or murine breast cancer cell line. To determine the role of macrophage-tumor cell TMCs *in vivo* we generated an M-Sec deficient mouse. In a small study using an *in vivo* model of experimental metastasis we detected a significant reduction in the number of metastatic lesions in M-Sec deficient mice compared to wild type mice. There was no difference in the size of the metastases, consistent with a defect specific to tumor cell extravasation and not metastatic outgrowth. Overall, our data indicate that macrophage TMCs play an important role in promoting the extravasation of circulating tumor cells in the lung.

CAR-Macrophages reprogram neighboring macrophages for efficient cancer cell phagocytosis

T. Waddell, Q. Xue, M. Roh-Johnson; University of Utah, Salt Lake City, UT.

Macrophages in the tumor microenvironment are influenced to function as pro-tumor immune cells, facilitating blood vessel growth, cancer cell proliferation, immune inhibition, and cancer cell migration. The interactions between these tumor-promoting macrophages and cancer cells lead to the recruitment and differentiation of other tissue-resident macrophages to also function as tumor-promoting macrophages. To disrupt the pro-tumor environment, we are testing whether chimeric antigen receptor-expressing macrophages (CAR-Macrophages) can convert tumor-promoting macrophages into an anti-tumor fate and facilitate cancer cell killing. We developed synthetic and inducible CAR-Macrophages using the FRB/FKBP/rapamycin system. Macrophages expressing FRB as an antigen receptor were cultured with melanoma cells expressing FKBP. Upon adding rapamycin, we visualized a significant increase in CAR-Macrophage-mediated phagocytosis compared to non-rapamycin treated

control. We then added naïve macrophages to these cultures and found that the naïve macrophages were induced to become anti-tumor-like and efficiently phagocytosed cancer cells. Bolstered by our findings using a synthetic CAR-Macrophage system, we then sought to develop a CAR-Macrophage that targets an endogenous tumor antigen. We designed CAR-Macrophages targeting chondroitin sulfate proteoglycan 4 (CSPG4), a large glycoprotein expressed on the plasma membrane and specific to and enriched in cancer cells. We cultured anti-CSPG4-CAR-Macrophages with melanoma cells and observed a significant increase in phagocytosis mediated by anti-CSPG4-CAR-Macrophages compared to non-specific control CAR-Macrophages. Current work focuses on using primary human cells and in vivo mouse models to further test whether tissue resident-macrophages are converted to anti-tumor-like macrophages and whether efficient melanoma cell phagocytosis is sustained. These results point to a powerful mechanism where CAR-Macrophages not only participate in tumor cell killing but facilitate a general anti-tumor state in endogenous macrophages.

B257/P1250

Intravital imaging of the myeloid immune cell landscape during tumor initiation and progression

T. D. Madsen, W. Wang, R. Weigert; NCI, CCR, LCMB, National Institutes of Health, Bethesda, MD.

How the immune cells transition from tumor-fighters to tumor-facilitators is still poorly understood. Early responders such as neutrophils, macrophages and other myeloid cells have been shown to undergo changes in gene expression and behavior, arguably being transformed in new cell types such as the poorly defined tumor-associated neutrophils (TANs) and macrophages (TAMs). Little is known about the sequence of events leading to this switch in the immune system, at what stage of cancer development it occurs, and what components in the tumor cells and surrounding microenvironment trigger these transitions. This knowledge would be highly valuable to design successful immunotherapies for cancer.To this end, we developed a mouse model in which we followed myeloid cell populations during the development of oral squamous cell carcinoma using state-of-the-art intravital multiphoton microscopy. Tumorigenesis was triggered by treatment with a carcinogen (4-Nitroquinoline 1-oxide) in the drinking water. The entire dorsal tongue epithelium was imaged at cellular resolution followed by focused imaging of developing tumors at sub-cellular resolution bi-weekly over a period of 24 weeks. By using transgenic mice that express fluorescent proteins specifically in myeloid cells, we recorded the history of their recruitment and infiltration before and during the development of the cancerous lesions from hyperplastic and dysplastic stages to invasive carcinoma. Moreover, the behavior and dynamics of the myeloid cells was correlated with the metabolic state of the tumor cells and the structure of the extracellular matrix.Preliminary results from multiple mice and tumors showed that myeloid infiltrations arose around week 3 from the administration of the carcinogen, epithelial hyperplasia around week 8, dysplasia at week 16 and carcinoma *in situ* around week 20-24. Interestingly, early lesions were often accompanied by peripheral recruitment of myeloid cells but not by their infiltration into the tumors. At more advanced stages, myeloid cells infiltrated inside the tumor, concomitantly with a reduction of both glycolytic and oxidative phosphorylation.
In conclusion, we have recorded the history of multiple tumors and their interactions with myeloid cells using our intravital imaging system on 4NQO-treated transgenic mice. This has shown a correlation between lesion size, metabolic state and myeloid cell infiltration and laid the groundwork for future in-depth characterization of the myeloid subtypes associated with each type of lesion.

Analysis of early cellular and sub-cellular changes during tumor initiation and progression in live animals.

W. Wang[1], K. Lee[1], R. Coffey[2], A. Sorkin[3], R. Weigert[1]; [1]National Institutes of Health, Bethesda, MD, [2]Department of cell and developmental biology, Venderbilt University Medical Center, Nashville, TN, [3]Department of Cell Biology, University of Pittsburgh, Pittsburgh, PA.

Head and neck squamous cell carcinoma (HNSCC) is one of the most common cancers with a 65 % 5-year survival rate. It accounts for more than 650,000 cases and 330,000 deaths worldwide annually and it is projected to increase by 30% in the next 10 years. Understanding the mechanisms that control initiation, progression, and spreading of the tumor to distal sites is of paramount importance to develop effective therapies. To this end, we have used a well-established carcinogen model in live mice that mimics the progression, histopathology, and molecular characteristic of the HNSCC observed in patients. Here, we show, for the first time, the visualization of the onset and progression of cancerous and pre-cancerous lesions through the various stages the same animal. We discovered that only 15% of the lesions fully develop into persistent in situ or invasive carcinomas, whereas the remaining lesions reach different stages (e.g. severe dysplasia and carcinoma) and then heal spontaneously. Using intravital subcellular microscopy (ISMic), we acquired information on the cellular and subcellular changes in the tumor cells and associated microenvironment (e.g., blood vessels, extracellular matrix, and immune cells). Specifically, we correlated the lesion progression with changes in the cell morphology, mitochondrial metabolism, immune cell response, autophagy, and EGFR signaling, thus providing a working hypothesis on the mechanism controlling tumor progression in vivo which can serve as a springboard to develop novel therapies.

The Chemokine Receptor CCR1 is Essential for Microglia Stimulated Glioma Invasion

S. J. Coniglio, N. Zeren, S. Morgan, M. Uppiliappan; SIST, Kean University, Union, NJ.

Glioblastoma Multiforme (GBM) is the most aggressive form of adult brain tumor with a median survival time of twelve months. GBM is highly resistant to conventional therapy which includes surgical resection of the tumor, radiation treatment and chemotherapy. GBM cells are highly motile and invasive resulting in infiltrative tumors with poorly defined borders. GBM tumors are heavily infiltrated with microglia cells which are known to stimulate GBM cell invasion. Our laboratory has previously demonstrated that microglia strongly stimulates GBM invasion both in-vitro and in orthotopic animal models. This interaction was found to be dependent on CSF-1R which is expressed on all tumor infiltrating macrophages/microglia. Blockade of the CSF-1R using compounds such as pexidartinib (PLX3397) can inhibit microglia/macrophage-stimulated GBM invasion *in-vitro* and *in vivo*. A variety of chemokines are upregulated in the GBM tumor microenvironment and facilitate “cross-talk” between microglia and GBM cells eliciting a chemotactic response. We postulated that inhibition of CCL3 associated receptors such as C-C receptor 1 (CCR1) might also inhibit GBM invasion, thus, a CCR1 antagonist could prove efficacious for blockade of microglia-induced glioblastoma invasion in vitro. Many potent CCR1 antagonists have been described in the literature. We chose four of these compounds with two distinct structural cores, all with reported IC50’s of less than 200 nM for inhibition of CCR1 binding versus CCL3. We examined the ability of these antagonists to block microglia-stimulated glioblastoma invasion using an in-vitro coculture invasion assay. Using quantitative PCR arrays, we also show that expression of

chemokines and chemokine receptor genes is greatly altered in GBM conditioned media-treated microglia. Understanding the pattern of tumor-associated macrophage/microglia chemokine secretion in GBM may present additional targets for chemotherapeutic intervention and enhance immunotherapy.

Optimizing a T cell suppression assay to test for the presence of myeloid derived suppressor cells (MDSC) in mouse models with soft tissue sarcomas

Z. Jamil[1,2]; [1]CUNY Brooklyn College, Brooklyn, NY, [2]John Hopkins University, Baltimore, MD

Optimizing a T cell suppression assay to test for the presence of myeloid derived suppressorcells (MDSC) in mouse models with soft tissue sarcomas

ABSTRACT

INTRODUCTION: In recent years, immunotherapy has emerged as a cancer treatment due toits potential to reinvigorate the immune system of patients for fighting cancer cells. However, insoft tissue sarcomas (STS), theTumor Immune Microenvironment largely consists ofimmunosuppressive cell types known as Myeloid Derived Suppressor Cells (MDSC). MDSCinhibits T cell activation and proliferation. Here, we optimize T cell proliferation conditions bystimulation beads via staining of T cells with a fluorescent tracking dye at differentconcentrations. Ultimately, utilizing this assay, we will assess the immunosuppressive function ofMDSC isolated from a STS mouse model by co-culturing them with spleen T cells.

METHODS: Wild-type mice had their spleens excised and processed to obtain splenocytes. Thenumber of live and dead cells present in the spleen were counted using a hemocytometer toestablish the stimulation beads to cell ratios of 0:1, 1:1, 1:2, and 2:1. The cells were observedunder the microscope to ensure bead to cell conjugation, cell viability, and media contamination.This was closely followed by the removal of beads and running the cells through flow cytometryto determine the optimal staining conditions and timeframes needed for T cell proliferation.

RESULTS: We revealed the 72 hour-mark to be the ideal timeframe for assessing T cellproliferation at the 0:1, 1:1, 1:2, and 2:1 beads to cells ratio. The staining conditions showcasedgood resolutions and peaks in flow cytometry for 1uL of dye in 10M cells and 5M cells and0.1uL of dye in 1M cells. Despite the resolution for 0.5 uL of dye in 5M cells and 0.5uL of dyein 1M cells being good, their peaks did not exhibit good distinction. For 0.1uL of dye in 5Mcells, the cells did not display a good resolution even though they seemed to be proliferating.

CONCLUSION: We determined that the 72 to 120 hours is the ideal condition for T cellactivation and proliferation in our system. In addition, our data suggests 1uL of dye for 10Mcells and 5M cells along with 0.1uL of dye for 1M cells to be the optimal staining conditions forflow cytometry studies. These parameters establish the ideal conditions for T cell activation andproliferation in our mouse model STS which will help us evaluate the immunosuppressivecapacity of MDSC in our in vitro assay and strengthen our understanding of immunotherapytreatment.

B261/P1254

Mre11 antagonizes nucleosome sequestration of cGAS to suppress tumorigenesis

M. Jo; University of North Carolina At Chapel Hill, Chapel Hill, NC

Oncogene-induced replication stress generates cytoplasmic chromatin fragments (CCF) that activate cGAS/STING-mediated innate immune signaling to inhibit tumor development. However, the mechanism of cGAS activation by CCF remains enigmatic, particularly given the constitutive inhibition of cGAS by high-affinity histone acidic patch (AP) binding. Here we show that the Mre11-Rad50-Nbn (MRN) complex is required for cGAS activation and p53-independent tumor suppression during Myc-induced mammary neoplasia. MRN binding to nucleosomes releases cGAS from sequestration, thereby enabling cGAS activation by cytosolic DNA. Mre11-dependent cGAS activation antagonizes mammary epithelial neoplasia by stimulating ZBP1/RIPK3/MLKL-mediated necroptosis. In human triple-negative breast cancer, ZBP1 downregulation correlates with increased genome instability, decreased immune infiltration, and poor patient prognosis. These findings establish Mre11 as essential for cGAS-dependent innate immune activation and necroptosis engagement during tumorigenesis.

High Mobility Group Box 1 Protein Localization and its Effect on the Immune Response in the Lung Tumor Microenvironment

K. Jafri[1], N. Andre[2], **G. E. Simmons, Jr**[2]; [1]Cornell University, Ithaca, NY, [2]Cornell University College of Veterinary Medicine, Ithaca, NY

High mobility group box protein 1 (HMGB1), a pro-inflammatory damage-associated molecular pattern protein, drives inflammation in the lung tumor microenvironment. Furthermore, HMGB1 has been previously demonstrated to suppress functional anti-tumor immune responses in this context. Recently, we have identified HMGB1 as a protein that is functionally dependent on monounsaturated fatty acid (MUFA) availability. Utilizing a combination of molecular assays and 3-dimensional cultures, we now show that HMGB1 is sequestered intracellularly, rather than being secreted extracellularly in a MUFA-dependent fashion. We hypothesized that MUFAs promote an anti-tumor immune response via modulating HMGB1 release from cancer cells. Thus, by restricting extracellular HMGB1 levels, HMGB1-responsive proinflammatory/tumor signaling pathways (e.g., NF-κB) will be suppressed. Taken together, these observations suggest an approach to decrease maladaptive immune and inflammatory responses mediated via innate immune cells. Exploiting the MUFA/HMGB1 signaling axis may increase the efficacy of cancer therapies targeting lung malignancies.

Cancer Stem Cells

Differential metabolic adaptations define responses of winner and loser oncogenic mutant cells in skin epidermis *in vivo*

A. Hemalatha[1], R. Perry[2], V. Greco[1]; [1]Genetics, Yale University - New Haven, CT, New Haven, CT, [2]Endocrinology, Yale University - New Haven, CT, New Haven, CT.

Skin epidermal stem cells detect, and correct aberrancies induced by oncogenic mutations. Different oncogenes invoke different mechanisms of epithelial tolerance: while wild-type cells outcompete β-

catenin-Gain-of-Function (βcatGOF) mutant cells, $Hras^{G12V}$ mutant cells outcompete wild-type cells. We asked how metabolic states change as wild-type stem cells interface with mutant cells, and how this ultimately drives different cell competition outcomes *in vivo*. Combining two powerful experimental modalities -1. optical redox imaging to visualize endogenous levels of the co-enzymes NAD(P)H/ FAD, adapted and evolved within our *in vivo* imaging platform to enable long term tracking and visualization of metabolic states of cells within the live animal, and 2.$^{13}C_6$- glucose tracer-assisted mass spectrometry to measure metabolic fluxes directly - we provide unprecedented resolution of the metabolic state at the interface of Mutant and Wild-type stem cells within the epidermis *in vivo*. By tracking endogenous redox ratio (NAD(P)H/FAD) with single cell resolution in the same mice over time, we show that wild-type epidermal stem cells maintain robust redox ratio despite their heterogeneous cell cycle states. We discover that both βcatGOF and $Hras^{G12V}$ models lead to a rapid drop in redox ratios. However, the "winner" cells in each model (wild-type cells in βcatGOF and mutant cells in $Hras^{G12V}$ model), rapidly recover their redox ratios, irrespective of the mutation induced. Glucose catabolic flux studies reveal that both βcatGOF and $Hras^{G12V}$ mutant epidermis upregulate flux through TCA cycle. Contrastingly, the "winner" mutation $Hras^{G12V}$ specifically upregulates pyruvate to lactate flux (glycolysis readout) while the "loser" βcatGOF mutation downregulates this step. Hence, we reveal the metabolic adaptations that define the hallmarks of winners and losers during cell competition *in vivo* and uncover the nodes of regulation unique to each cell fate. These novel findings are in contrast to the expectations of Warburg effect, a fundamental concept in cancer metabolism, wherein proliferative cells expressing oncogenic mutations are expected to upregulate glycolysis at the expense of downstream TCA cycle and mitochondrial oxidation. Instead, our study suggests that decoupling lactate levels (glycolysis) and mitochondrial oxidation could be a strategy used by "winners" in cell competition. This study also reveals a metabolic plasticity inherent to epidermal stem cells that affect cell competition outcome with profound implications for therapeutically eliminating oncogenic mutations from the skin epidermis.

Role of HOX gene expression in differentiation of colon cancer stem cells

B. Osmond[1,2], C. O. B. Facey[2], L. M. Opdenaker[2], C. Zhang[1,2], B. M. Boman[1,2,3]; [1]Biological Sciences, University of Delaware, Newark, DE, [2]Cawley Center for Translational Cancer Research, Helen F Graham Cancer Center & Research Institute, Newark, DE, [3]Thomas Jefferson University, Philadelphia, PA.

HOX genes are a highly conserved subset of genes that encode transcription factors critical for stem cell (SC) function and embryonic development. Several HOX genes have also been implicated in a myriad of cancers, including colorectal cancer (CRC). However, how HOX genes play a role in SC regulation and how dysregulation of HOX genes contributes to cancer development is still not fully understood. Current research indicates that HOX expression is regulated by the WNT and retinoic acid (RA) signaling, which are signaling pathways that become dysregulated in cancer. *Goal*: To determine how regulation of HOX genes specifies differentiation of colonic SCs into specialized cell lineages in the colon and how dysregulation of HOX genes contributes to CRC development. *Hypotheses*: *i*) Each of the different cell types within the human colonic epithelium has a distinct HOX gene expression signature; *ii*) All-trans retinoic acid (ATRA) induced differentiation of CRC cells leads to changes in HOX gene expression that correlate with specific HOX expression signatures. *Results*: Immunostaining shows that specific HOX proteins (e.g., HOXA9 & HOXC9) are selectively expressed in ALDH-positive SCs and expression of these HOX genes is increased in CRC tissues compared to normal epithelium. Bioinformatics analysis predicts that these HOX genes, along with HOXA4, HOXA10, and HOXC8, are regulated by the RA signaling

pathway. To investigate the effect of RA signaling on HOX gene expression, we studied how ATRA influences CRC cells (HT29 & SW480). We found that ATRA treatment of CRC cells: 1) Decreased proliferation and increased cellular differentiation, particularly along the neuroendocrine cell (NEC) lineage; 2). Significantly changed HOX gene expression. For example, western blot and qPCR analyses showed that treatment of CRC cells with ATRA decreases expression of HOXA4, HOXA9 & HOXD10 and increases expression of HOXC8 & HOXC9. Nanostring mRNA profiling also shows that ATRA treatment of CRC cells increases HOXA3 & HOXA5 and decreases HOXA10, HOXB6 & HOXB9. By defining how these HOX gene expression changes in response to ATRA treatment in comparison to the HOX gene signatures of different colonic cell lineages will help us understand the role HOX genes play in SC differentiation along specific cellular lineages and how to target HOX gene in cancer treatment.

B265/P1258

p27 Increases Breast Cancer Stem Cell (CSC) Expansion by Recruiting STAT3 and CBP on Chromatin to Induce Angptl4 and Jag1 Expression

S. Razavipour[1], K. Jang[2], H. Yoon[2], M. Kim[2], M. Shin[2], D. Zhao[2], D. Van Booven[2], A. Bagheri[1], J. Slingerland[1]; [1]Georgetown University, Washington, DC, [2]University of Miami, Miami, FL.

p27 is a key regulator of the cell cycle. It plays a dual role during tumorigenesis. p27 acts as a tumor suppressor through its cell cycle inhibitory role, and as an oncogene to promote cancer invasion and metastasis when phosphorylated at T157 and T198 by PI3K activated kinases. Our lab demonstrated that p27 activates STAT3, a driver of Embryonic Stem Cell (ES) and Cancer Stem Cell (CSC) self-renewal, to induce Epithelial-Mesenchymal Transition (EMT). In mice, knock-in of the cell cycle defective p27 mutant (p27CK-) was previously shown to promote stem cell expansion in multiple tissues, suggesting p27 may regulate stem cells. Here, we showed that C-terminally phosphorylated p27 increases CSC properties, including tumor sphere formation and CSC markers by recruiting STAT3 and a histone acetyltransferase, CBP, on the promoter of the stem cell-driver genes to induce their expression. Our RNA-seq data in breast cancer cell lines with overexpression and knockdown of phosphomimetic p27CK-T157D/T198D (p27CK-DD) showed that p27-activated genes are associated with stem cell pathways. We have confirmed that overexpression of p27CK-DD increases tumor spheres, ALDH1 activity and expression of embryonic stem cell transcription factors (ES-TFs) to increase tumor initiating stem cells in vivo in limiting dilution assays. ChIP-seq of p27 and STAT3, analyzed together with RNA seq has identified that p27 cooperates with STAT3 to induce expression of genes governing CSC self-renewal. Our Chip-seq data revealed that 65% of STAT3 target genes are co-bound with p27 and p27 knockdown decreases STAT3 binding enrichment on p27/STAT3 co-target gene promoters. Combined p27/STAT3 ChIP-seq/ RNA-seq analysis in our cell lines revealed that p27 modulates STAT3 recruitment on several stem cell-driven genes including *MYC*, *SOX2*, *JAG1,* and *ANGPTL4* promoters to regulate their expression. These targets were validated by qPCR and ChIP-qPCR experiments. We also showed that p27 recruits CBP to p27/STAT3 co-target gene promoters and increases chromatin accessibility by increasing H3K27acetylation. Knocking down of *ANGPTL4,* a known regulator of stem cell properties and anoikis resistance, in p27CK-DD overexpressed cell lines further indicate that p27CK-DD-driven upregulation of sphere formation and ES-TF expression is mediated through Angptl4.Taken together, these data reveal a novel function for p27 as a transcriptional regulator of CSC-promoting genes. In breast cancer cell lines, p27 recruits STAT3/CBP to several stem cell-driver gene promoters to induce their expression and promote CSC expansion.

Intestinal epithelial cell proliferation and gut growth regulated by steroid sex hormones

T. Kandelouei, M. R. Lewis, B. Edgar; Oncological Sciences, Huntsman Cancer Institute, Salt Lake City, UT.

Intestinal epithelial cell proliferation & gut growth regulated by steroid sex hormones Study objective: To establish a mechanistically detailed paradigm of how a sex-specific steroid regulates progenitor cells function in the intestinal tissue as a non-sex organ. **Methods:** We use Drosophila and mice as model systems. Drosophila mid-gut is similar to the mammalian intestine, has a simple structure, and powerful genetic tools exist for probing the molecular genetic mechanisms. The major steroid hormone in *Drosophila* is 20- hydroxyecdysone (20HE). We perform genetics tests, including RNA-Seq of whole mid-gut and FACS-sorted progenitor cells, metabolomics and lipidomics analysis, and Cut&Tag. These experiments help us identify the genes that are transcriptionally regulated by 20HE and how 20HE signaling affects other signaling pathways and physiological processes such as ISC metabolism, proliferation, lineage symmetry/asymmetry, and gut growth. We will also explore whether sex steroids regulate proliferation and gut epithelial homeostasis in mice to test if a *Drosophila* like system operates in mammals. We investigate the effects of sex steroid hormones, assaying effects on GI tract size, morphology, cell proliferation, and gene expression. **Results:** A recent discovery in *Drosophila* has shown that 20HE, produced by ovaries after mating, stimulates intestinal stem cell (ISC) proliferation and gut growth. We look through the detailed mechanisms underlying the 20HE contribution to ISC proliferation and gut growth. Our RNA-Seq data has shown the upregulation of genes involved in peptide and glutathione metabolic processes and proliferation in 20HE-Fed compared to control flies; we followed this with metabolomics and lipidomics analysis that we currently working on data sets. Our preliminary results in mice showed higher crypts and tissue thickness/ growth effect in E2 (estrogen) and E2/P4 (E2/progesterone) treated mice compared to the control group. We will look further into the detailed mechanisms that might be induced by steroids to regulate ISC division in mice. **Conclusion:** This work will provide lead data for a better understanding of how sex steroids regulate intestinal physiology & pathology. This work will advance our knowledge of how steroid signaling affects the sex-biased incidence of many human diseases, notably those involving altered stem cell behavior, such as cancer.

B267/P1260

Uncovering the role of microRNAs that target stem cell genes in the emergence of cancer stem cell heterogeneity during colorectal cancer development

M. Lausten[1,2], V. A. Stark[1,2], C. O. B. Facey[2], L. M. Opdenaker[2], B. M. Boman[1,2,3]; [1]Biological Sciences, University of Delaware, Newark, DE, [2]Cawley Center for Translational Cancer Research, Newark, DE, [3]Thomas Jefferson University, Philadelphia, PA.

Our goal is to identify microRNAs (miRNAs) that target genes that encode different proteins involved in stem cell (SC) signaling pathways involved in tumorigenesis of colorectal cancer (CRC). One reason behind the lack of efficacy in cancer treatment is due to the development of SC overpopulation. *Hypothesis*: specific miRNAs target different SC genes, which leads to the emergence of multiple cancer SC (CSC) sub-populations and tumor heterogeneity. Accordingly, we used flow cytometry to identify CSC sub-populations based on expression of SC markers including ALDH1, CD166, LGR5, and LRIG1 in the HT-29 CRC cell line. We quantified and isolated CSC sub-populations using FACS and measured the expression of miRNAs in each CSC sub-population using NanoString profiling. The level of miRNA upregulation in each CSC sub-population was then ranked based on differential expression of the

miRNAs between different CSC sub-populations. We further analyzed the LGR5 and ALDH SC sub-populations because they showed the largest difference between CSC sub-population sizes with the lowest size (<1%) of the co-positive (LGR5+/ALDH+) cell sub-population. LGR5+ and ALDH+ CSC subpopulations had the highest numbers of differentially expressed miRNAs. This is relevant because WNT signaling mainly occurs via LGR5+ CSC and retinoic acid (RA) signaling mainly occurs via ALDH+ CSCs. We report herein miRNAs that are differentially expressed between ALDH+/LGR5- compared to ALDH-/LGR5- subpopulation and LGR5+/ALDH- versus ALDH-/LGR5-. The mRNAs expressed in CSC subpopulations from Nanostring profiling were analyzed using bioinformatics for their predicted target mRNA binding by upregulated miRNAs. Our results show that: *1*) multiple CSC subpopulations exist in the HT-29 cell population; *2*) each CSC subpopulation has a unique miRNA signature. Notably, we identified miR-660-3p to be specifically upregulated in the LGR5+/ALDH- CSC subpopulation. Moreover, we found, using target prediction tools, that miR-660-3p is predicted to bind to the 3'UTR of *RXRA* mRNA. The binding of miR-660-3p to *RXRA* mRNA was validated utilizing luciferase assay in HT-29 cells. *RXRA* mRNA is significantly upregulated in the ALDH+/LGR5- CSC sub-population but not in the LGR5+/ALDH- CSC subpopulation. We previously reported that RXRA is selectively expressed in ALDH + CSC sub-populations. Taken together, these results indicate that expression of miR-660-3p, by inhibiting *RXRA* expression, decreases RA signaling in LGR5+ CSCs. It is also known RXRA binds with β-catenin suppressing protein expression and transcriptional activity. Thus, upregulated miR-660-3p targets a key gene in the RA signaling pathway (*RXRA*) which could contribute to the emergence of SC sub-populations during CRC development.

B268/P1261

Altered Keratinocyte Stem cell conditioning through Polycomb group proteins leads to accelerated skin tumorigenesis in animals prenatally exposed to arsenic

A. Chauhan[1,2], S. Gangopadhyay[1,2], V. Sharma[3], S. Singh[1,2], K. Koshta[1,2], V. Srivastava[1,2]; [1]Developmental Toxicological Division, CSIR Indian Institute of Toxicological Research, Lucknow, INDIA, [2]Academy of Scientific and Innovative Research(AcSIR), Ghaziabad, INDIA, [3]Department of Biotechnology, Faculty of Engineering and Technology, Manav Rachna International Institute of Research and Studies, Haryana, INDIA.

Exposure to arsenic has been linked with several chronic conditions, including lung, bladder, and skin malignancies. In endemic regions, prenatal exposure to arsenic is linked with worse health outcomes in children. In our animal experiments, we observed that gestational exposure to arsenic(0.04mg/kg) accelerated skin tumorigenesis, accompanied with amplified and activated keratinocyte stem cell (KSCs) pool in the skin of offspring. The function of these KSCs is unknown. In present study, female BALB/c mice were exposed to sodium arsenite (0.04mg/kg) in drinking water during gestation, with no further dose administration to the offspring. Primary arsenic conditioned KSCs isolated from2-day pups were evaluated for their differentiation, proliferation, and invasive potential and underlying mechanisms involved. Our study shows that only prenatal exposure to arsenic is enough to increase proliferative and differentiative capacity in KSCs as measured by increased PCNA, Involucrin, Krt1,Krt5 & CD34 expression in both *in vivo* and *in vitro* systems. Pulse chasing stem cells by BrdU incorporation in 2 day pups revealed increased stem cell pool in maternally exposed animals. *In vitro* BrdU uptake and scratch assay verified high division & migratory potential with high survival rate as observed by decreased bax/bcl-xL ratio and low TUNEL positive cells. Early life exposure to As contributed to the activation of MAPK proteins via IGF2R in KSCs as revealed by high phosphorylated levels of b-raf, MEK1, ERK1/2 & IGF2Rin

immunoblot assay. The results were further validated by inhibiting pERK1/2 by U0126. An increased ratio of activating H3K4me1 to deactivating H3K27me3 methyl marks on IGF2R promoter was confirmed by ChIP assay in As conditioned cells with reduced binding of PRC2 group silencer, EZH2 in the same region. The data suggested disrupted imprinting of IGF2R gene responsible for hyper-activating MAPK cascade in KSCs that further contributed to enhanced epidermal proliferation and tumorigenesis. Overall our study shows a positive association between maternal arsenic exposure at environment relevant doses and accelerated skin tumorigenesis. The arsenic conditioned KSCs possessed high differentiation and proliferative potential which was modulated by epigenetic memory modules of the PRC2 group. This contributed to a reduced tumor latency period and enhanced tumor invasiveness in exposed progeny.

Anti-tumor response of retinoic acid agents based on the retinoid signaling pathway genotype of colorectal cancer cells

V. O. Hunsu, C. O. B. Facey, L. Opdenaker, B. M. Boman; Helen F Graham Cancer Center, Newark, DE.

There are no curative treatments for advanced colorectal (CRC) due to stem cell (SC) overpopulation that drives tumor growth and from resistance of cancer SCs (CSCs) to conventional treatments. An alternative strategy is to discover ways to therapeutically sensitize human CRC stem cells to differentiation-inducing effects of retinoic acid (RA) agents. Indeed, all-*trans*-retinoic acid (ATRA) is known to be a highly effective treatment for acute promyelocytic leukemia (APL) which is caused by translocation in the RA receptor alpha (*RARA*) gene. Results from our bioinformatics analysis on mutations and overexpression of RA signaling component genes in CRC showed that RA pathway genes are often altered in CRCs. Thus, we surmised that the response of retinoic acid (RA) agents may have effects on CRC cells depending on their pathway genotype. Our ***hypothesis*** is that the ability of RA agents to induce differentiation of CSCs depends on the RA pathway genotype expressed in CRC cells. Our ***approach*** was to test the ability of RA agents (ATRA, 13-*cis* retinoic acid, 9-*cis* retinoic acid) and RA metabolism blocking agents (Liarozole, Talarozole) to inhibit proliferation and induce differentiation of CRC cell lines that have different mutations in RA signaling components. Nanostring Profiling was also used to measure the effects of the agents on mRNA expression of CSC markers, indicators of cell differentiation, and RA receptors. Our ***results*** show that the RA pathway genotype affects the anti-response of RA agents on CRC cell lines. Indeed, both HCT116 and SW480 CRC cell lines, which have mutants in *RARA* and/or *RXRG* displayed resistance to ATRA. In contrast, HT29 CRC cells, which have wild- type RA receptors, are sensitive to ATRA. All three of these CRC cell lines showed similar dose responses to the CYP26A1 inhibitor Liarozole. This latter finding indicates that regardless of RA receptor mutations, inhibition of ATRA metabolism increases intracellular RA levels in a similar manner on all 3 cell lines. Nanostring mRNA profiling showed that ATRA-treated HT29 cells have increased expression of RARA, CYP26A1 (ATRA metabolizing enzyme) and KRT20 (differentiation marker); and a decreased expression of CSC markers LGR5 and ALDH1A1. This indicates that CRC cells with a normally-functioning RA signaling pathway can be induced to increase differentiation and to decrease CSC numbers. In ***summary***, we show that colonic SC differentiation can be induced by RA signaling but anti-tumor responses are attenuated by RA pathway mutations. These findings have vast clinical importance for designing differentiation-type therapies.

Cancer stem cells as the novel origin of myeloid-derived suppressor cells

S. Afify, M. Seno; Department of Cancer Stem Cell Engineering, Faculty of Interdisciplinary Science and Engineering in Health Systems, Institute of Academic and Research, Okayama, Japan

BACKGROUND:Tumor microenvironment contains a variety of stromal cells, including myeloid-derivedsuppressor cells (MDSCs). MDSCs have been described as a non-lymphoid populationof immune suppressor cells enriched in cancer patients.AIM: In the current study we are aiming at uncovering the relationship between cancerstem cells and the generation of MDSCs.METHODS:Monocytes in peripheral blood collected from healthy donors were first reprogrammedinto pluripotent stem cells (PSCs). Then the human PSCs were converted into CSCs inthe presence of the conditioned medium derived from human liver cancer cell line. Thecharacteristics of CSCs were assessed for the potential of self-renewal, differentiation,and tumorigenicity together with the expression of genetic markers.RESULTS:The resultant cells are confirmed as CSC exhibiting sphere-forming potential, anddifferentiation potential in vitro and developing malignant tumors with micrometastasesin the liver of nod-scid mice. The primary cells derived from the malignant tumor,exhibited strong immunoreactivity to anti-human CD34 and anti-c-KIT antibodiessuggesting that they were enriched with hematopoietic progenitor cells. Markersassociated with MDSCs were found expressed in both of the converted cells and theprimary cells. According to these results, CSCs are implied to be capable ofdifferentiation into MDSCs that support the growth and survival of tumor cells. CONCLUSIONS: The results of this study will provide new insights into CSCs andtheir relationships with tumor microenvironments supporting chronic inflammationenriched with cytokines and growth factors, inducing regulatory T cells suppressingimmune responses, and maintaining CSCs themselves as the result.

B271/P1264

Restoring the balance between WNT and retinoic acid signaling to promote differentiation of cancer stem cells in treatment of colorectal cancer

C. O. B. Facey[1], V. O. Hunsu[1,2], B. T. Osmond[1,2], C. Zhang[1,2], L. M. Opdenaker[1], B. M. Boman[1,2,3]; [1]Helen F. Graham Cancer Center and Research Institute, Newark, DE, [2]University of Delaware, Newark, DE, [3]Thomas Jefferson University, Philadelphia, PA

Mutation in the *APC* gene causes dysregulated WNT signaling in 80-90% of CRC cases. Overpopulation of ALDH+ stem cells occur in a progressive manner in the development of CRC in patients with familial adenomatous polyposis (FAP). Given that ALDH is a key member of the retinoic acid signaling (RA) pathway, we hypothesize that human CRC develops due to an imbalance between dysregulated WNT and RA signaling. Herein, we aim to restore proper WNT and RA signaling and identify a common link or target that could promote differentiation of CSCs along the neuroendocrine cell (NEC) lineage. Accordingly, to determine the effects of restoring wt-*APC* in *APC*-mutant HT29 CRC cells, we conducted *in vitro* experiments to examine Wnt/β-catenin signaling, sensitivity to retinoids, cell proliferation, expression of stem cell markers, quantification of ALDH+ stem cells, and NEC maturation. We utilized Nanostring profiling, TCF reporter assay, western blot, and fluorescence activated cell sorting analyses to ascertain these effects. We found that induction of *wt-APC* expression decreased WNT/β-catenin signaling and reduced protein expression of WNT-target genes. Notably, inducing *wt-APC* decreased ATRA-induced expression of the WNT target gene *CYP26A1* (by 50%), which is predicted to, in turn,

increase RA signaling by lowering degradation of RA. Indeed, inducing w*t-APC* increased sensitivity of CRC cells to ATRA-induced apoptosis and inhibition of cell proliferation in a dose-dependent manner. Expression of ALDH1A1 decreased (3-fold) with ATRA treatment and inducing *wt-APC* extended the decrease by an additional 2-fold. Furthermore, upon inducing *wt-APC,* we found an increase in the protein expression of several NEC markers including CHGA, GLP2R, NSE (ENO2), and SSTR1, and an increased number of GLP2R+ NECs. Based on Nanostring profiling and bioinformatic analysis, we discovered a protein network and cell signaling mechanism that links the WNT and retinoic acid pathways via CYP26A1. Thus, by inducing *wt-APC* expression and exogenously activating RA signaling, we found a way to increase differentiation of SCs along the NEC (and other) lineage(s). Translating this strategy *in vivo* might lead to new, more effective treatments involving retinoids for CRC patients.

B272/P1265

Modulation of AXIN2 expression leads to changes in cell cycle, apoptosis, & the colon cancer stem cell population.

C. Zhang[1,2], C. O. B. Facey[1], L. M. Opdenaker[1], B. M. Boman[1,2]; [1]Cawley Center for Translational Cancer Research, Helen F. Graham Cancer Center & Research Institute, NEWARK, DE, [2]Department of Biological Sciences, University of Delaware, Newark, DE.

Colorectal cancer (CRC) is driven by stem cell (SC) overpopulation yet diagnosed via tissue disorganization. Etiology of CRC is complex and much effort has focused on studying SC overpopulation in tumor biology and tissue disorganization in cancer pathology, but regulatory mechanisms linking these neoplastic processes which occur in CRC need clarification. The initiating event in development of most CRCs is increased WNT-signaling caused by APC mutations. The negative regulator of WNT-signaling activity is the beta-catenin destruction complex, which is organized by AXIN1 & AXIN2 scaffold proteins. A growing body of scientific evidence shows that AXIN proteins are key to destruction complex function and CRC development. Our HYPOTHESIS is that aberrant expression of AXIN2 leads to changes in cell cycle, apoptosis, and cancer stem cells that promotes CRC growth and development. Accordingly, we created siRNA-mediated AXIN2 knockdown and lentiviral-based AXIN2 overexpressing CRC cell models (HT29 & SW480) to study the effect of modulating AXIN2 levels in vitro. Our RESULTS show that AXIN2 is involved in multiple regulatory mechanisms: 1) AXIN2 knockdown or overexpression led to decreased CRC cell proliferation; 2) Modulating AXIN2 led to changes in expression of WNT-target genes & SC markers ALDH & LGR5 3) ALDH+ SC population size increased in response to increasing AXIN2, and vice versa. 4) Cell cycle was delayed in both AXIN2 knockdown and overexpressing CRC cell lines. Moreover, our bioinformatics analyses of the effect of tankyrase inhibitors (TIs), which prevent AXIN degradation, in treatment of CRC indicate that efficacy of TIs against CRC cells depends on the APC genotype. CONCLUSION Taken together, our findings show that AXIN2 - a critical factor in WNT signaling - plays a significant role in the cancer cell phenotype including changes in the cell cycle, apoptosis, and CSC population. SIGNIFICANCE: Changes in AXIN2 levels appear to impact critical functions that contribute to SC overpopulation and tissue disorganization that drives tumor development. Thus, discovering ways to target AXIN2-based mechanisms has vast clinical importance.

B273/P1266

Effects of sulforaphane association to conventional therapy for treating triple-negative breast cancer

L. L. Coutinho[1], R. Cheng[2], L. Ridnour[2], M. S. Junqueira[1], R. Chammas[1], D. Wink[2], T. C. Tortelli[1], **M. Rangel**[1]; [1]University of Sao Paulo, Sao Paulo, Brazil, [2]National Cancer Institute, Frederick, MD

Most tumors are comprised of functionally heterogeneous cells, and only a limited, but highly dynamic subpopulation of cells known as cancer stem cells(CSCs) can self-renew and initiate tumors at a high frequency. The triple-negative subtype of breast cancer(TNBC) shows a significantly higher number of CSCs when compared to non-TNBC tumors. This characteristic contributes to the aggressive phenotype exhibited by TNBC and impacts the treatment of patients harboring these tumors since CSCs are involved in the acquisition of resistance to conventional antineoplastic therapies. The embryonic master regulator Cripto-1(CR-1) is known to be increased in TNBC, mainly in the CSCs population contributing to the maintenance of their stem-like phenotype. Also, studies have shown that the 'REDOX' molecules Nitric Oxide (NO) and one of the enzymes involved in its synthesis, Nitric Oxide Synthase 2(NOS2), are able to induce carcinogenesis through different processes, including the promotion of stem-like properties in TNBC cells. Here, we sought to sensitize TNBC cells to conventional chemotherapy by negatively modulating CR-1 and NOS2/NO using sulforaphane(SFN), a nutraceutical agent known to especially target the CSCs population. This natural isothiocyanate compound found in cruciferous vegetables has also been shown to interfere with both CR-1 and NO activity in pathological conditions, such as TNBC and *H. pylori* infection, respectively. To address our hypothesis that SFN would sensitize cells to chemotherapy, we used in this study four cell lines representing the distinct TNBC subtypes, MDA-MB-468, HCC70, MDA-MB-453, and MDA-MB-231. We tested their response to doxorubicin(DOX), and cisplatin(CIS), and found that all of them were sensitive to DOX, displaying a significant reduction in cell viability at very low doses. On the other hand, only the basal-like MDA-MB-468 and HCC70 cells responded to CIS at low doses. The luminal androgen receptor MDA-MB-453 and the mesenchymal MDA-MB-231 cells showed resistance to CIS treatment, with a subtle decrease in cell viability only at higher doses. However, when SFN was associated with CIS treatment, both cell lines, exhibited a significant reduction in cell viability accompanied by elevated early apoptosis activation and cell death. Additionally, we observed that MDA-MB-231 cells treated with CIS alone exhibited increased expression of the pluripotency genes *CR-1* and *Oct-4*, and the epithelial-to-mesenchymal transition marker *N-cadherin*, but the combination therapy CIS-SFN was able to revert this effect. Finally, our results revealed that SFN treatment alone was able to impair cytokine-induced *CR-1*, *NOS2,* and *COX2* overexpression in MDA-MB-231 cells and decrease DETANO(NO-donor)-induced HIF-1α stabilization in these cells.

Oncogenes and Tumour Suppressors - Protein Degradation and Cell Death

Palmitoylation-driven PHF2 Ubiquitination Remodels Lipid Metabolism through SREBP1c Axis in Hepatocellular Carcinoma

D. Jeong[1], J. Seo[1,2], J. Fukuda[2], Y. Chun[1]; [1]Seoul National University College of Medicine, Seoul, KOREA, REPUBLIC OF, [2]Yokohama National University, Yokohama, JAPAN.

Oncogenic signals and malignant phenotypes are closely correlated with lipids and lipid-related enzymes. Palmitic acid (PA) is the most common saturated fatty acid in humans and is known to mediate

palmitoylation of target proteins. Although PA and palmitoylation affect many oncogenic proteins, its pathophysiological functions are not thoroughly understood. In this study, we presented that PA acts as a molecular checkpoint of lipid reprogramming and cancer progression in hepatocellular carcinoma (HCC). Mechanistically, a palmitoyl-transferase ZDHHC23 palmitoylates plant homeodomain finger protein 2 (PHF2) at cysteine 23, which subsequently mediates ubiquitin-dependent degradation of PHF2. Further experiments using a mutant containing a cysteine-to-alanine substitution showed that PA-induced lipid accumulation and cell proliferation is largely dependent on PHF2 palmitoylation. We also found that PHF2 functions as a tumor suppressor by acting as an E3 ubiquitin ligase of sterol regulatory element-binding protein 1c (SREBP1c), a master transcription factor of lipogenesis. PHF2 directly interacts with and destabilizes SREBP1c, thereby reducing SREBP1c-dependent proliferation and lipogenesis in HCC cells. Notably, SREBP1c increases free fatty acids in HCC cells, and the consequent PA induction triggers the PHF2/SREBP1c axis. Clinical dataset of HCC patients revealed that the higher ZDHHC23 and SREBP1c and the lower PHF2 expression are closely associated with poor prognosis of cancer. As a result, the circuit of PA/PHF2/SREBP1c modulates HCC progression and could be a potential marker in patients with HCC. Since PA seems to be central to this axis, we suggest that levels of dietary PA should be carefully monitored in patients with HCC.

Fbxw7 triggers degradation of WDR7 to prevent mitotic slippage

S. Haenle-Kreidler, K. T. Richter, **I. Hoffmann**; Cell Cycle Control and Carcinogenesis, F045, DKFZ, Heidelberg, GERMANY.

During prolonged mitotic arrest induced by anti-microtubule drugs, cell fate decision is determined by two alternative pathways, one leading to cell death, the other inducing premature escape from mitosis by mitotic slippage. Cancer cells are able to evade mitotic cell death by performing mitotic slippage, which means that they exit from mitosis without completing a normal cell division. Therefore, mitotic slippage promotes survival and chemoresistance of cancer cells and represents a major problem in chemotherapy. FBWX7, a member of the F-box family of proteins and substrate-targeting subunit of the SCF (SKP1-CUL1-F-Box) E3 ubiquitin ligase complex promotes mitotic cell death and prevents mitotic slippage. Most of the FBXW7 substrates are widely studied protooncogenes including Cyclin E, c-Myc, Notch and c-Jun. FBXW7 functions as tumor suppressor and mutations in the FBXW7 gene have been observed in a variety of human cancers. We find that WDR5, a component of the mixed lineage leukemia (MLL) complex of Histone 3 Lysine 4 (H3K4) methyltransferases is a substrate of FBXW7. WDR5 binds to FBXW7 in vivo and in vitro and its ubiquitin-mediated proteasomal degradation is mediated by FBXW7. Furthermore, we find that WDR5 depletion counteracts FBXW7 loss-of-function by reducing mitotic slippage and polyploidization. Our data elucidate a new mechanism in mitotic cell fate regulation which might contribute to prevent chemotherapy resistance in patients after anti-microtubule drug treatment.

B276/P1269

Basal Gp78-dependent mitophagy promotes mitochondrial health and limits mitochondrial ROS

P. Alan[1], **K. Vandevoorde**[1], B. Joshi[1], B. Cardoen[2], G. Gao[1], Y. Mohammadzadeh[1], G. Hamarneh[2], I. R. Nabi,[1]; [1]University of British Columbia, VANCOUVER, BC, CANADA, [2]Simon Fraser University, Burnaby, BC, CANADA.

Mitochondria are major sources of cytotoxic reactive oxygen species (ROS) that contribute to cancer progression. Mitophagy, the selective elimination of mitochondria by autophagy, monitors and maintains mitochondrial health and integrity, eliminating ROS-producing mitochondria. However, mechanisms underlying mitophagic control of mitochondrial homeostasis under basal conditions remain poorly understood. Gp78 E3 ubiquitin ligase is an endoplasmic reticulum membrane protein that induces mitochondrial fission and mitophagy of depolarized mitochondria. Here, we report that CRISPR/Cas9 knockout of Gp78 in HT-1080 fibrosarcoma cells increased mitochondrial volume and rendered cells resistant to carbonyl cyanide m-chlorophenyl hydrazone (CCCP)-induced mitophagy. These effects were phenocopied by knockdown of the essential autophagy protein ATG5 in wild-type HT-1080 cells. Use of the mito-Keima mitophagy probe confirmed that Gp78 promoted both basal and damage-induced mitophagy. Application of a spot detection algorithm (SPECHT) to GFP-mRFP tandem fluorescent-tagged LC3 (tfLC3)-positive autophagosomes reported elevated autophagosomal maturation in wild-type HT-1080 cells relative to Gp78 knockout cells, predominantly in proximity to mitochondria. Mitophagy inhibition by either Gp78 knockout or ATG5 knockdown reduced mitochondrial potential and increased mitochondrial ROS. Live cell analysis of tfLC3 in HT-1080 cells showed the preferential association of autophagosomes with mitochondria of reduced potential. Basal Gp78-dependent mitophagic flux is therefore selectively associated with reduced potential mitochondria promoting maintenance of a healthy mitochondrial population and limiting ROS production.

Pharmacological PIP4K2 inhibition disrupts mitochondrial homeostasis and autophagy in acute leukemia

K. Lima[1], D. A. Pereira-Martins[1], L. B. L. de Miranda[2], J. L. Coelho-Silva[3], R. C. Cavaglieri[1], J. J. Schuringa[4], E. M. Rego[1], J. A. Machado-Neto[2]; [1]Laboratory of Medical Investigation in Pathogenesis and Targeted Therapy in Onco-Immuno-Hematology, Faculdade de Medicina, University of São Paulo, São Paulo, BRAZIL, [2]Department of Pharmacology, Institute of Biomedical Sciences, University of São Paulo, São Paulo, BRAZIL, [3]Department of Medical Imaging, Hematology, and Oncology, Ribeirão Preto Medical School, University of São Paulo, Ribeirão Preto, BRAZIL, [4]Department of Experimental Hematology, Cancer Research Center Groningen, University Medical Center Groningen, University of Groningen, Groningen, NETHERLANDS.

Introduction: PIP4K2s comprise a family of lipid kinases responsible for the production of phosphoinositides with structural and signal transduction functions. PIP4K2A and PIP4K2C expressions have been identified as prognostic factors in acute myeloid leukemia (AML) patients. Ancestry-related polymorphisms in the PIP4K2A gene are associated with the risk of developing acute lymphoblastic leukemia (ALL). Recently, a selective pharmacological inhibitor of PIP4K2s was developed (THZ-P1-2). **Aims:** To evaluate the antineoplastic potential of THZ-P1-2 in AML and ALL cells. **Methods:** A panel containing 12 AML and 9 ALL cell lines was used. Cell viability was evaluated by MTT assay, apoptosis by annexin V/PI and flow cytometry (FC), mitochondrial membrane potential by JC-1 and FC, formation of

acidic vesicular organelles (AVO) by acridine orange and FC, cell cycle by propidium iodide and FC, and cell signaling by qPCR and Western blot. ANOVA and Bonferroni post-test were used. A p-value < 0.05 was considered significant. **Results:** In AML and ALL cells, THZ-P1-2 reduced cell viability in a concentration-dependent manner. THZ-P1-2 induced apoptosis, loss of mitochondrial membrane potential, and AVO formation (all p < 0.05). Cell cycle analysis indicated an increase in cells in subG1 and a decrease in cells in G2/M (all p < 0.05). Molecular analysis indicated that THZ-P1-2 has a paradoxical role in autophagy, at first the compound induced the initiating stages of autophagy (increased LC3II) and then inhibited the final stages of autophagy flux (reduction of p62/SQSTM1), which may trap the cell in a state of inertia. DNA damage (γH2AX) and apoptosis (PARP1 cleavage) markers were induced by THZ-P1-2. Gene expression profile indicated that processes such as intrinsic apoptotic signaling pathway, signal transduction in absence of ligand, autophagosome organization, macroautophagy, and response to starvation are involved in the mechanism of action of the compound (all FDR *q* < 0.05). **Conclusion:** The contribution of PIP4K2-related genes to acute leukemias has been revealed in recent years, ranging from prognostic markers to the association with genetic susceptibility. Our study provides insight into pharmacological PIP4Ks inhibition targeting mitochondrial homeostasis and autophagy shedding light on a new class of drugs for these diseases. Supported by FAPESP and CNPq.

AD80 inhibits aurora kinases and induces mitotic catastrophe and autophagy in pancreatic cancer cells

K. Lima[1], L. B. L. de Miranda[1], A. D. B. Garnique[1], B. O. de Almeida[1], M. C. do Nascimento[2], G. M. Machado-Santelli[1], E. M. Rego[2], **J. A. Machado-Neto**[1]; [1]Institute of Biomedical Sciences, University of São Paulo, São Paulo, Brazil, [2]Faculdade de Medicina, University of São Paulo, São Paulo, Brazil

Introduction: Pancreatic cancer is one of the most lethal human neoplasms and its therapeutic repertoire remains limited. Advances in the understanding of the molecular complexity involved in the biology of the disease have paved the way for new therapeutic opportunities. AD80 is a multikinase inhibitor that inhibits S6K as well as RET, RAF, and SRC and displays antineoplastic effects in hematological and solid tumors. **Aims:** To uncover cellular and molecular effects of AD80 in pancreatic cancer cells. **Methods:** MIA PaCa-2, PANC-1, and AsPC-1 pancreatic cancer cell lines were used. Cell viability was evaluated by MTT assay, clonogenicity by colony formation assay, DNA content analysis by propidium iodide and flow cytometry, morphology by immunofluorescence (IF), formation of acidic vesicular organelles (AVO) by acridine orange and fluorescence microscopy, and cell signaling by PCR array and Western blot. Spheroid was also used to access the effects of the drug in 3D models. ANOVA and Bonferroni post-test were used. A *p*-value < 0.05 was considered significant. **Results:** In pancreatic cancer cells, AD80 reduced cell viability in a concentration- and time-dependent manner (all $p < 0.05$). AD80 also strongly decreased clonogenicity (all $p < 0.05$). DNA content analysis indicated an increase in polyploidy cells (all $p < 0.05$), which was confirmed by IF. In the molecular scenario, AD80 reduced S6RP and histone H3 phosphorylation and induced γH2AX and PARP1 cleavage. AURKA phosphorylation and expression were markedly decreased by the drug. In PANC-1 cells, AD80 strongly induced autophagic flux (consumption of LC3B and SQSTM1/p62). A total of 32 out of 84 autophagy-related genes were modulated by AD80 and it was associated with vacuole organization, macroautophagy, response to starvation, cellular response to nitrogen levels, and cellular response to extracellular stimulus (all FDR *q* < 0.05). In 3D pancreatic cancer models, AD80 also effectively reduced cell viability (all $p < 0.05$). **Conclusion:** AD80 induces mitotic aberrations, DNA damage, autophagy, and apoptosis in pancreatic cancer cells. Our exploratory study establishes novel targets underlying the antineoplastic activity of the

drug and provides insights into the development of therapeutic strategies for this disease. Supported by FAPESP, CNPq, and CAPES.

Doramectin induces apoptosis in B16F10 melanoma cells

M. Crotts, J. Jacobs, R. Baer, J. L. Cox; A T Still University, Kirksville, MO

Introduction: Metastatic melanoma is resistant to current pharmacologic regimens that act mainly through apoptotic mechanisms. This indicates novel therapies are needed, specifically those acting via alternative cell-death pathways. Doramectin has shown promising results inhibiting neuroblastoma growth via autophagy. Our research question was will doramectin induce autophagy in murine melanoma B16 cells as a means for cell-death.
Method: B16 viability and proliferation were assessed with MTT analysis. Cells were treated with doramectin (15 uM), both doramectin and an indicator of cell-death, as compared to untreated control cells (media). Likewise, MDC analysis was completed to observe autophagy. Flow cytometry and Western blot analyses were conducted to observe protein amplification with doramectin treatment to assess cell-death pathways. Mitotracker was used to analyze post treatment cellular morphology.
Results: MTT analysis of doramectin treated cells displayed a significant increase in cell death when compared to control. Furthermore, time-course analysis of doramectin treatment over 24 hours yielded significant differences in nuclear morphology with apoptotic indications such as shrunken nuclei and nuclei fragments. Flow cytometry analysis of doramectin treated cells showed apoptosis as a major mode of cell death with some necrosis. Western blot analysis showed increased levels of CHOP with doramectin treatment. Mitotracker yielded significant differences in mitochondrial morphology.
Conclusion: Doramectin does not induce autophagy in murine melanoma B16 cells *in vitro*. Rather, it induces cell-death via apoptosis. However, morphological changes and the presence on necrosis suggest an alternative mechanism which may include reactive oxidative species. Further work exploring novel mitochondrial targeted therapies are needed.

Silibinin protects against staurosporine-induced apoptosis in malignant melanoma B16F10 cells

J. Jacobs, M. Crotts, R. Baer, J. L. Cox; A T Still University, Kirksville, MO

Background: Rare melanoma subtypes have few therapeutic options to treat advanced disease and current treatments show minimal anti-tumor effect. Patients minimally benefit from combined targeted therapy with immunotherapy and kinase pathway inhibitors. Silibinin from milk thistle is characterized as having pharmacological activity through anti-carcinogenic and anti-inflammatory effects. PKC inhibitor Staurosporine is pro-apoptotic and currently undergoing phase II clinical trials for treatment of rare melanoma subtypes. The current study provides a possible mechanism as to why combined therapy shows minimal results and contradicts previous studies describing the use of silibinin as a potential clinical combination therapy. Our data suggests silibinin protects against staurosporine- induced cell death in B16F10 melanoma cells. Individual treatment of either silibinin or staurosporine on B16F10 melanoma cells is pro-apoptotic in a dose- and time-dependent manner. MTT assays show increased cell death, NucBlue staining shows decreases in cell volume and nuclear size in addition to changes in nuclear morphology, and further studies indicated DNA fragmentation and decreased p-AKT and p-iKBa levels. However, pretreatment with silibinin prior to staurosporine treatment decreases cell death,

increases cell volume and nuclear size, and decreases apoptosis significantly. This indicates that silibinin protects cells from staurosporine-induced apoptotic cell death and should not be used in combined targeted therapy in patients with rare melanoma subtypes undergoing treatment with a staurosporine derived PKC inhibitor.

CDK5 interacts with MST2 and modulates the Hippo pathway

M. Passi, S. Zahler; Ludwig-Maximilians-Universität München, Munich, Germany

The Hippo-YAP/TAZ pathway is a prevalent evolutionary conserved pathway from *Drosophila* to mammals and plays a key role in controlling organ size, cell growth, self-renewal, and tissue homeostasis. The Hippo pathway consists of a MST/LATS kinase module and a YAP/TAZ-TEAD transcription module, and regulates the transcriptional activity of YAP and TAZ, responding to a broad range of mechanical clues from shear stress to cell shape, cell-cell contact, extracellular matrix rigidity and stiffness. In general, the Hippo pathway kinases are considered tumour suppressors. Activation of YAP/TAZ is inhibited by phosphorylation caused by LATS1/2 and MST kinases, which results in cytoplasmic sequestration and degradation of YAP/TAZ. While unphosphorylated, YAP/TAZ translocate to the nucleus and bind to TEAD family transcription factors to induce gene expression. We have recently identified an interaction between CDK5, an unusual member of the family of cyclin-dependent kinases, and MST2 in a yeast-two-hybrid screen. Accordingly, in the current study, we aim to shed a light on the involvement of CDK5 in the Hippo pathway by employing. CDK5 knockdown and overexpression in Huh-7 cells. While CDK5 did not directly affect phosphorylation of MST2, phosphorylation of LATS1 (at Thr1079) was changed by knockdown of CDK5. Transcriptional YAP activity was also changed accordingly (measured by reporter gene assay). Since the kinase activity of CDK5 seems not to be crucial for the process (inhibition by roscovitine, a CDK5 inhibitor), CDK5 seems to act like a scaffold bringing the other proteins together and providing a platform for the Hippo pathway cascade.

Keywords: - CDK5, Hippo pathway, YAP/TAZ, MST1/2, LATS1/2, kinases, overexpression, knockdown.

CYPRESS ESSENTIAL OIL LIMITS PROLIFERATION OF FIBROSARCOMA CELLS

D. Garcia, M. Catalfumo, D. Lobo, D. Lobo; Monmouth University, West Long Branch, NJ

CYPRESS ESSENTIAL OIL LIMITS PROLIFERATION OF FIBROSARCOMA CELLS

Dianelys Garcia, Michael Catalfumo, and Dorothy LoboBiology Department, Monmouth University, West Long Branch, NJ 07764

Cypress oil is an essential oil derived from evergreen coniferous trees native to Southern Europe and Western Asia. Cypress oil exerts anticancer properties due to their natural terpenes which induce apoptosis and cell cycle arrest, in turn limiting tumor growth and metastasis. The components of cypress essential oil include a total of 20 constituents which represent 98.1% of the oil. These include: α-pinene (48.6%), δ-3-carene (22.1%), limonene (4.6%) and α-terpinolene (4.5%) which are the main components comprising 79.8% of the oil. A cell line of HT-1080 (fibrosarcoma) cells were treated with cypress essential oil at different concentrations and the effects were determined. Proliferation was measured by direct cell counting using trypan blue dye exclusion and MTT assay. Proliferation of HT-1080 fibrosarcoma cells demonstrated a significant decrease with increased concentration of cypress essential oil. In addition, high concentrations of cypress essential oil also decreased MTT activity which

therefore confirmed a decrease in viability due to essential oil treatment. Western blot analysis will be used to ascertain if the decreased viability is a result of apoptosis by detection of PARP cleavage. The effects of cypress essential oil will also be tested on normal fibroblast cells to compare differences in signaling. The signaling of normal-contact inhibited cells treated with cypress will be compared to the cancerous cell line.

B283/P1276

Manuka Essential Oil Decreases Proliferation and Causes Apoptosis in HT-1080 Fibrosarcoma Cells

N. I. Bass, **D. Hutter Lobo**; Monmouth University, West Long Branch, NJ

Since research on the effects of essential oils on human cell lines is limited, the goal of this project was to treat cancer cells lines with manuka essential oil at different concentrations and ascertain the effects on cell proliferation on a variety of cell lines, including normal fibroblast (CUA-4) and fibrosarcoma (HT-1080) cells. Manuka oil is popular in many skincare products because of its antibacterial and anti-inflammatory properties that treat several skin conditions. However, manuka oil also contains an active ingredient that is commonly found in herbicides and is potentially toxic to human cells at certain concentrations. To study the effects of this essential oil on cultured cells, cell lines were grown on 24-well plates, and subconfluent cultures were treated with varying concentrations of manuka oil for 24 hrs. The effect of the oil on proliferation and viability was measured through direct cell counting using trypan blue dye exclusion and through the use of an MTT assay. As the concentration of oil increased, viability of all cell lines tested decreased. MTT assay results also reflected this trend, with a significant decrease in MTT activity seen in cells treated with 500 µg/ml manuka oil. To determine if the decreased cell numbers observed from manuka oil treatment is the result of apoptosis, PARP cleavage assays were performed in HT-1080 cells. HT-1080 cells were found to have significant levels of PARP cleavage after 4 hours of treatment with manuka essential oil, indicating that the cells were undergoing apoptosis.

Regulatory and Noncoding RNAs

B285/P1277

Effects of Osteoclasts on Transcriptional Regulation of Non-Coding RNAs in Osteoblasts Grown on Titanium with Nanotopography

R. L. B. Trevisan[1], E. P. Ferraz[2], J. A. R. Gordon[3], C. Tye[3], J. B. Lian[3], G. S. Stein[3], J. L. Stein[3], A. L. Rosa[1], **M. M. Beloti**[1]; [1]School of Dentistry of Ribeirão Preto, University of São Paulo, Ribeirão Preto, BRAZIL, [2]School of Dentistry, University of São Paulo, São Paulo, BRAZIL, [3]Department of Biochemistry and Vermont Cancer Center, University of Vermont Larner College of Medicine, Burlington, VT.

The bone remodeling process is crucial for titanium (Ti) osseointegration and depends on the crosstalk between osteoclasts and osteoblasts, which may be affected by epigenetic mechanisms, including the action of long non-coding RNAs (lncRNAs) and microRNAs (miRNAs). Ti with nanotopography (Ti Nano), generated by H_2SO_4/H_2O_2 treatment, attenuates the negative effects of osteoclasts on osteoblasts. Thus, we hypothesized that osteoclasts affect transcriptional regulation of non-coding RNAs (ncRNAs) in osteoblasts grown on Ti Nano in a different way than on machined Ti (Ti Control). We aimed to investigate the effects of osteoclasts on the regulation of ncRNAs in osteoblasts grown on Ti Nano compared to Ti Control. Osteoblasts were cultured on Ti Nano or Ti Control, and osteoclasts were cultured in inserts in a co-culture model for 48 h; non-cocultured osteoblasts were used as control.

Using RNA-seq (DESeq2: FC>1.7; p<0.05), we identified 4328 modulated mRNAs and 252 modulated lncRNAs, plotted in a heatmap according to their expression patterns. Correlation analyses between lncRNAs and mRNAs as well as the cluster distribution were identified through K-Means and Elbow methods (RStudio), considering the Pearson correlation and coefficients 1.0 and -1.0. Many genes were regulated by osteoclasts, mainly in osteoblasts grown on Ti Nano. The real-time PCR (p≤0.05) showed that osteoclasts upregulated the gene expression of *H19*, *Snhg1*, *Neat1* and *Zfas1* and downregulated *Carmn*, *Tug1*, *Dnm3os* and*Kcnq1ot1* in osteoblasts cultured on Ti Nano. In osteoblasts grown on Ti Nano, positive correlations between the expression of *Kcnq1ot1*, a lncRNA that contributes to osteogenic differentiation by sponging miR-214, and the bone marker mRNAs *Alpl*, *Bglap*, *Bmp8a*, *Col1a1* and *Vim* in the absence of osteoclasts, and negative correlations in the presence of osteoclasts, were observed. Although osteoclasts downregulated *Kcnq1ot1* and upregulated miR-214 in osteoblasts grown on both Ti surfaces (p≤0.05), such effects were more pronounced on Ti Nano. Thus, we conclude that Ti Nano induces osteoblast resistance to the negative effects of miR-214, which is reversed by the presence of osteoclasts due to, at least in part, the modulation of osteogenic mRNAs through a *Kcnq1ot1*-miR-214 circuit. **Financial support:** FAPESP-Brazil (# 2017/12622-7, 2017/23888-8, 2018/17356-6 and 2019/09349-2) and NIH-USA (R01AR039588 and R01DE029311).

Diagnostic potential of circulating miRNAs in metabolic syndrome

M. Khan[1], A. Dandare[1,2], A. Liaquat[3], M. Rafiq[1,3]; [1]COMSATS University Islamabad, Islamabad, PAKISTAN, [2]Usmanu Danfodiyo University Sokoto, Nigeria, Sokoto, NIGERIA, [3]Shifa Tameer-E-Millat University, Islamabad, PAKISTAN.

The global prevalence of metabolic syndrome (MS) is 20-25 %. Inadequate information about underlying pathophysiological factors of MS is a major challenge for designing treatment approaches that target the root of the disease, and the reasons for the increasing cases of the syndrome in the world. This study aimed to evaluate the potential role of miRNAs for novel treatment and diagnostic approaches to the MS. Dysregulation of miRNAs and their target genes was measured in MS patients and healthy controls. The serum level of insulin, C-reactive protein, and adiponectin were quantified using ELISA. Relative expression of miR-17-5p, miR-320a, miR-548c-3p, miR-579-3p, and miR-21-5p along with their target genes of JAK/STAT signaling pathway; *STAT3, JAK2, SOCS4, IL6R, AKT1, PIK3CB, PIAS1,* and *PTPN11* was measured using qPCR. We observed the existence of dyslipidemia, elevated level of serum insulin, and C-reactive protein (CRP) accompanied by decreased adiponectin in MS patients compared to the control group. miR-17-5p, miR-320a, miR-548c-3p, and miR-579-3p were significantly up-regulated, whereas *STAT3, JAK2, SOCS4,* and *IL6R* genes were down-regulated in the MS patients. Existence of positive correlation was observed between the up-regulated miRNAs and insulin or CRP and inversely correlated with adiponectin concentrations. Interestingly, the miRNAs exhibited the order of diagnostic accuracy as miR-320a > miR-579-3p >> miR-548c-3p > miR-17-5p. The involvement of miR-17-5p, miR-320a, and miR-548c-3p in the pathogenesis of MS via the regulation of the JAK/STA signaling pathway was suggested, thus could be promising candidates for both treatment and diagnostic approaches to the disease.

B287/P1279

SARS-CoV-2-derived microRNAs activate inflammasome and interferon pathways in human lung and blood immune cells

L. G. Bimerew[1], F. Meng[1], Z. Azam[1], N. Wong[1], T. Lee[2], S. Yip[1], C. Huang[1,3]; [1]Department of Health Technology and Informatics, The Hong Kong Polytechnic University, Kowloon, HONG KONG, [2]Department of Biomedical Engineering, The Hong Kong Polytechnic University, Kowloon, HONG KONG, [3]Research Institute for Future Food, The Hong Kong Polytechnic University, Kowloon, HONG KONG.

The causative agent of COVID-19, SARS-CoV-2 controls the host immune function for its benefit through various mechanisms. The role of virus-derived microRNAs (v-miRNAs) in COVID-19 pathogenesis has recently been reported, while the mechanism behind this process is incompletely understood. We aimed to identify the v-miRNAs in SARS-CoV-2 infected cells and their role in host immune regulation. Small RNA-seq library was prepared on-site and sequenced using the Illumina platform on RNA samples isolated from SARS-CoV-2 infected Calu-3 human lung cells and peripheral blood mononuclear cells (PBMCs). A number of SARS-CoV-2 encoded v-miRNAs were identified using stringent bioinformatics approaches. V-miRNAs and control miRNA mimics were synthesized and transfected into Calu-3 and PBMCs. Next, RT-qPCR, flow cytometry, western blotting, ELISA, and single-cell RNA-seq (scRNA-seq) were performed to identify and validate the putative targets of v-mRNAs and their global response on immune cell populations. ScRNA-seq data is analyzed in the 'R' (version 4.1.2) environment using the 'iCellR' package and graphs and charts are prepared in GraphPad Prism. We identified the top three SARS-CoV-2-*N* encoded v-miRNAs (v-miRNA-Ns) and we further validated the expressions in COVID-19 patients' nasopharyngeal aspirate and *ex vivo* infected PBMCs. Further cellular pathway analysis showed that PBMCs transfected with v-miRNA-N-mimics express significantly higher IL-1β, Caspase 1, and NLRP3 protein levels, indicating their involvement in inflammasome activation. *N* encoded v-miRNAs induce COVID-19-like features demonstrated by our scRNA-seq platform in both overall and individual immune cell groups (in PBMCs), featured by upregulation of key COVID-19-related gene activity. Functional analysis of differentially expressed genes identified interferon signaling as the most enriched pathway along with apoptosis signaling genes in the v-miRNA-N groups. In line with previous findings, our analysis showed a similar trend of interferon signaling genes in the v-miRNA groups (e.g., *XAF1, IFI44L, IFI44, HERC6, STAT1, TRAF3, MX1 and ISG15*). We show here for the first time that SARS-CoV-2 *N* encoded v-miRNAs could modulate inflammatory and cell death processes by hijacking host gene regulations and downstream signaling networks.

B288/P1280

Unveiling the potential role of myopia-SNPs on non-coding RNA-mediated ceRNA network in human iPSC-derived retinal ganglion cells

N. Wong[1,2], Z. Jiang[1], R. Kwarteng[1], S. Luo[1], V. Choh[2,3], S. Yip[1,2], C. Huang[1,2]; [1]Department of Health Technology and Informatics, The Hong Kong Polytechnic University, Kowloon, HONG KONG, [2]Centre for Eye and Vision Research Limited, Sha Tin, HONG KONG, [3]University of Waterloo, Waterloo, ON, CANADA.

Myopia is a multifactorial visual disorder characterized by axial elongation of the eyeball along with structural changes in the choroid, retina, and sclera. The specific etiology is still unclear but both genetics and environmental factors are considered to be contributors to myopia. Our study aimed to characterize the regulatory role of non-coding RNAs in retinal ganglion cells (RGCs), which may

potentially contribute to myopia. Human induced pluripotent stem cells (iPSCs) were differentiated into RGCs under specified culture conditions. The differentiated cells were collected on day 40 and subjected to RT-qPCR and flow cytometry analysis to check the cell identity. RNA-seq and small RNA-seq were performed to identify differentially expressed genes (DEGs) (| $\log_2$FoldChange | >2, adjusted *P*-values < 0.05), including differentially expressed-long non-coding RNA (DE-lncRNA) and microRNA (DE-miRNA). Moreover, bioinformatics analyses of potential competing endogenous RNA (ceRNA) interactions involved in RGC differentiation was completed. A significant upregulation of RGC marker genes (ATOH7, BRN3A, ISL1, SNCG) was detected by RT-qPCR, and flow cytometry analysis showed >60% $THY1^+$ cells, which represents an enriched population of RGC lineage. RNA-seq data revealed 7,753 DEGs in 40-day RGCs compared to iPSCs, while 2,944 of them are lncRNAs. 18,432 SNPs associated with myopia (myopia-SNPs) were identified from genome-wide association studies and mapped to the genomic location of DE-lncRNA. MAPT-AS1 and MAPT-IT1 were two upregulated DE-lncRNAs showing >10 myopia-SNPs located on their exons. By *in silico* analyses, putative binding regions of DE-miRNA with myopia-SNPs located on them were identified on MAPT-AS1 and MAPT-IT1. MiR-302a-5p and miR-6797-5p were found to be the top downregulated DE-miRNAs that have binding sites on MAPT-AS1 and MAPT-IT1, respectively. Further analyses revealed a list of mRNAs that are potentially targeted by miR-302a-5p and miR-6797-5p, which could subsequently construct ceRNA networks in RGCs. To conclude, putative lncRNA-miRNA-mRNA networks were identified during RGC differentiation and myopia-SNPs may alter such interactions by disrupting the miRNA-binding sites.

B289/P1281

Long non-coding RNA H19 regulates retinal gene expression during neural retina/photoreceptor differentiation of human mesenchymal stem cells

F. Meng[1], **Z. Jiang**[1], J. Sun[1], N. Wong[1,2], T. Krause[1,3], V. Choh[2,4], S. Yip[1,2], C. Huang[1,2]; [1]Department of Health Technology and Informatics, The Hong Kong Polytechnic University, Kowloon, HONG KONG, [2]Centre for Eye and Vision Research Limited, Sha Tin, HONG KONG, [3]FH IMC University of Applied Sciences, Krems, AUSTRIA, [4]University of Waterloo, Waterloo, ON, CANADA.

Degenerative retinal diseases cause impairment of retinal cellular functions, resulting in premature cell death and ultimately direct vision damage. There is currently still no effective treatment for these degenerative retinal diseases. Therefore, understanding the molecular mechanisms in addition to further optimization for stem cell-based retina lineage differentiation may provide an improved cellular and regenerative therapy. The objective of this study is to investigate the regulatory role of long non-coding RNA H19 and its derived microRNA miR-675 in the differentiation of human mesenchymal stem cells (hMSCs) into neural retina/photoreceptor cells. Bone marrow-derived hMSCs were induced to undergo retinal differentiation by cytokine cocktail treatment (DKK1, IGF-1, Noggin, and bFGF). Total RNA was isolated from hMSCs cultured in the differentiation medium for 3, 7, 14 and 72 hours post H19-siRNA transfection. Expressions of retina-relevant marker genes NRL, OPN1MW, and RORB plus H19/miR-675-3p and -5p were determined by quantitative RT-qPCR. The mRNA targets and functional networks of H19/miR-675 were analyzed using bioinformatics tools with a focus on genes involved in retina development. Up-regulation of H19, OPN1MW, and RORB was detected in hMSCs after 3-day retinal differentiation, and peaked at day 14. After H19-siRNA transfection, the expression of H19 was inhibited 11.3-fold, and down-regulation of OPN1MW and RORB were shown on day 3 (11.9-fold and 2.7-fold) compared to control-siRNA-transfected hMSCs. The major H19 isoform H19_203, which contains the miR-675 region, was detected in hMSCs instead of H19_206. By *in silico* analysis, we

identified 49 potential miRNAs that targeted the retinal relevant genes. Among them, DKK3, NEUROD1/2, OPN1MW, OPN1SW, OPN4/5, OTX1, PAX6, RORA/B/C, and RXRG were the targets of miR-675-3p and -5p. In addition, H19 contains the binding sites of 13 of these miRNAs. This implies that H19 may act as the miRNA sponge during retinal differentiation. Gene Ontology enrichment analysis showed that these putative miRNA-lncRNA-mRNA interactions may be involved in the functional pathways of intraciliary transport and visual learning and behavior. Specifically, this newly identified H19-mediated miRNA-lncRNA-mRNA interactome may play an important role in neural retina/photoreceptor differentiation through targeting genes involved in retina development.

B290/P1282

Phase separation of Lysine Specific Demethylase-1 recruits TERRA on telomere to trigger R-loop mediated ALT pathway

M. Xu[1], D. Senanayaka[2], D. Chenoweth[3], N. Reiter[2], H. Zhang[1]; [1]Carnegie Mellon University, Pittsburgh, PA, [2]Marquette University, Milwaukee, WI, [3]University of Pennsylvania, Philadelphia, PA.

Histone methyl regulatory enzymes and chromatin-associated RNAs influence the dynamic organization of the genome and modulate gene expression. The lysine-specific demethylase 1A (LSD1 or KDM1A) catalyzes the removal of histone mono- and dimethyl functional groups (H3K4me1/2 or H3K9me1/2), resulting in repressive or activating transcriptional marks respectively. Here we report a new function of LSD1 through its phase separation with RNA in telomere maintenance via the alternative lengthening of the telomere (ALT) pathway that is based on homology-directed DNA synthesis. We find LSD1 localizes to ALT telomeres, and LSD1 deficiency leads to a loss in ALT signatures, such as telomere clustering and telomeric DNA synthesis. The presence of LSD1 on ALT telomeres requires the telomere repeat-containing RNA (TERRA), a lncRNA that promotes ALT pathway via R-loop formation. Interestingly, the presence of TERRA on ALT telomeres also requires LSD1. To determine the mechanism underlying the mutual dependence of LSD1 and TERRA on telomeres, we used a chemical dimerization approach to recruit LSD1 to telomeres and observed increased TERRA level and R-loop formation. In addition, LSD1 recruitment triggered local phase separation on telomeres. In vitro reconstitution shows that TERRA and LSD1 indeed undergo phase separation. The formation of LSD1 condensates depends on the structure of TERRA, with condensate formation preferentially occurring in a length-dependent manner that correlates with the number of UUAGGG hexanucleotide repeats. Our findings reveal a new pathway where LSD1 undergoes phase separation with TERRA to facilitate R-loop formation for telomere maintenance in ALT cancer cells.

B291/P1283

MicroRNA profiling in pseudoexfoliation syndrome using next-generation sequencing

A. Khera, S. Pandav, F. TT; Postgraduate Institute of Medical Education and Research, Chandigarh, India

Aim: XFS etiopathogenesis is linked to multiple genes and microRNAs. However, the precise etiopathogenesis is unknown. The goal of this study was to use NGS to profile miRNA expression in XFS. **Material & Methods:** During cataract surgery, anterior lens capsules (ALC) from XFS, XFG, and cataract (CAT) patients were obtained. ALC was used to extract RNA. Insilico analysis of significantly expressed genes and miRNAs was performed. qPCR was used to confirm the expression levels of 6 miRNAs, LOXL1 and elastin. **Results:** In all groups, insilico analysis revealed differential expression of genes and miRNAs. The Kegg pathway analysis showed various pathways involved in disease pathology. The expression of

LOXL1 and elastin, and the miRNAs involved in LOXL1 transcription revealed that miR-141 and miR-200 may be involved in disease pathogenesis. **Conclusion:** More research on the expression of miR-141 and miR-200 in large number of samples of XFS is required to come to the conclusion.

Differential Gene Expression Analysis of the Anterior Cingulate Cortex Shows Highly Divergent Molecular Response Between Depressive and Resilient Groups in a Mouse Model of Major Depression

J. Cortés Silva[1,2,3], T. Peña-Centeno[1], L. Kaurani[1], J. Zhou[1], S. Burkhardt[1], A. Fischer[1,3]; [1]German Center for Neurodegenerative Diseases (DZNE), Göttingen, Germany, [2]International Max Planck Research School for Genome Science, Göttingen, Germany, [3]Universitätsmedizin Göttingen, Göttingen, Germany

Major Depression (MD) is one of the most common neuropsychiatric disorder with incidence numbers that currently exceed 300 million people suffering from this disease worldwide. Although the symptoms and treatment for MD follow well-defined guidelines, the mechanisms of action at the molecular level are still unknown. In the present study the Social Defeat (SD) paradigm was applied to mice to study the genetic basis of MD, and the molecular mechanisms that may mediate resilience to environmental stressors. The presentation of chronic SD over a period of 10 days allowed us to distinguish between those subjects who responded to the stress-induced procedure (depressive group), and those who did not show any effect (resilient group) at the behavioral level. The distinction of the groups was made considering the immobility times of the mice during the Forced Swim Test (FST) compared to a control group. Cognitive function, specifically the processes related to spatial, reference and working memory, were addressed using the Morris Water Maze (MWM) and the Y-Maze test when the SD and FST procedure was completed. After the identification of the groups and the cognitive tests, the Anterior Cingulate Cortex (ACC) of the subjects was dissected to perform TotalRNA-seq gene expression analysis. Animals: 21 wildtype B6J C57bl and 14 CD1 mice. TotalRNA-seq: Illumina Stranded Total RNA Prep Ligation with Ribo-Zero Plus: Dual-indexed libraries. Results: RNA-seq gene expression analysis of the ACC confirms a clear distinction between the depressive (n=7), resilient (n=7) and control (n=7) groups, as it was seen in the behavioral tests. Gene ontology (GO) from the Differential Gene Expression (DGE) analysis, indicated an upregulation of the circadian process in the depressive group, a biological function that appears to be intensely affected in people suffering from MD. Along the same lines, a negative regulation of the glucocorticoid receptor signaling pathway, which has been shown to be reactive to stressful stimuli from the environment, is present. Biological function analysis shows a significant downregulation of the defense and immune response in the depressive group. All dysregulation observed in the depressive group after the DGE analysis, was absent in the resilient and control groups. Conclusions: the results will be discussed.

RNA Localization and Transport

Novel Microscopy Tools Reveal Dynamic Sub-cellular Distributions of Circadian Clock Components in Filamentous Fungus

Z. Wang[1], B. M. Bartholomai[1], J. J. Loros[2], J. C. Dunlap[1]; [1]Molecular and System Biology, Geisel School of Medicine at Dartmouth, Hanover, NH, [2]Biochemistry & Cell Biology, Geisel School of Medicine at Dartmouth, Hanover, NH.

Circadian rhythms are endogenous daily oscillations driven by an intracellular molecular clock that helps organisms better coordinate their lives with the environment. Organisms from fungi to animals share a similar phosphorylation-driven transcription/translation negative feedback loop as the core clock mechanism, an oscillator composed of positive and negative elements. Research on the filamentous fungus model organism, *Neurospora crassa*, has provided answers to many fundamental clock-related questions. In *N. crassa*, the White Collar Complex (WCC), a heterodimeric transcription factor, serves as the positive element driving the transcription of *frequency* (*frq*). Frequency protein (FRQ), with Casein Kinase-1 (CK-1a) and other regulators, forms the negative element complex that inhibits the function of WCC and stops *frq* transcription. Molecular components of the circadian clock have been described over decades of genetic and molecular biological studies. However, little is known about their dynamics and regulation at the subcellular level. *Neurospora crassa* grows as a syncytium analogous to muscle cells, but the subcellular distribution of transcripts must facilitate precise temporal control throughout the syncytium. We applied single molecule RNA-FISH (smFISH) for analysis of mRNA spatial patterning in fixed cells. While *frq* mRNA cycles in abundance throughout the circadian day, we found surprising heterogeneity in the proportion of transcriptionally active nuclei. Moreover, *frq* transcripts are spatially clustered near to nuclei in a time-of-day dependent manner. The intrinsically disordered RNA-binding protein PRD-2, which binds both *frq* and *ck-1a* mRNAs and displays liquid-liquid phase separation, is crucial to the clustering. This spatiotemporal clustering may organize clock mRNAs to facilitate local translation and assembly of clock protein complexes, while the ability to undergo fission/fusion of PRD-2-mediated biomolecular condensates containing *frq* and *ck-1a* mRNAs may prevent local heterogeneities in the distribution of clock components. Recently, live-cell imaging has emerged as a useful tool in circadian research. We implemented novel microscopy tools for filamentous fungi along with strategies, including 4-color imaging and microfluidics compatible with multi-day growth and imaging, to facilitate live-cell imaging of low-abundance circadian proteins. Through 3-color live-cell imaging of WCC, FRQ and a nuclear marker in single cells, we have followed the circadian dynamics of their subcellular localization in high spatiotemporal resolution. We also optimized and are using FRAP and photoconvertible fluorescent proteins for investigating the nucleocytoplasmic transport mechanism of clock proteins.

Transport of Myelin Basic Protein mRNA is Essential for Myelination

J. C. Nowacki[1], L. M. Meservey[2], A. Valenzuela[2], H. S. Richardson[1], H. Nguyen[2], J. Lin[2], H. Zeng[2], M. Fu[1]; [1]NINDS, NIH, Bethesda, MD, [2]Stanford, Stanford, CA.

mRNA transport is an evolutionarily conserved cellular phenomenon observed even in the simplest of organisms (yeasts). Oligodendrocytes, the myelin-producing cells of the central nervous system, have an

elaborate cytoskeletal architecture and can myelinate up to 50 axons per cell. Myelin basic protein (MBP) is one of the two most abundant proteins expressed by oligodendrocytes, and *in vitro* studies have established that the 3'UTR is necessary for *Mbp* mRNA localization outside the cell body. Our lab previously generated a mouse model lacking the *Mbp* 3'UTR to investigate whether transport and local translation is necessary for myelination *in vivo.* Preliminary qPCR data has indicated that *Mbp* coding-region mRNA is downregulated in 3'UTR KO mice. Here, we show that oligodendrocytes cultured from Mbp 3'UTR KO animals show *Mbp* mRNA transport defects, KO animals are hypomyelinated, and display tremors and gait defects, thus supporting the necessity of *Mbp* mRNA transport for myelination.

Localization of mRNAs to Centrosomes Requires the Pericentriolar Material Scaffold

W. Tian, J. Fang, D. A. Lerit; Emory University, Atlanta, GA.

Pericentriolar material (PCM) is a proteinaceous matrix surrounding the centrioles that promotes centrosome microtubule-nucleating activity. We and others previously showed the pericentriolar components Centrosomin (Cnn) and Pericentrin-like protein (PLP) functionally cooperate to organize a PCM scaffold required for centrosome structure and microtubule organization. We recently showed that several centrosomal mRNAs are localized to the centrosome and contribute to centrosome function under regulation of RNA-binding proteins. However, whether the PCM is required to recruit or anchor mRNA to the centrosome remains incompletely understood. We hypothesize that PCM functions as a scaffold to anchor centrosomal mRNAs at centrosomes. To test our hypothesis, we used a classic *cnn* allele to disrupt PCM organization and investigated consequences to the localization of *centrocortin* (*cen*) and *plp* mRNAs. We used single molecule fluorescence in situ hybridization (smFISH) and Asterless-YFP (Asl-YFP) to label mRNAs and centrosomes, respectively, to visualize mRNA enrichments at the centrosome in syncytial *Drosophila* embryos. Given the significantly smaller volume of Asl-labeled centrioles as compared to centrosomes, we adapted our customizable Subcellular Distribution computational pipeline and compared mRNA distributions as quantified from either the centroid or surface of centrosomes to permit quantification using a variety of centrosome markers. Upon disrupting PCM organization, our preliminary data indicate that the enrichment of *cen* mRNAs at centrosomes and the number of mRNAs in granules are significantly decreased. These data demonstrate that proper PCM organization is needed for *cen* mRNA localization to centrosomes. In contrast, we observed no significant difference in *plp* mRNA localization to centrosomes in controls vs. *cnn* mutants, suggesting mechanisms of *cen* and *plp* mRNA localization are separable. We are presently increasing sample sizes to strengthen our quantification and studying additional mRNAs to investigate whether the PCM scaffold is more generally required for mRNA localization to the centrosome. Our work will help elucidate the mechanisms and biological significance of mRNA localization to centrosomes.

Single Molecule Spatial Transcriptomics Demonstrates Spatial Heterogeneity of miRNA and Classifies beta Cells in Type 1 Diabetes

G. Chang[1], C. Seitz[1], F. Syed[2], C. Evans-Molina[2], J. Liu[1]; [1]Physics, Indiana University-Purdue University Indianapolis, Indianapolis, IN, [2]School of Medicine, Indiana University-Purdue University Indianapolis, Indianapolis, IN.

Recently emerged spatial transcriptomics approaches combine the RNA sequencing (RNA-Seq) with spatial localization to reveal the spatial heterogeneity of transcriptome in pancreatic islet. However, the interrogation of the transcriptomic expression in a single cell is missing, particularly the spatial distribution of each RNA molecule. Here we proposed studying the spatial distribution of the miRNA in single β cells obtained from human pancreatic tissues. A multi-dimensional quantitative model was established to describe the spatial distribution of individual RNAs as a library of “features”, which includes RNA expression, locations, clustering/dispersion, and reciprocal positions. In particular, the degree of RNA clustering/dispersion was described by the mathematical model of clusters, i.e. Ripley's H function. Features are first extracted from spatial distribution of miRNA 146 and 155 in β cells of human pancreatic tissues from non-diabetic and diabetic donors. Extracted features are then analyzed by statistical distribution modelling and supervised machine learning. Machine learning enables the classification of 3 groups of β cells (control, T1D, and AAb+) using spatial transcriptomic features with high accuracy (65%±3%). Furthermore, it offers quantitative evaluation of those distinctive features contributing to the classification and phenotyping. Expression levels of miRNA 146 and 155 in β cells are significantly different among pancreatic sections from non-diabetic donors and nPOD donors with T1D and AAb+. This differentiation further exhibits a spatial disparity, where there exists more nuclear miRNA 146/155 than cytoplasmic miRNA for β cells in the T1D and AAb+ samples. More interestingly, it is revealed that the distribution of miRNA is directly associated with β cell phenotype and T1D disease status. The Ripley's H function at 457 nm suggests a different degree of miRNA 155 dispersion of control and T1D. All evidence suggests the spatial heterogeneity of transcriptome of β cells in T1D, and this transcriptomic disparity has been leveraged to classify β cells into different pathological conditions. This work will not only disclose fundamental mechanisms that are associated with β cell survival in T1D; more practically, it could lead to important transcriptomic features of β cells that could have clinical relevance in stratifying the T1D phenotypes.

Dynamic transcription start site usage and RNA binding protein complexing regulate *GJA1* mRNA translation to modulate gap junction formation.

E. E. Shrontz[1,2], M. J. Zeitz[1], J. González Velázquez[1], C. C. James[1,3], J. W. Smyth[1,2,4]; [1]Fralin Biomedical Research Institute, Roanoke, VA, [2]Virginia Tech Carilion School of Medicine, Ronaoke, VA, [3]Graduate Program in Translational Biology, Medicine, and Health, Virginia Tech, Blacksburg, VA, [4]Department of Biological Sciences, College of Science, Virginia Tech, Blacksburg, VA.

Gap junctions comprising connexin proteins enable direct electrical and metabolic intercellular communication and alterations in gap junction coupling underly several human pathologies including dementia, cancer progression, and cardiac arrhythmias. The most ubiquitously expressed connexin is connexin43 (Cx43, gene name *GJA1*). Investigation of Cx43 gap junction biology has historically focused on transcription, vesicular trafficking, and post translational modifications. The importance of

translational regulation, however, is highlighted by the recent discovery that Cx43 mRNA undergoes internal translation initiation to yield truncated protein isoforms, including GJA1-20k, which regulate gap junction formation. We previously reported that during TGF-β stimulation or stress, shortening of *GJA1* mRNA 5'UTRs occurs through alternate transcription start site (TSS) usage and limits GJA1-20k translation resulting in fewer gap junctions. The IMP family (also termed IGF2BPs) of RNA binding proteins (RBPs) regulate alternative and canonical translation initiation of several genes, which led us to investigate how they may impact *GJA1* mRNA. We hypothesize that alternative TSS usage modifies the inclusion of *cis* acting elements in the *GJA1*-5'UTR affecting RBP binding to regulate translation. Employing mouse and human *GJA1* knockout epithelial cells generated through CRISPR/Cas9, we introduced *Gja1* mRNA harboring various 5'UTR sequences to test what *cis*-elements confer specific localization and/or complexing with RBPs, including the IMPs. Using single molecule FISH to label *GJA1* mRNA, and antibodies targeting IMP1, IMP2, or IMP3 we find IMP1 complexes with *GJA1* mRNA predominantly and this complexing is reduced during TGF-β stimulation. Biochemical assays confirm *GJA1*/IMP1 binding by RNA-IP and synthetic reduction of IMP1 expression by RNA interference or CRISPR/Cas9 alters *GJA1* mRNA localization, reduces internal translation of GJA1-20k, and limits gap junction formation. We find comparable results during hypoxia in primary mouse cardiomyocytes and human induced pluripotent stem cell derived cardiomyocytes. Dynamic Gja1-5'UTR composition therefore represents a powerful mechanism connecting alterations in transcription to gene-specific translational regulation by RBPs such as IMP1, fine tuning intercellular communication during stress.

Single molecule imaging reveals a conserved family of centrosomal mRNAs and a novel translation-dependent localization mechanism

A. Safieddine[1], E. Coleno[1], S. Salloum[1], A. Imbert[2], O. Kwon[3], R. Chouaib[1], M. Robert[1], X. Pichon[1], H. Le Hir[4], F. Mueller[5], T. Walter[2], **E. Bertrand**[1]; [1]IGH, CNRS, Montpellier, FRANCE, [2]MINES ParisTech, PSL-Research University, CBIO-Centre for Computational Biology, Paris, FRANCE, [3]Institut de Biologie de l'Ecole Normale Supérieure (IBENS), Ecole Normale Supérieure, CNRS, Paris, FRANCE, [4]IGH, CNRS, Institut de Biologie de l'Ecole Normale Supérieure, FRANCE, [5]Imaging and Modeling Unit, Institut Pasteur, Paris, FRANCE.

Local translation allows for a spatial control of gene expression. Here, we performed RNA localization screen using high-throughput smFISH and discovered mRNAs locally translated at unexpected locations, including cytoplasmic protrusions, cell edges, endosomes, Golgi, the nuclear envelope and centrosomes. Surprisingly, mRNA localization frequently required ongoing translation, indicating widespread co-translational RNA targeting. We also discovered that several mRNAs accumulated in foci distinct from P-bodies, which served as specialized translation sites, i.e. translation factories. Most interestingly, we found a conserved family of mRNAs that localize to centrosomes in both human and drosophila cells. These mRNAs localize to centrosomes at different stages of the cell cycle and some also localize to cilia in quiescent cells. Drug treatments and reporter analyses revealed that mRNA localization required translation of the nascent protein. Moreover, using *ASPM* and *NUMA1* as models, single mRNA and polysome imaging revealed active movements of endogenous polysomes towards the centrosome at the onset of mitosis, when these mRNAs start localizing. These data identify a conserved family of centrosomal mRNAs, which localize by a novel mechanism involving active polysome transport mediated by nascent proteins.

B299/P1291

mRNA Location and Translation Rate Determine Nuclear Import Efficiency

A. N. Gasparski, K. Moissoglu, S. Meydan, N. R. Guydosh, S. Mili; National Institutes of Health, Bethesda, MD.

Numerous mRNAs are actively targeted to peripheral protrusions of mammalian migrating cells. However, the functional consequences of peripheral mRNA targeting are largely unexplored. Here, we investigate how peripheral localization of the *NET1* mRNA affects NET1 protein function. The NET1 protein exhibits dual localization. It functions in the cytosol as an activator of the RhoA GTPase, an important regulator of cell motility. NET1 is additionally imported into the nucleus through the action of nuclear localization signals (NLSs) found at the N-terminus. By specifically altering the location of the *NET1* mRNA between peripheral and perinuclear areas, we show that NET1 produced at peripheral locations associates less with importin β1 and persists to a higher extent in the cytoplasm. This mechanism requires an internal PH domain as well as rapid translation of the intervening sequence between the NLS and PH domains. By contrast, perinuclear mRNA location and slower translation rate favor NET1 association with importin β1 and nuclear targeting. Modulation of this mechanism profoundly impacts NET1 function in cell motility. Perinuclear *NET1* RNA localization causes reduced RhoA activity, impedes focal adhesion maturation and results in slower cell migration to an extent similar as that observed upon knockdown of NET1 expression. Overall, these results reveal that the location of protein synthesis and the rate of translation elongation can influence the ability of competing domains within a polypeptide to determine protein distribution and function.

B300/P1292

Genome-wide analysis of anterior-posterior mRNA localization in a giant single cell reveals a role for the microtubule cytoskeleton

A. Albright, W. Marshall; University of California, San Francisco, San Francisco, CA.

Compared to the development of pattern in multicellular tissues, far less is known about how individual cells can develop their own patterns and organization. Several studies in yeast and *Drosophila* embryos show a clear role of a polarized cytoskeletal system in the localization of specific mRNAs; however, these have largely relied on studies of individual genes and the genome-wide extent of this phenomenon remains unexplored. The giant ciliate *Stentor coeruleus* is a classical model that shows promise in investigating subcellular pattern formation owing to its large size, easy manipulability, and its ability to regenerate; all of which allow us to cut individual cells in half. To determine the dependence of mRNA localization on the microtubule cytoskeleton on a genome-wide scale, we knocked down beta-tubulin, a key component of the microtubule cytoskeleton, using RNAi and conducted single-cell RNA-sequencing and half-cell RNA-sequencing in *Stentor coeruleus* cells bisected along the anterior-posterior axis. Here, we show significant differential gene expression in many genes upon depletion of beta-tubulin in both the anterior and posterior regions of the cell when compared to the whole cell as well as to a negative control. Altogether, our results suggest that the microtubule cytoskeleton is critical for proper mRNA localization and expression of many genes along the anterior-posterior axis. Moving forward, our goal is to develop additional technologies in *Stentor coeruleus* and validate these data with an orthogonal method such as single-molecule fluorescence *in situ* hybridization (smFISH) or microinjection of fluorescent RNAs.

B301/P1293

Spatial Coordination of Cytosolic and Mitochondrial Translation

W. Li[1], E. Yun[1], C. Osman[2], R. H. Singer[1]; [1]Program in RNA Biology, Albert Einstein College of Medicine, Bronx, NY, [2]Faculty of Biology, Ludwig-Maximilians-Universität München, München, GERMANY.

Mitochondria produce the energy to fuel various biological activities. The mitochondrial DNA encodes a handful of genes that are essential for ATP production. A class of protein complexes, including the ATP synthase, have dual genetic origins-some of their subunits are encoded by the nuclear DNA while the other subunits are encoded by the mitochondrial DNA. It remains unclear how cells coordinate the nuclear and mitochondrial gene expressions to maintain the subunit stoichiometry. Here, I will present the novel single-molecule imaging methods to study the nuclear- and mitochondrial-encoded mRNAs. We found that the cytosolic and mitochondrial translation co-localize on opposite sides of the mitochondrial double membrane, thereby promoting the assembly of the ATP synthase. This study uncovers a new layer of regulation of the mito-nuclear crosstalk that is fundamental to organelle biogenesis.

This work is supported by American Heart Association Postdoctoral Fellowship #903024 (WL), and 1R35 GM136296-01 (RHS).

B302/P1294

Control of viral RNA translation via SARS-CoV-2 nucleocapsid protein condensation

C. Roden, A. Gladfelter; The University of North Carolina At Chapel Hill, Chapel Hill, NC.

Infections of SARS-CoV-2 virus have resulted in Covid-19, a global pandemic. The SARS-CoV-2 RNA genome encodes enzymatic machinery to initiate copying itself in the host cytosol and the structural proteins necessary to build new virions. How the virus controls the timing, localization, and specific levels of production of these varied proteins is poorly understood. The non-structural proteins are produced by Orf1ab and structural proteins are produced from sub-genomic RNAs (sgmRNAs) that must be individually processed. Notably, each individual structural protein encoding RNA and Orf1ab share the same 5'UTR sequence yet are not translated with equal timing or efficiency. Orf1ab is translated first followed by nucleocapsid (N-protein) then other structural proteins such Spike, Membrane, and Envelope which all are present in unequal abundance. This study focuses on understanding how translation is controlled through N-protein interactions with RNA sequence features. The SARS-CoV-2 N-protein is an intrinsically disordered RNA-binding protein that has been shown to form biomolecular condensates with viral RNA both cell free and in infected cells. Specific viral RNA sequence and structural features promote N-protein condensation. These include transcription regulatory sequences (TRS) which are recognized by the N-terminal (NTD) domain of N-protein in a structure dependent manner and long, double-stranded RNA stem loops recognized by C-terminal (CTD) domain. We report here that interaction between N-protein NTD and TRS-promotes translation of TRS-containing mRNAs present on 5'UTRs of viral RNAs. Blocking TRS-NTD interaction with mutations, small molecules, or a nanobody results in enhanced translational repression. N-protein is able to differentially regulate all TRS containing RNAs based on the degree the TRS is structured in each 5'UTR with different structures associated with each viral coding sequence. These data support a model by which SARS-CoV-2 N-protein regulates the translation efficiency of Orf1ab and sgmRNAs differentially via the strength of TRS-Nucleocapsid interactions present on the 5'UTRs of viral RNA. In this way, the virus can spatially and

temporally regulate translation for optimal replication. Disrupting N-protein condensation mediated translational regulation may provide a therapeutic target for coronavirus infections.

B303/P1295

Subcellular mRNA localization across tissue architecture and polarity type

D. Mason, S. Mili; National Cancer Institute, NIH, Bethesda, MD

Localization of mRNAs to distinct subcellular domains is a widely observed phenomenon that influences the function of the encoded proteins. In motile mesenchymal cells several mRNAs localize to the cell periphery to regulate protrusion formation and migration. This work has established a role for transcript localization in mesenchymal cells with a front-rear polarity, but comparatively little is known about the localization or function of these mRNAs in apical-basal polarized epithelia. To determine whether protrusion-localized mRNAs are localized in normal epithelia, we surveyed the localization of several endogenous mRNAs in various mouse epithelial tissues with different architectures (skin, tongue, intestine, and kidney). We observed that some, but not all, protrusion-localized mRNAs were preferentially polarized towards the basal cell membrane in all tissues tested. Interestingly, in multilayer epithelial tissues (i.e. skin and tongue) mRNA polarization was more prominent in the basal cell layer, relative to the suprabasal layers. This suggests that mRNA polarization is altered by a basal cell-specific polarization cue.To probe the underlying mechanism of basal mRNA polarization we tested whether we could recapitulate basal mRNA localization in a monolayer of MCF10A cells, a normal breast epithelial cell line. Consistent with our *in vivo* findings, basal mRNA enrichment occurs in *in vitro*monolayers. Intriguingly, however, we did not observe prominent basal mRNA localization in a multilayered organotypic skin culture model. To understand the mechanism of mRNA localization, we used a combination of anti-sense oligonucleotides and ectopically expressed mutants to identify regions in the 3’ untranslated region (3’UTR) of basal mRNAs that promote localization. Interestingly, the same sequence determinants are required for both basal localization in normal epithelia and for protrusion localization in mesenchymal cells. Overall, these results suggest that the same underlying molecular mechanism targets mRNAs to different subcellular locations, dependent on cell polarization (mesenchymal vs. epithelial) and tissue type. However, additional tissue-specific factors like topology may influence the execution of this mechanism. Our current efforts focus on establishing tissue-specific regulation and the physiologic function of polarized mRNAs in epithelial tissues.

B304/P1296

DEAD Box RNA Helicase 3-dependent RNA composition of Stress Granules

B. Cui, H. Ji, M. Aksenova, M. Wyatt, **M. Shtutman**; University of South Carolina, Columbia, SC

In response to stress, cytoplasmic RNA localizes to insoluble ribonucleoprotein granules, principally known as stress granules (SGs). DEAD-Box RNA helicase 3 (DDX3), a noted protein that plays a critical role in RNA metabolism, has recently been shown to modulate SG composition. But the role of DDX3 activity in SG dynamics is not well understood. We elucidate this question by determining the effects of DDX3 inhibition on the whole transcriptome of stress-induced SGs by using a small molecule inhibitor of DDX3, RK33, that targets DDX3's ATPase activity. We identified a differential modulation of DDX3-dependent sequestration of RNAs to SGs not only for coding but, more interestingly, for noncoding RNAs as well. Here we biochemically separated sodium arsenite-induced insoluble stress granules from soluble cytosolic fractions. We found specific classes of intronic and circular RNAs that are distinctly

targeted to SGs. Collectively, these results reveal that the enzymatic activity of DDX3 modulates the transcriptomic composition of SGs, and previously unexplored intronic RNA profiling in the SGs may contribute to understanding human diseases that associate with SG-dysfunction, such as viral infection and neurodegeneration.

B305/P1297

A Motor-Adaptor Complex Mediating Protrusion Localization of APC-Dependent mRNAs

K. Moissoglu, T. Wang, A. N. Gasparski, S. Mili; National Cancer Institute, NIH, Bethesda, MD

RNA localization to specific subcellular compartments is important for the spatiotemporal control of gene expression. We have previously identified a group of mRNAs that exhibit a characteristic peripheral distribution within protrusive regions of the cytoplasm. Work from our laboratory has established that this localization pathway is biologically relevant. Indeed, disrupting the localization of specific APC-dependent mRNAs, such as *RAB13* and *NET1*, results in inhibition of cell migration on 2D surfaces or invasion in 3D environments (Moissoglu et al, 2020; Chrisafis et al, 2020). This peripheral mRNA localization pattern depends on GA-rich sequences in the 3' untranslated region (UTR) of these transcripts and requires the function of the tumor suppressor protein APC as well as the presence of a stable, de-tyrosinated network of microtubules. We have now identified two additional elements, the kinesin KIF1C and the RNA binding protein CNBP (CCHC-type zinc finger Nucleic acid Binding protein), that operate in concert to mediate transport of APC-dependent mRNAs to peripheral locations. KIF1C associates with APC-dependent mRNAs and is required for their transport to the periphery and their ability to exhibit long and linear movements characteristic of active transport on microtubules. In these events, single KIF1C motors can be visualized moving together with individual mRNAs. Thus, KIF1C serves as a motor that actively transports APC-dependent mRNAs to peripheral protrusions (Pichon, Moissoglu et al, 2021). Using proteomic approaches, we have now further identified CNBP as an RNA-binding protein that participates in this transport mechanism. Specifically, CNBP associates directly with APC-dependent mRNAs and this interaction depends on the same GA-rich elements on the 3'UTR that are important for protrusion localization. CNBP additionally interacts with the KIF1C motor. Furthermore, CNBP is required for peripheral mRNA localization, and also importantly, for the interaction of APC-dependent mRNAs with KIF1C. We propose a model in which CNBP serves as an adaptor between the kinesin KIF1C and APC-dependent mRNAs in the transport pathway to their target peripheral locations.

Nucleocytoplasmic Transport

B307/P1298

Impaired Nucleocytoplasmic Transport in Neurological Diseases

B. Ding; Biochemistry and Molecular Biology, Louisiana State University Health Sciences Center, Shreveport, LA.

In eukaryotic cells, transcription and translation processes are physically separated by the nuclear envelope (NE). Newly transcribed mRNAs must be exported to the cytoplasm for protein synthesis, while some proteins require to be imported into the nucleus to fulfill their nuclear functions. This nucleocytoplasmic transport (NCT) across the NE is tightly regulated and is critical for maintaining cellular homeostasis. Its dysregulation leads to aging and many neurological diseases, including

amyotrophic lateral sclerosis (ALS), Huntington's disease (HD), and Alzheimer's disease (AD). To decipher the pathophysiological mechanisms underlying NCT-impaired neurological diseases, the examination of NCT activities at the single cell level is critical. Recently, we reported the techniques for measuring the nuclear transport of both mRNA and protein cargos. *Fluorescent In Situ Hybridization* (FISH) coupled with oligo-dT probes were used to measure the distribution of Poly(A) RNAs (mRNA). A dual reporter (GFP-NES and RFP-NLS) was used to examine the protein nuclear transport. These approaches together with imaging analysis enable us to systematically quantify the NCT activities in cultured neurons. We modeled movement disorder dystonia using patient-derived motor neurons (MNs), which have been generated via direct conversion from patient fibroblasts and the differentiation of induced pluripotent stem cells (iPSCs). We first reported the disease-dependent cellular deficits of dystonia in patient-derived neurons, including deformed nucleus, mislocalized proteins, and impaired nucleocytoplasmic transport, providing another example of the impairment of NCT in neurological diseases. Our study also demonstrates the high value of patient-derived neurons in modeling neurological diseases.

B308/P1299

Hexokinase 2 translocates to the nucleus when glucose is depleted and does not regulate gene expression

M. A. Lesko[1], D. G. Chandrashekarappa[2], E. M. Jordahl[1], M. C. Schmidt[2], J. D. Durrant[1], A. F. O'Donnell[1]; [1]Biological Sciences, University of Pittsburgh, Pittsburgh, PA, [2]Microbiology and Molecular Genetics, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Glucose is a critical energy source for cells and serves as a building block for key biosynthetic processes. Hexokinases are central regulators of glucose metabolism, facilitating the first committed step in glycolysis: conversion of glucose to glucose-6-phosphate. Hexokinases are conserved across eukaryotes, and we use *S. cerevisiae* as a model to study hexokinase function. Yeast express three hexokinases with hexokinase 2 (Hxk2) as the predominant isoform in glucose-grown cells. In addition to phosphorylating glucose, Hxk2 has been proposed to regulate the glucose repression pathway by translocating into the nucleus to regulate transcription of metabolic genes with the transcriptional repressor Mig1. Nuclear shuttling of Hxk2 is thought to be regulated by phosphorylation, and this modification also controls the dimer to monomer transition for Hxk2, suggesting that these two states may be intimately linked. Using advanced confocal microscopy and automated image quantification approaches, we refine the model of Hxk2 nuclear shuttling, refuting the long-held view that Hxk2 translocates into the nucleus in high-glucose conditions. We instead present evidence that Hxk2 shuttles to the nucleus when glucose is depleted, a response also observed in mammalian hexokinases. We expand our understanding of cytosolic-nuclear shuttling for Hxk2 by identifying Tda1, a kinase known to control Hxk2 multimerization in response to glucose depletion, as key for controlling Hxk2 nuclear localization. We show that phosphorylation of Hxk2 at residue serine 15, once thought to be critical for regulating nuclear shuttling, is dispensable for Hxk2 localization changes, but does control monomer-dimer transition which is consistent with findings from the Kriegel lab. We further identify a single lysine in the N-terminal region of Hxk2 that is required for the regulated nuclear shuttling of Hxk2. Finally, we perform RNAseq analyses and demonstrate that Hxk2 plays almost no role in transcript regulation in cells either in replete glucose or in glucose starvation, with only three genes changing their expression profiles (Hxk1, Hxt1, and Suc2), likely a result of metabolic changes rather than direct transcription regulation. Taken together, our studies provide insight into the critical roles hexokinases play in regulating fundamental metabolic responses in cells.

5-FU induces calpain mediated disruption of nuclear transport in cancer cells.

E. Stewart, K. Resendes; Westminster College, New Wilmington, PA.

Nuclear Pore Complexes (NPCs) mediate the travel of molecules into and out of the nucleus with help of nuclear transporters. The GTPase Ran assists these nuclear transporters in the binding/unbinding of their protein cargo. RanGTP exists primarily in the nucleus, with RanGDP in the cytoplasm, creating a strong gradient across the nuclear envelope. Disruption of this gradient can cause cell stress, which can then lead to apoptosis. 5-Fluorouracil (5-FU) is a widely used chemotherapy drug that we have previously demonstrated to disrupt the Ran gradient and nuclear transport by altering NPC permeability. These effects of 5-FU are Ca2+ dependent, but the exact mechanism is unknown. Calpains are calcium activated non-lysosomal cysteine proteases, which may be triggered by 5-FU. Ubiquitously expressed calpain 1 or calpain 2 are thought to, when activated by Ca2+, cleave certain nucleoporins, altering the permeability of the NPC by disrupting its structural integrity. Using western blot analysis, we have demonstrated that the cleaved active form of calpain 2, but not calpain 1, is present in HeLa cervical cancer cells in response to 5-FU. Additionally, use of the calpain inhibitor calpeptin significantly reduced the 5-FU induced increase in nuclear pore permeability. Specifically, addition of calpeptin reduced the number of 5-FU induced leaky HeLa cell nuclei from 25% to 14% and blocked the 5-FU Ca2+ mediated disruption of the Ran gradient. Our current studies seek to determine if 5-FU similarly induces activation of calpain 1 or 2 to disrupt nuclear transport in PANC1 cells, as pancreatic cancer is often treated with this chemotherapy. Together these studies will further our understanding of how 5-FU induces apoptosis, which in turn can help with the development of mechanisms to counteract the risk of 5-FU resistance encountered in cancer cells, in particular by building on the growing evidence that calcium supplementation may enhance the potency of 5-FU.

B310/P1301

The role of PCID2 and Centrin2 in nuclear export and centrosomal localization of BRCA1/BRCA2 in Hs578t breast cancer cells

L. Turturice, N. Polio, T. Gatesman, K. Resendes; Westminster College, New Wilmington, PA.

Centrin2 is a small calcium-binding protein ubiquitously expressed in eukaryotic cells that aids in centrosome stability and microtubule nucleation, as well as functioning in the TREX2 mRNA export complex. We have previously shown that Centrin2 and another member of the TREX2 complex, PCID2, both facilitate nuclear protein export in addition to mRNA export. PCID2, like Centrin2, also localizes to the centrosome during the process of duplication. Therefore, we propose that PCID2 and Centrin2 may play roles in regulating nuclear to centrosomal transport of centrosome duplication regulators. We found that siRNA knockdown of PCID2 led to an accumulation of the centrosomal regulators, BRCA1 and BRCA2 in the nuclei of Hs578T breast cancer cells. Co-localization studies with γ-Tubulin also indicated a loss of BRCA1 at the centrosome after PCID2 knockdown; however, the loss of PCID2 had no significant impact on the ability of BRCA2 to localize to centrosomes. These results indicate that PCID2 is involved in the nuclear export of both BRCA1 and BRCA2 but may only be important for the centrosomal localization of BRCA1. Current studies are exploring the possible impact of Centrin2 siRNA knockdown on the nuclear export and centrosomal localization of BRCA1 and BRCA2. Preliminary results suggest that a lack of Centrin2 also leads to nuclear accumulation of BRCA1 and BRCA2, with more replicates

underway. Additionally, studies of the centrosomal localization of both BRCA1 and BRCA2 following Centrin2 siRNA knockdown have been performed; however, the loss of Centrin2 disrupted localization of y-tubulin at the centrosome hampering our analyses and alternative markers are currently being explored. Together our findings will provide fundamental knowledge on the role of PCID2 and Centrin2 in nuclear transport and the centrosome cycle, leading to a better understanding of centrosomal amplification and tumorigenesis in a variety of cancer types.

B311/P1302

Nucleocytoplasmic transport is regulated by forces on the nucleus

K. L. Scott[1], P. Purkayastha[2], T. P. Lele[2,3,4], K. J. Roux[1,5]; [1]Enabling Technologies Group, Sanford Research, Sioux Falls, SD, [2]Artie McFerrin Department of Chemical Engineering, Texas A&M University, College Station, TX, [3]Department of Biomedical Engineering, Texas A&M Universeity, College Station, TX, [4]Department of Translational Medical Sciences, Texas A&M University, Houston, TX, [5]Department of Pediatrics, Sanford School of Medicine, University of South Dakota, Sioux Falls, SD.

The facilitated diffusion of molecules between the nucleus and cytoplasm through nuclear pore complex (NPC) channels that reside in the nuclear envelope (NE) is a key regulator of myriad cellular processes. Here, we used a light inducible transport reporter (LINuS) and a naturally occurring, inducible transcription factor (glucocorticoid receptor) to demonstrate that facilitated nucleocytoplasmic transport is significantly increased when force on the NE is decreased, either dramatically in the case of cell rounding or more selectively by disrupting mechanical tethers between the nucleus and the cytoskeleton. Loss of the A-type lamins that resist cytoskeletal mechanical forces leads to decreased transport, but that decrease in transport can be overcome by the disruption of those mechanical forces on the cell. Ran-GTPase, the driver of facilitated diffusion, leaves the nucleus at a higher rate in cells with reduced forces on the nucleus and results in a redistribution of Ran-GTPase to the cytoplasm. This redistribution can be rescued by overexpression of Ntf2, which is responsible for recycling Ran back to the nucleus. Disruption of forces on the nucleus led to an increase in the cytoplasmic levels of RNA, the export of which depends on facilitated transport. The passive diffusion of larger proteins through NPCs is also enhanced by profound relaxation of cellular forces. These results support the idea that nucleocytoplasmic transport is mechanosensitive, providing another mechanism by which cells can respond to their environment.

Testing key physical parameters of an osmotic model for nuclear size control in fission yeast

Z. Tan[1,2], J. Lemière[1], F. Chang[1]; [1]University of California, San Francisco, San Francisco, CA, [2]Nankai University, Tianjin, China

In many cell types, the size of the nucleus scales with cell size so the nuclear-to-cell volume ratio (N/C ratio) is maintained as a constant. Recently our lab and others (Lemière et al., Deviri et al) proposed a physical “bag within a bag model” of two nested vesicles for nuclear size control based upon colloid osmotic pressure. In this model, nuclear volume is determined by a balance of osmotic pressures on the nuclear envelope and its membrane tension. In the fission yeast *S. pombe* the nucleus acts as an ideal osmometer whose size is determined by its osmotic environment, suggesting that nuclear membrane tension is negligible in these cells. Thus, key determinants of nuclear size are the numbers of macromolecules in the nucleoplasm and cytoplasm that produce colloid osmotic pressure. Here, we test

this osmotic model with experiments in which we vary key parameters in fission yeast. To alter relative colloid osmotic pressure, we will vastly overexpress mCherry-GST in the nucleus or cytoplasm. We predict that increasing mCherry protein content in the nucleus will increase the N/C ratio while overexpressing cytoplasmic mCherry may decrease the N/C ratio. To increase the mechanical effect of nuclear envelope on nuclear size, we plan to express human nuclear lamin constructs in fission yeast. We predict that increased nuclear envelope stiffness may decrease the N/C ratio and dampen nuclear swelling under hypoosmotic shock similar to what has been observed in Chondrocytes. These studies will provide critical quantitative experimental tests of this osmotic model for nuclear size.

B313/P1304

Mlv reverse transcription can occur in the nucleus

K. Salas-Briceno, S. R. Ross; University of Illinois, Chicago, IL

Reverse transcription plays an essential role in retroviral replication. It is thought to initiate from within the capsid and uses the reverse transcriptase enzyme to synthesize DNA from an RNA template. Since reverse transcription initiates within the capsid, uncoating and reverse transcription are probably mutually dependent. HIV can infect non-dividing cells, because there is active transport of the preintegration complex (PIC) across the nuclear membrane. There is still much debate regarding the timing and cellular location of reverse transcription for HIV, and whether it occurs solely in the cytoplasm or nucleus or both. Moreover, while it is known that Moloney Leukemia Virus (MLV) replication depends on cell division for replication in tissue culture cells, whether its reverse transcription is solely cytoplasmic has not been studied. In this study, we used NIH3T3 and primary mouse dendritic cells to determine where the different stages of reverse transcription occur and whether cell division is needed for nuclear entry. Our data strongly suggest that in both NIH3T3 cells and dendritic cells, the initial step of reverse transcription occurs in the cytoplasm and not in the nucleus. We also found that the MLV PIC requires cell division to enter the nucleus of NIH3T3 cells. However, we also detected MLV RNA/DNA hybrid intermediates in the nucleus of dividing NIH3T3 cells, suggesting that reverse transcription can continue after nuclear entry. In contrast to NIH3T3 cells, we found that MLV could infect non-dividing primary dendritic cells and that knockdown of a number of nuclear pore proteins dramatically reduced the appearance of integrated MLV DNA in these cells. These findings suggest that simple retroviruses, like HIV, also might have some mechanism to gain nuclear entry by traversing the nuclear pore complex in non-mitotic cells.

B314/P1305

The *Drosophila* EGFR ligand mSpitz is delivered to cytoplasmic capes at sites of non-canonical RNA export on the nuclear envelope *via* the endosomal system

F. Mattie[1], P. Kumar[2], M. Travor[3], K. Browder[4], **K. Shill**[1], C. Thomas[1]; [1]Pennsylvania State University, Unviersity Park, PA, [2]Government College for Women, Unviersity Park, India, [3]Pennsylvania State University, University Park, PA, [4]Genentech Inc., South San Francisco, CA

Nuclear-cytoplasmic communication is not limited to nuclear pores, with both proteins and RNA using alternative routes between these compartments. We previously characterized cytoplasmic capes (large invaginations of the nuclear envelope in *Drosophila*), that are enriched for the membrane-bound EGF receptor ligand mSpitz, endosome-related organelles and ubiquitylated proteins. Closely associated with capes are groups of perinuclear vesicles between the outer and inner nuclear membranes that resemble

those seen at sites of non-canonical ribonucleoprotein (RNP) export *via* budding. Here, we demonstrate that mSpitz delivery to cytoplasmic capes requires passage through the endosomal system. We also show that capes are indeed closely associated with sites of non-canonical RNP export as well as the *D*Frizzled2 receptor C terminal fragment (*D*Fz-2c), a core component of this export pathway. Timelapse microscopy of glands in intact larvae indicates that cytoplasmic capes are stable structures that persist for at least 90 minutes without conspicuous growth. We further show that capes appear with the growth of the salivary gland rather than at a specific developmental stage, suggesting that capes do not form in response to ecdysone signaling. We also demonstrate that the large F-actin binding protein β_H-spectrin that modulates endosomal trafficking, as well as spectrin tetramer formation are required for cape formation. Finally, we find that there is a slight elevation in the level of *D*Fz-2c at the nuclear envelope when β_H is knocked down. Cytoplasmic capes therefore represent a sub-specialization of the nuclear envelope where endosomal trafficking and RNP export are closely associated and may be functionally interdependent.

PP2A-B55^{SUR-6} promotes nuclear envelope breakdown in *C. elegans* one-cell embryo

S. Kapoor, K. Adhikary, S. Kotak; Indian institute of Science (IISc) Bangalore, Karnataka, INDIA.

The nucleus constrains the cell's genetic material by forming a selective barrier to the entry of macromolecules from the cytoplasm. In animal cells, nuclear envelope breakdown (NEBD) allows the spindle microtubules to access and attach to the chromosomes within the nucleus at the onset of the M-phase. Proper chromosome-microtubule attachment ensures faithful segregation of genetic material into the two daughter cells. NEBD is regulated by the activity of critical kinases such as CDK-1, AIR-1 (Aurora A), and PLK-1. While these mitotic kinases are clearly crucial for NEBD, no phosphatase has yet been linked with NEBD at the mitotic entry. Here, we identified PP2A-B55^{SUR-6} as an essential regulatory subunit of PP2A phosphatase critical for timely NEBD in the one-cell *Caenorhabditis elegans* embryo. We found that in embryos that are depleted for PP2A-B55^{SUR-6}, nuclear membrane permeabilization is significantly delayed, and nuclear lamin and nucleoporins persist throughout mitosis. As a result, chromosomes' segregation is impaired. Notably, we found that the impact of PP2A-B55^{SUR-6} depletion on NEBD is not because of its effect on cell cycle progression or mislocalization of essential kinases such as PlK-1 or AIR-1. By performing a genetic epistasis experiment, we uncovered that nuclear lamin (LMN-1), but not nucleoporins, could be the target of PP2A-B55^{SUR-6}. Notably, genomically-tagged GFP- PP2A-B55^{SUR-6} localizes to the nucleus just before the onset of NEBD-suggesting PP2A-B55^{SUR-6} might directly regulate nuclear envelope breakdown. Overall, our findings implicate the PP2A phosphatase complex in a key process of NEBD in animal cells.

B316/P1307

Uncovering mechanisms by which barrier-to-autointegration factor controls dynamics of nuclear leakage and repair following nuclear envelope rupture

C. T. Halfmann[1], R. M. Sears[1,2], K. L. Scott[1], K. J. Roux[1,2]; [1]Sanford Research, Sioux Falls, SD, [2]Department of Pediatrics, Sanford School of Medicine, University of South Dakota, Vermillion, SD.

The nuclear envelope (NE) creates a critical barrier between the cytosol and nucleus during interphase that is key for cellular compartmentalization and protecting genomic DNA. However, the NE can rupture, a process that has been implicated in several NE-associated diseases and cancer. We and others previously reported that barrier-to-autointegration factor (BAF), a highly mobile DNA-binding protein, is required for repair of NE ruptures. Following NE rupture, BAF rushes into the nucleus, rapidly binds to nuclear DNA that is newly exposed to the cytosol, and recruits components to repair the NE, including LEM-domain proteins, A-type lamins, membranes, and ESCRT-III membrane repair machinery. To further reveal the mechanisms by which BAF aids in repairing NE ruptures, we expressed untagged BAF variants that modify its various interactions and/or localization in human fibroblasts depleted of endogenous BAF and analyzed the dynamics of NE rupture leakage and repair. We observed that BAF needs to be cytoplasmic and retain phosphoregulatable DNA binding in order to control rupture leakage and repair NE ruptures. Unexpectedly, loss of BAF's ability to recruit LEM-domain proteins or lamins via expression of a LEM-binding deficient BAF (L58R) or lamin-binding deficient BAF (A12T) did not substantially impact initial NE rupture leakage or repair efficiency, suggesting that recruitment of these proteins contribute little to the control of rupture leakage or the initial repair of NE ruptures. Inhibition of BAF dimerization prevented BAF enrichment at NE ruptures, exacerbated rupture leakage, and prevented efficient rupture repair. This was rescued by artificially tethering two BAF monomers together, suggesting that it is not just BAF's ability to bind but also crosslink DNA that leads to reduced leakage and efficient rupture repair. Our evidence also suggests that BAF creates a size-dependent diffusion barrier for proteins, with larger proteins being more significantly impeded by BAF's presence at the rupture. Surprisingly, the loss of A- or B-type lamins enables the repair of NE ruptures in BAF-depleted cells, suggesting that the nuclear lamina is inhibitory to rupture repair. Our ongoing studies seek to further understand the mechanisms by which BAF regulates rupture-induced nucleocytoplasmic exchange and the repair of NE ruptures, and mechanisms by which the nuclear lamina inhibits proper rupture repair in BAF-depleted cells.

B317/P1308

The dynamin-like protein Dnm1 mediates scission of the outer nuclear membrane in nuclear autophagy

P. J. Mannino, S. Chandra, D. J. Thaller, N. R. Ader, T. J. Melia, C. P. Lusk; Cell Biology, Yale University, New Haven, CT.

Autophagy is a catabolic process that encompasses the capture and delivery of cellular material into the lytic compartment for degradation. Autophagy can be leveraged to selectively capture and degrade damaged portions of organelles thereby maintaining homeostasis and preventing age-related decline in cellular function. How organelle membranes are remodeled in a manner that produces sub-compartments amenable to degradation by autophagy while also maintaining organelle identity and function is an open question. In comparison with other organelles (e.g., the endoplasmic reticulum and mitochondria) where many molecular details have been worked out, how the nuclear envelope (NE) is remodeled during nuclear autophagy (nucleophagy) remains ill-defined. We have been exploring nucleophagy by leveraging Atg39, a type-II integral membrane protein in budding yeast that is the only known NE cargo adaptor. We have demonstrated that Atg39 localizes to the outer nuclear membrane (ONM) likely by direct interactions between predicted amphipathic alpha helices in its lumenal domain and the lumenal leaflet of the inner nuclear membrane (INM). These sequence elements are also required for the coordinated remodeling of both the INM and ONM that captures integral INM proteins

and nuclear contents within lumenal vesicles upon Atg39 overexpression. To better understand the molecular players that execute nucleophagy, we are applying lattice light sheet microscopy (LLSM) with targeted genetic deletions to directly observe, and perturb, physiological Atg39-mediated nucleophagic events in living cells. Our data suggest that there are likely several genetically-dissectible steps in nucleophagy beginning with the condensation of Atg39 at the ONM, the capture of INM and nuclear cargo, the release of a NE fragment from the nucleus, and finally fusion with the vacuole. The entire process typically occurs within ~5 minutes. We homed in on dynamin-like protein 1 (Dnm1) as a potential factor that contributes to the cytosolic release of the NE fragment. Consistent with this hypothesis, Dnm1 colocalizes with Atg39 upon activation of nucleophagy. Analysis of *dnm1Δ* cells by LLSM revealed a stall in nucleophagy and retention of Atg39 at the nuclear periphery. Correlative light and electron microscopy at sites of Atg39 accumulation at the nuclear periphery in *dnm1Δ* cells revealed that Atg39 localized to lumenal vesicles derived from the INM that were surrounded by ONM. These data suggest that INM and ONM fission are genetically-dissectible and are likely temporally distinct events. Thus, we provide a quantitative and morphological timeline of nucleophagy and evidence that Dnm1 not only functions at mitochondria but also at the ONM.

B318/P1309

Nemp1 supports the nuclear envelope in the face of mechanical stresses to promote metazoan fertility

H. McNeill[1], A. Ganguly[1], B. Hakim[1], D. Hodzic[1], K. Ha[2], A. Pathak[1], H. Zmuda[1], Y. Tsatskis[3], A. Jurisicova[4]; [1]Washington University School of Medicine, St. Louis, MO, [2]Lunenfeld-Tanenbaum Research Institute, Toronto, ON, CANADA, [3]Sickkids, Toronto, ON, CANADA, [4]Luenfeld-Tannenbaum Research Institute, Toronto, ON, CANADA.

Nemp1 is an inner nuclear membrane protein we have shown is critical for fertility of worms, fish, flies and mice. Although Nemp1 KO mice are overtly normal, females are severely subfertile with a reduced ovarian reserve. We now show that Nemp1 mutant oocytes in mice are lost to death that occurs during early postnatal stages. Knockdown of Nemp in the *Drosophila* germline also leads to oocyte loss. Importantly knockdown of ATM and Chk2 rescue egg laying in *Drosophila*. These data suggest loss of Nemp activates a germline checkpoint. Preliminary data indicate that loss of Chk2 also rescues oocyte loss in mouse Nemp1KO ovaries. Loss of Nemp1 mutant oocytes occurs in the highly cross-linked ovarian cortex and loss of Nemp1 leads to a softer nuclear envelope (NE) in AFM studies. We hypothesized that the highly cross-linked ovarian cortex provided a mechanical stress that led to death of Nemp1KO oocytes. Collagen cross-linking is mediated by enzymes known as lysyl oxidases. We now show that loss of one genomic copy of LOX leads to a softer ovary. Remarkably, Nemp1KO, LOX+/- females have a partial restoration of fertility, supporting the proposal that Nemp1 acts to protect oocytes against mechanical stresses. Cultured cell experiments show that lethality associated with loss of Nemp1 is rescued when cells are plated on soft substrates. These data highlight the importance of Nemp1 and the nuclear envelope in protecting cells against mechanical stresses.

B319/P1310

The role of Prm3p in nuclear envelope expansion during yeast mating response

E. C. Morgan, V. Meleshkevich, O. Cohen-Fix; National Institutes of Health, Bethesda, MD

Despite the essential role the nucleus plays in numerous physiological processes, several fundamental features of its morphology and function remain unexplored. In particular, the mechanisms that determine nuclear size and shape are largely unknown. Altered nuclear size is observed in diseases such as cancer, and abnormal nuclear shape is often seen in aging cells. Nuclear morphology also changes in several developmental contexts. For example, hematopoietic stem cells possess a large oval-shaped nucleus that forms increasingly large invaginations during differentiation into a mature neutrophil, resulting in a large multi-lobed nucleus. Given this link between cell function and nuclear morphology, we sought to characterize the processes that regulate nuclear size and shape. The nucleus is surrounded by the nuclear envelope (NE), which is composed of two nuclear membranes that are continuous with the endoplasmic reticulum (ER). To study how the nucleus remodels its shape we use the budding yeast *Saccharomyces cerevisiae,* which displays altered nuclear morphology when exposed to mating pheromone. As part of the mating response, yeast cells arrest in G1 and their nuclei elongate. We determined that this takes place through an expansion of the NE without a proportional increase in nuclear volume. Since the yeast mating response is controlled largely by the transcription factor Ste12p, we conducted a high-throughput screen to determine which Ste12p-induced genes are necessary for the observed NE expansion. We found that absence of *PRM3*, which is highly induced upon pheromone exposure, resulted in significantly rounder nuclei during alpha factor treatment despite an otherwise robust transcriptional response. Thus, Prm3p appears to be a key regulator of NE expansion during yeast mating response. Prm3p is a 133aa protein that localizes to the nuclear envelope via a C-terminal anchor, and is conserved in budding yeasts. Prm3p may influence NE expansion in a variety of ways, from recruiting phospholipid synthesis-linked enzymes to influencing local membrane composition to permit expansion. We are currently generating a suite of *PRM3* partial deletion mutants with CRISPR-Cas9 to assess which portions of the protein are specifically necessary for NE expansion, and what mechanism of NE expansion Prm3p may facilitate.

Cell type-specific response to rupture of the nuclear envelope

Y. Kamikawa[1], A. Saito[1], Z. Wu[1], K. Imaizumi[2]; [1]Hiroshima University, Hiroshima, Japan, [2]Hiroshima University, 広島市南区霞1, Japan

Recent works have highlighted that the nuclear envelope (NE) is damaged by various stress, such as mechanical stress under confined cellular migration, referred to as NE stress. NE stress leads deformation of the nucleus and even rupture of the NE. The molecular mechanisms that repair ruptured NE are extensively studied and crucial repair factors have been identified including a DNA binding protein BAF and its binding partner LEM domain proteins. We previously identified an endoplasmic reticulum resident trans-membrane transcription factor OASIS/CREB3L1 as a factor that responds to NE stress. The expression of OASIS is restricted to specific types of cells such as astrocytes and osteoblasts, suggesting cell-type specific response to the NE stress. To test this idea, the consequences of NE stress were compared in a variety of cancer cell lines using Boyden chamber assay, where cells migrate through constricted space of the porous membrane. We found that nuclear deformation as well as DNA damage induced by NE stress varies among these cell lines. Furthermore, live cell imaging revealed the

failure of repairing of ruptured NE in a certain type of cell line. Collectively, the response to NE stress and its underlaying molecular mechanisms are likely cell-type specific.

B321/P1312

Small, fat-filled lipid droplets are sufficiently rigid to indent a nucleus, dilute the lamina, and cause rupture

I. Ivanovska, M. Tobin, **D. Discher**; University Pennsylvania, Philadelphia, PA

The nucleus in many cell types is a stiff organelle, and yet fat-filled lipid droplets (FD's) in the cytoplasm are somtimes seen to indent and displace the nucleus. FD's are phase-separated liquids with a poorly understood interfacial tension γ that determines how FD's interact with other organelles. Here, micron-sized FD's remain spherical as they indent both the nucleus and peri-nuclear actomyosin, dilute Lamin-B1 locally independent of Lamin-A,C, and trigger rupture with locally persistent accumulation in the nucleus of cGAS, a cytosolic DNA sensor. FD-nucleus interactions initiate rapid mis-localization of the essential DNA repair factor KU80, and nuclear rupture associates with DNA damage and perturbed cell cycle. Similar results are evident in FD-laden cells after constricted 3D-migration, which is impeded by FD's. Spherical shapes of small FD's are consistent with a high γ that we measure for FD's mechanically isolated from fresh adipose tissue as ~40_mN/m - which is far higher than other liquid condensates, but typical of oils in water and sufficiently rigid to disrupt cell structures.

B322/P1313

Investigating the role of nuclear envelope permeability during budding yeast meiosis

M. Walsh, G. King, K. Chetlapalli, E. Ünal; University of California, Berkeley, Berkeley, CA

The nuclear envelope functions to separate nuclear material from cytoplasm, which is important for regulating cellular processes, separating transcription from translation, and protecting DNA. Studying natural changes to the nuclear envelope allows us to gain better insight as to how nucleocytoplasmic transport is established and maintained. In some types of cells, the nuclear envelope is disassembled during cell division, whereas other cells maintain the integrity and transport capabilities of the nuclear envelope throughout division. In the budding yeast *Saccharomyces cerevisiae*, mitotic divisions and the first meiotic division maintain nuclear integrity. However, during meiosis II, there is a transient change in the nuclear barrier which allows for nucleoplasmic proteins to diffuse throughout the cell. Notably, the nuclear envelope remains largely intact by electron microscopy (EM). This phenomenon also occurs in the fission yeast *Schizosaccharomyces pombe*, but its regulation and function remain enigmatic in both yeasts. This project aims to investigate the changes in nuclear envelope permeability in *S. cerevisiae* and determine the underlying regulatory mechanism(s).

B323/P1314

The role of Vps4 in ESCRT-III-mediated nuclear sealing

L. Chen, N. R. Ader, M. C. King, C. P. Lusk; Yale, New Haven, CT

Abstract Title: *The role of Vps4 in ESCRT-III-mediated nuclear sealing*Track: Cellular DynamicsAuthors: Linda Chen, Nicholas R. Ader, Megan C. King*, and C. Patrick Lusk**co-last authors
During metazoan cell division, the nuclear envelope (NE) disassembles upon mitotic entry before reassembling in mitotic telophase just prior to cytokinesis. Perturbation of this process is associated with

DNA damage and cell death. In human cells, the ATPase associated with diverse cellular activities (AAA+ ATPase) VPS4 has been implicated in the sealing of holes in the reassembling NE in concert with the endosomal sorting complexes required for transport-III (ESCRT-III) machinery. However, how VPS4 mediates this sealing in conjunction with the ESCRT-III machinery remains unclear. Specifically, it is an unresolved question whether VPS4 acts solely as a "disassemblase" for ESCRT-III filaments, or rather, if it is required for the maturation of the ESCRT-III complex early in the NE sealing process. Here, we use the sealing of the singular mitotic NE hole that occurs in the fission yeast *Schizosaccharomyces pombe* to investigate the precise role of Vps4 in regulating ESCRT-III activity at the NE. We find that endogenous expression of a Vps4 hypomorph is sufficient to drive the aberrant and constitutive localization of the first ESCRT protein to be recruited to the NE, Cmp7. Notably, this phenotype contrasts with our observations in cells lacking the downstream ESCRT-IIIs, Did4 and Vps24, where Cmp7 accumulates but is still removed at the following cell cycle. Surprisingly, cells expressing this Vps4 do not display a defect in nucleocytoplasmic compartmentalization, as measured by a fluorescent reporter of nuclear integrity. Overall, our work suggests that Vps4 plays a key role in ESCRT-III processive remodeling by allowing for the removal of Cmp7 and complete ESCRT-III filament assembly.

B324/P1315

CTDNEP1 inhibits interphase nuclear membrane rupture

A. I. Yashchenko, A. L. Gunn, E. M. Hatch; Fred Hutchinson Cancer Center, Seattle, WA

The nuclear envelope serves as a barrier between the DNA and the cytoplasm and transient loss of NE compartmentalization in interphase leads to increased genome instability, cell invasion, and metastasis. Several conditions contributing to nuclear membrane rupture, including nuclear compression and loss of lamin proteins, have been identified, but many factors regulating nuclear membrane stability and the molecular mechanisms of membrane repair remain unclear. To comprehensively identify proteins regulating nuclear membrane rupture and repair, we used a fixed-cell nuclear integrity reporter, based on the persistence of large cytoplasmic proteins in the nucleus after membrane repair, to develop a high-content siRNA screening pipeline. We performed a pilot screen and identified CTD nuclear envelope phosphatase 1 (CTDNEP1) as a top hit that increased nuclear membrane rupture upon depletion. CTDNEP1 localizes to the inner nuclear membrane, activates lipin 1, an enzyme catalyzing diacylglycerol (DAG) synthesis, and is critical for proper nuclear envelope assembly. We confirmed CTDNEP1 knockdown by qRT-PCR and observed an expected increase in ER area after siRNA transfection by immunofluorescence. We validated our screen result using two independent siRNAs against CTDNEP1 and observed a 2.4-fold increase in NE rupture frequency upon CTDNEP1 depletion and a modest increase in rupture duration by live-cell imaging with both siRNAs. To determine how CTDNEP1 depletion increases membrane rupture, we analyzed known rupture factors by immunofluorescence, including actin organization, nuclear lamina protein localization, and nuclear lamina organization. Qualitative analysis did not identify gross changes in any of these categories upon CTDNEP1 depletion, suggesting that CTDNEP1 acts in a new pathway, potentially directly on membrane mechanics. We are currently working to quantify our immunofluorescence assays and observe changes in membrane characteristics to better understand how CTDNEP1 regulates nuclear membrane stability.

B325/P1316

Biochemical analysis of lamin subunits suggests mutiple layers of regulation for lamin filament assembly

R. T. A. Pedersen, Y. Zheng; Carnegie Institution of Washington, Baltimore, MD

In metazoan cells, type V intermediate filaments proteins called lamins form a meshwork that underlies the nuclear envelope and supports the shape, organization, and function of the nucleus. During open mitosis, lamin filaments disassemble at mitotic entry and reassemble after anaphase. Disassembly of the lamin network has been shown to be triggered by phosphorylation of lamin subunits. Dephosphorylation of lamin subunits as the activity of mitotic kinases subsides is presumed to lead to reassembly of lamin filaments as the nucleus reforms, but the precise molecular pathway of lamin network reassembly remains obscure.
Here, we present analysis of endogenous lamin proteins in *Xenopus laevis* egg extracts that suggests that dephosphorylation alone cannot fully account of the regulated reassembly of lamin filaments following mitosis. Although metaphase-arrested extracts are characterized by high mitotic kinase activity and interphase-arrested extracts are characterized by high phosphatase activity, we find that the egg- and embryo-specific lamin isoform lamin-B3 is largely soluble in both types of extracts. The more ubiquitous B-type lamin, lamin-B1, is less soluble in both metaphase and interphase extracts, although this disparity between lamin-B3 and lamin-B1 is due at least in part to lamin-B1's larger membrane-bound population. The observation of soluble lamin protein in interphase extracts could be explained at least three ways: (1) lamin subunits are not dephosphorylated in these extracts, (2) dephosphorylation of lamin subunits is not alone sufficient to drive assembly, or (3) lamin assembly has a high critical concentration, so there is a large pool of soluble lamin subunits even after filament assembly. Analysis of the phosphorylation states of lamin-B1 and lamin-B3 demonstrates that both are hyperphosphorylated in interphase extracts, much as they are in metaphase extracts, suggesting that dephosphorylation of lamins at mitotic exit may be a regulated process rather than a widespread phenomenon. We propose that lamin assembly may be subject to multiple layers of molecular control, including both temporal regulation by the cell cycle state and spatial regulation by lamin subunit binding proteins.

Endosomes, Lysosomes, and Lysosome-related Organelles

B327/P1317

Golgi-derived vesicles facilitate the fission of lysosomal tubules by modulating lysosomal PI(3)P levels

M. Boutry[1], L. DiGiovanni[1], N. Demers[1], A. Fountain[2], S. Mamand[2], R. Botelho[2], P. K. Kim[1]; [1]Program in Cell Biology, The hospital for Sick Children, Toronto, ON, CANADA, [2]Toronto Metropolitan University, Toronto, ON, CANADA.

Lysosome reformation requires the recycling of lysosome membrane components from lysosomal organelles such as autolysosomes, endolysosomes and phagolysosomes. Membrane recycling involves the formation and fission of tubules emerging from lysosomal organelles. However, the mechanisms governing these processes in the different forms of lysosomal organelles are poorly understood. Further complicating the field is the potential differences in the recycling mechanism between lysosomal organelles. For instance, phosphatidylinositol-4-phosphate (PI(4)P) has been shown to promote the formation of tubules from phagolysosomes, whereas PI(4)P formed by PI4KIIIβ on autolysosomes has

been proposed to inhibit tubules formation. Using super-resolution live-cell imaging and manipulation of PI(4)P at lysosomal organelles, we investigated the role of PI(4)P in the formation of tubules from three different forms of lysosomal organelles. We find that PI(4)P is required to generate tubules from lysosomal organelles. Moreover, we show that PI4KIIIβ-dependent Golgi-derived vesicles are recruited to lysosomal organelles tubules fission sites where they actively contribute to the fission process by mediating a PI(3)P signaling. Our findings suggest a unifying mechanism for tubule formation and fission from lysosomal organelles, where PI(4)P promotes the formation of lysosomal tubules and PI4KIIIβ-mediated Golgi-derived vesicles regulate lysosomal PI(3)P to drive the fission process.

Lysosomes contain an expansion compartment that mediates zinc transporter delivery to promote zinc homeostasis in*C.elegans*

A. Mendoza[1], N. Dietrich[2], C. Tan[3], D. Herrera[1], J. Kasiah[1], Z. Payne[1], D. Schneider[1], K. Kornfeld[1]; [1]Washington University, St. Louis, MO, [2]NIEHS, Epigenetics and Stem Cell Biology Laboratory, Durham, NC, [3]California Institute of Technology, Pasadena, CA.

Zinc is a transition metal that is essential for all life. Conserved zinc homeostatic mechanisms exist to respond when cytosolic levels are too low or too high. The Kornfeld lab uncovered high and low zinc homeostasis pathways in *C. elegans* that are involved in sensing cytosolic zinc levels and responding to return to homeostasis. Zinc dyshomeostasis leads to multiple human pathologies. Intestinal lysosomes are a site of zinc trafficking. The zinc exporter, CDF-2 stores zinc within lysosomes. We predicted that a mechanism exists to release zinc from lysosomes since there is one that stores it. To identify the zinc transporter that imports zinc we performed confocal fluorescence microscopy and showed that ZIPT-2.3 co-localizes with CDF-2. To determine ZIPT-2.3 function, we performed genetic and biochemical assays to show that ZIPT-2.3 imports zinc into the cytoplasm, and that the *zipt-2.3* gene is necessary for this function in zinc deficient conditions. Because CDF-2 and ZIPT-2.3 co-localize to gut granules, we tested their relationship by measuring their changes in expression in zinc replete, deficient, and excess conditions. Analysis showed that *cdf-2* and *zipt-2.3* mRNA and CDF-2 and ZIPT-2.3 protein expression is reciprocally regulated. Super resolution microscopy revealed that in addition to housing CDF-2 and ZIPT-2.3, lysosomes alter their morphology in response to available cytosolic zinc. Using line scans, we defined specific compartments and membrane boundaries across zinc conditions. Lysosomes contain acidified and expansion compartments. ZIPT-2.3 and CDF-2 populate membranes that surround the acidified compartment, while CDF-2 is localized to the expansion compartment. The acidified compartment is comprised of distinct regions named the LysoTracker and zinc regions. The expansion compartment is highly dynamic and deviates greatly in size. Our model predicts that in zinc deficient conditions, ZIPT-2.3 expression increases and CDF-2 expression decreases, promoting the net flow of zinc into the cytosol. In zinc excess conditions, CDF-2 expression increases, and ZIPT-2.3 expression decreases, facilitating net flow into the gut granule. The expansion compartment expands in zinc excess conditions but shrinks in zinc deficient and zinc replete conditions. Based on our observations we conclude that the purpose of the expansion compartment is to provide a structure for zinc trafficking while allowing the lysosome to participate in its canonical activities. Future studies will focus on how the expansion compartment is formed and if expansion compartment form in human lysosomes

B329/P1319

Fig4/PIKfyve/Vac14 complex loss of function results in altered PI4P subcellular distribution and calcium homeostasis

C. Kutchukian, V. A. Lam, M. Casas, A. J. Yarovaya, R. E. Dixon, E. J. Dickson; Physiology and Membrane Biology, University of California, Davis, Davis, CA.

At endosomal membranes, the phosphoinositide (PI) 5-phosphatase Fig4 and the PI 5-kinase PIKfyve function in a complex with the scaffold protein Vac14 to finely tune the synthesis and turnover of the low-abundant signaling lipid PI(3,5)P_2, essential for membrane trafficking and endocytosis. In humans, loss-of-function mutations in the genes encoding Fig4 and Vac14 cause severe neurological disorders including the amyotrophic lateral sclerosis, Charcot Marie Tooth disease and Yunis-Varón syndrome, highlighting a pivotal role for this complex in maintaining neuronal integrity. Multiple studies have reported that despite their divergent roles, Fig4, PIKfyve, or Vac14 loss-of-function result in similar decreases in PI(3,5)P_2, suggesting a common pathomechanism. An important unanswered question is whether Fig4/PIKfyve/Vac14 complex disruption impairs the cellular distribution of other PIP species. In the present study, we report that PI4P levels are significantly decreased at the trans-golgi network (TGN) in *FIG4*, *PIKFYVE* or *VAC14*-deficient HAP1 cells and in neurons treated with pharmacological inhibitors of class III PI 3-kinase and PIKfyve. We demonstrate that these changes are likely caused by reduced TGN levels of PI4P-generating enzymes PI4KIIα and PI4KIIIβ, as well as an enhanced oxysterol-binding protein (OSBP)-mediated PI4P transfer from the TGN to the endoplasmic reticulum at membrane contact sites (MCS). Functionally, decreases in TGN PI4P result in alterations in trafficking patterns from the TGN that influence plasma membrane voltage-gated calcium channels. We determined, using super-resolution microscopy and electrical field stimulation, that voltage-gated calcium channel distribution and activity is altered in neurons treated with class III PI 3-kinase and PIKfyve inhibitors. Upstream of changes in voltage-gated calcium channel dynamics is enhanced nuclear translocation of the transcription factor EB. Overall, our results suggest that the Fig4/PIKfyve/Vac14 complex tunes the molecular contents of ER-Golgi MCS to influence anterograde membrane trafficking and voltage-gated calcium channel distribution and activity. We propose that these deviant changes in lipid and calcium signaling pathways contribute to neurodegeneration in neurons with disrupted Fig4/PIKfyve/Vac14 complex function.

B330/P1320

The gastrosome: a new compartment in the phagocytic pathway

J. Zareba, E. Cattaneo, F. Peri; Department of Molecular Life Sciences, University of Zurich, Zurich, SWITZERLAND.

Phagocytosis is a central process for immunity and maintenance of tissue homeostasis. This way, professional phagocytes, such as tissue-resident macrophages, efficiently remove foreign particles and large apoptotic cells. While the engulfment of these targets is well understood, their subsequent digestion and recycling remain mostly unclear, even though these steps are essential to ensure proper phagocytosis. Recent work in zebrafish microglia and mammalian macrophages led to the discovery of the "gastrosome," a new compartment in the phagocytic pathway. Live imaging has shown that this unique vesicle fuses with mature phagosomes and functions as a collection compartment. Increased phagocytosis causes the dramatic enlargement of the gastrosome affecting cellular morphology and motility. To uncover the regulation and role of this newly discovered compartment we have taken chemical and reverse genetic approaches. This identified Npc1 and ABC transporters as essential in

phagocytosis and gastrosome biology. The development of new phagocytic markers in zebrafish has allowed real-time mapping of vesicular interactions over time providing new insights into the spatio-temporal coordination of phagocytosis, the role of the gastrosome, and how microglia react when these transporters are blocked.

B331/P1321

Toll-like receptor signaling remodels the lysosomal system in macrophages

N. Ilic, A. Logli, R. Botelho; Biology, Toronto Metropolitan University, Toronto, ON, CANADA.

Pattern recognition receptors (PRRs) play a central role in innate immunity by binding to conserved microbe-associated molecular patterns (MAMPs) displayed by microbes. PRR-MAMP binding leads to the downstream activation of several signalling pathways to prime the immune system for defence against these infectious threats. There are several families of PRRs that recognize specific types of MAMPs associated with specific classes of microbes. One such family of PRRs is the Toll-like receptors (TLRs), a group of transmembrane receptors found in the plasma membrane or the endosomes. Another family of PRRs are the NOD-like receptors (NLRs), a family of cytosolic receptors. Lipopolysaccharides (LPS) from gram-negative bacteria engage the plasma membrane TLR4 signalling. Previously, LPS-TLR4 signalling was shown to remodel the lysosomal system in macrophages and dendritic cells into an expanded, tubular network that appears to promote uptake of extracellular fluid and antigen presentation. These adaptations caused by TLR4 were found to be dependent on the mechanistic target of rapamycin (mTOR) pathway. However, there is little evidence of whether other TLRs and PRRs like NOD proteins also cause lysosome remodelling. Since lysosomes are critical in digesting microbes engulfed by phagocytosis, processing antigens, and antigen presentation, we aimed to analyze whether all other members of the TLR family (TLR1-9) and members of the NLR family (NOD1-2) caused lysosome remodelling in murine bone marrow-derived macrophages. We stimulated macrophages with cognate ligands of each TLR for 2 h and found that this caused lysosome tubulation and expansion, though to varying degrees. For example, Pam3CSK4, which stimulates TLR1/2, caused extensive tubulation, while HKLM, a TLR2 ligand, was more subdued. TLR ligands also had varying effects on lysosome expansion; while ODN1826, a TLR9 ligand, caused the largest expansion, stronger than LPS, there was no significant difference in total lysosome volume by ligands activating TLRs2-7. In contrast, agonists of NOD1 and/or NOD2 were relatively less potent in both tubulating and expanding total lysosome volume within 2 h of stimulation. To further investigate, we seek to identify if the mTOR pathway is required for the lysosome adaptations in activated macrophages and their impact on uptake of extracellular material and antigen presentation. Overall, we aim to determine the similarities and differences in the actions of endosomal and plasma membrane TLRs, which can potentially be helpful for future adjuvant research. Overall, our research provides a better understanding of PRR signalling and how lysosome remodelling may aid in immunity.

B332/P1322

Understanding the Significance of Unconventional Golgi Lysosome Interplay in Epidermis Homeostasis

S. MAHANTY[1], P. Bergam[2], D. Nair[3], V. Belapurkar[3], L. Eluvathingal[3], G. Raposo[2], S. Rao Gangi Setty[1]; [1]Department of Microbiology & Cell Biology, Indian Institute of Science, Bangalore, INDIA, [2]UMR 144, Structure and Membrane Compartments, Institut Curie, Paris, FRANCE, [3]Centre for Neuroscience, Indian Institute of Science, Bangalore, INDIA.

The outer skin layer epidermis provides a hydrophobic and antimicrobial barrier to the body and, is critical in maintaining skin health and hygiene. Keratinocytes are the major cellular constituent of epidermis which maintains skin barrier homeostasis through regulated differentiation. During differentiation, keratinocytes produce a class of lysosome-related organelles (LRO) called epidermal lamellar bodies (LBs) which critically regulate the skin barrier formation and homeostasis. In line, impairment in LBs formation is associated with life-threatening skin disorders. However, the molecular mechanism of LBs biogenesis/secretion remain unknown. Even though LBs share part of their cargoes with the conventional lysosomes and, their *trans* Golgi origin is speculated on the basis of electron microscopy (EM) observation, the role of neither of these organelles is elucidated so far in the context of LBs biogenesis. We revealed unique dispersed Golgi morphology and extensive dispersion of lysosomes in our *in vitro* model of differentiated keratinocytes. Remarkably, dispersed Golgi stacks make frequent contact with the lysosomes as observed by super-resolution live and steady-state experiments. Further observation by conventional EM and, immunogold labeling of ultrathin cryosections (immuno-EM) of differentiated keratinocytes show extensive vesicular Golgi morphology and its contact with the lysosomes. The Golgi lysosome contact is possibly tethered by peripheral Golgi protein GRASP65. In line, siRNA-mediated inhibition of GRASP65 led to the loss of Golgi-lysosome contact which in turn results in aberrant lysosome morphology and perinuclear accumulation of giant lysosome structures. Exploiting specific inhibition and gene expression approaches, we further reveal a possible direct role of functional Golgi and, the Golgi to lysosome contact respectively in the generation and maintenance of keratinocyte lysosomes. Taken together, our study highlights the modulation of Golgi morphology and, unravels its coordination in the generation of keratinocyte lysosomes which play a critical role in epidermis homeostasis. In my presentation, I will further emphasize how this interplay between Golgi and lysosomes possibly favors the biogenesis of LBs and its overall significance in keratinocyte physiology.

Syntaxin 12 and COMMD3 are new factors that function with VPS33B in the biogenesis of platelet α-granules

A. L. Ambrosio, H. P. Febvre, S. M. Di Pietro; Colorado State University, Fort Collins, CO.

Blood circulating platelets are megakaryocyte-derived cells that mediate blood clotting and regulate angiogenesis, inflammation and malignancy. They accomplish these functions by releasing the content of their granules to circulation upon platelet activation. In particular, platelet α-granules are lysosome-related organelles that contain hundreds of proteins including growth and angiogenic factors and cytokines. Despite the fundamental role of α-granules, both in health and disease, their biogenesis is unclear. Mutations in only three proteins are known to cause α-granule defects and bleeding disorders in humans. Two such proteins, VPS16B and VPS33B, form a complex mediating transport of newly synthesized α-granule proteins through megakaryocyte endosomal compartments. It is unclear how the VPS16B/VPS33B complex accomplishes this function. Here we report VPS16B/VPS33B associates

physically with Stx12, a SNARE protein that mediates vesicle fusion at endosomes. Importantly, Stx12 deficient megakaryocytes display reduced α-granule numbers and overall levels of α-granule proteins, thus revealing Stx12 as new component of the α-granule biogenesis machinery. VPS16B/VPS33B also binds CCDC22, a component of the CCC complex working at endosome exit sites. CCDC22 competes with Stx12 for binding to VPS16B/VPS33B suggesting a possible hand-off mechanism. Moreover, the major CCC form expressed in megakaryocytes contains COMMD3, one of ten COMMD proteins. Deficiency of COMMD3/CCDC22 causes reduced α-granule numbers and overall levels of α-granule proteins, establishing the COMMD3/CCC complex as a new factor in α-granule biogenesis. Furthermore, P-Selectin traffics through the cell surface in a COMMD3-dependent manner and depletion of COMMD3 results in lysosomal degradation of P-Selectin and PF4. In conclusion, we identified two new players in α-granule biogenesis, Stx12 and COMMD3/CCC, making them candidates for platelet storage pool disorders of unknown molecular etiology. Mechanistically, our results suggest VPS16B/VPS33B coordinates the endosomal entry and exit of α-granule proteins by linking the fusogenic machinery with a ubiquitous endosomal retrieval complex that is repurposed in megakaryocytes to make α-granules.

B334/P1324

OCA7 defines pigmentation by regulating early stages of melanosome biogenesis

W. Beyers, A. Detry, S. Di Pietro; Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO.

Mutations in C10orf11 (OCA7) cause OculoCutaneous Albinism, a disorder that presents with hypopigmentation in skin, eyes and hair. The OCA7 pathophysiology is unknown and there is virtually no information on the OCA7 protein and its cellular function. Here, we discover that OCA7 localizes to the limiting membrane of melanosomes, the specialized pigment cell organelles where melanin is synthesized. OCA7 is recruited through interaction with a canonical effector binding surface of melanosome proteins Rab32 and Rab38. Using newly generated OCA7-KO MNT1 cells, we show OCA7 regulates overall melanin levels in a melanocyte autonomous manner by controlling melanosome maturation. Interestingly, we found OCA7 regulates PMEL processing, impacting fibrillation and the striations that define transition from melanosome Stage I to Stage II. Furthermore, the melanosome lumen of OCA7-KO cells displays lower pH than control cells. Together, our results reveal OCA7 regulates pigmentation through two well established determinants of melanosome biogenesis and function, PMEL processing and organelle pH.

B335/P1325

Effect of a Minor Phosphatidylinositol Phosphate on a Secretory Granule in Platelet and Megakaryocyte

C. Lu[1,2], A. Lee[1], L. Li[2], F. Pluthero[2], W. Kahr[2,1]; [1]Biochemistry, University of Toronto, Toronto, ON, CANADA, [2]Cell Biology, The Hospital for Sick Children, Toronto, ON, CANADA.

Platelets are blood cells that play a key role in hemostasis, inflammation and wound healing. They are derived from megakaryocytes (MKs) which mostly reside in bone marrow. Many aspects of platelet function are related to the release of proteins from α-granule, a lysosome-related-organelle which contain proteins such as fibrinogen and Von Willebrand factor (VWF). Neurobeachin-like 2 (NBEAL2) is required for the retention of cargo proteins by α-granules. NBEAL2 deficiency in MKs leads to the bleeding disorder Gray Platelet Syndrome (GPS), so called because patient platelets look pale in a blood

smear due to the lack of α-granules. The mechanism by which NBEAL2 recognizes α-granules to facilitate the maturation and stability of is unclear.Phosphatidylinositol phosphates (PIPs) comprise less than 1% of cellular lipids, yet they regulate fundamental biological processes including signalling, vesicle trafficking, and membrane dynamics. The specific intracellular distribution of PIPs is key to their role in regulating membrane trafficking and downstream signaling pathways. $PI(3,5)P_2$, a minor PIP localized to multivesicular bodies (MVBs) and lysosomes, plays a pivotal role in endosomal maturation. $PI(3,5)P_2$ can be only generated by the PIKfyve (phosphoinositide kinase, FYVE-type zinc finger containing) lipid kinase.NBEAL2 has a Pleckstrin homology (PH) domain, which is commonly found in PIP binding proteins. We hypothesize that NBEAL2 interacts with the membranes of α-granules via interaction with granule-associated PIPs. Our in-vitro data shows NBEAL2 and its PH-BEACH subdomain preferentially binds $PI(3,5)P_2$. One GPS-associated missense mutation abrogates $PI(3,5)P_2$ binding. We demonstrate that NBEAL2 interacts with PIKfyve complex using co-immunoprecipitation. Pharmaceutical inhibition of $PI(3,5)P_2$ synthesis in MKs causes a disassociation between NBEAL2 and α-granule membrane. We also observe a premature secretion of VWF from α-granules which recapitulates the phenotype of NBEAL2 deficient MKs. Our data suggests that the interaction of NBEAL2 and $PI(3,5)P_2$ is critical in α-granule maturation and MK cargo protein trafficking.

B336/P1326

In vitro reconstitution of calcium-dependent recruitment of the human ESCRT machinery in lysosomal membrane repair

S. Shukla, K. P. Larsen, C. Ou, K. Rose, J. H. Hurley; Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA.

The endosomal sorting complex required for transport (ESCRT) machinery is central to endolysosomal and plasma membrane repair. ESCRT recruitment to sites of damage occurs on a fast time scale, and Ca^{2+} has been proposed to play a key signaling role in the process. However, the upstream components needed to orchestrate the membrane repair process are poorly understood. With the goal of bridging this gap in understanding, we biochemically reconstituted the membrane repair machinery. Here, we show that the Ca^{2+}-binding regulatory protein ALG-2 binds directly to negatively charged membranes in a Ca^{2+}-dependent manner. Next, by monitoring the colocalization of ALIX with ALG-2 on negatively charged membranes, we attest to the upstream role of ALG-2 in bringing ALIX to the membrane. Furthermore, we show that ALIX recruitment to membrane orchestrates the downstream assembly of late-acting CHMP4B, CHMP3, and CHMP2A subunits along with the AAA+ ATPase VPS4B. Finally, we show that ALG-2 can also recruit the ESCRT-III machinery to the membrane via the canonical ESCRT-I/II pathway. Our reconstitution experiments delineate the minimal sets of components needed to assemble the entire membrane repair machinery and open a new avenue for the mechanistic understanding of endolysosomal membrane repair.

B337/P1327

Proinflammatory macrophages are better at clearing aggregated LDL and are more prone to foam cell formation

C. J. Ma, N. Steinfeld, F. R. Maxfield; Biochemistry, Weill Medical College/Cornell University, New York, NY.

Atherosclerosis is a chronic disease associated with long-term dyslipidemia and inflammation. The development of atherosclerotic plaque starts with foam cell formation, where macrophages infiltrate the intima of the aortic wall to digest modified low-density lipoproteins (LDLs). Pathology of atherosclerotic lesions showed that most of the modified LDLs are aggregated (agLDL) and retained in the aortic wall. Our lab has previously described the formation of an extracellular, acidic, hydrolytic compartment (lysosomal synapse), by which macrophages catabolize agLDL in a process termed digestive exophagy. In a recent study, we further demonstrated that macrophage-mediated digestive exophagy of agLDL is regulated by the Toll-like receptor 4 (TLR4) signaling pathway. Because TLR4 is a known regulator of inflammation, we hypothesized that macrophage interacting with agLDL would activate the macrophages into a pro-inflammatory state, and this activation would further enhance the catabolism of agLDL- leading to increased foam cell formation. To investigate whether digestive exophagy of agLDL results in an inflammatory response, we showed that agLDL treated-macrophages showed an increase in NFκB phosphorylation. In addition, we cultured macrophages expressing the inflammasome marker ASC-citrine with agLDL or acetylated LDL (AcLDL). We observed a gradual increase in the number of inflammasomes over a 24 h period in agLDL treated cells, whereas no changes were observed in AcLDL treated cells. Furthermore, lipopolysaccharide-primed and pro-inflammatory (M1) macrophages also demonstrated increased exocytosis of lysosomal contents to agLDL, an indication for increased digestive exophagy, when compared with non-activated (M0) or anti-inflammatory (M2) macrophages. Interestingly, M2 macrophages showed a decrease in lysosome exocytosis when compared to M0 macrophages. A similar trend is observed in their ability to form lysosomal synapses, which is measured by the degree of local actin polymerization around agLDL. Lastly, treating macrophages with MCC950, an NLRP3 inhibitor that blocks inflammasome formation and IL-1β release, significantly decreased exocytosis of lysosomal content. Overall, our data provide evidence that pro-inflammatory macrophages are the main contributors to the digestive exophagy of agLDL, and it is possible to modulate digestive exophagy by altering the inflammatory state of macrophages.

B338/P1328

Characterizing a novel mechanism that contributes to the development of atherosclerosis

N. Steinfeld, C. J. Ma, F. R. Maxfield; Weill Medical College/Cornell University, New York, NY.

The development of atherosclerosis is characterized by excessive cholesterol ester and lipid accumulation in macrophages, leading to foam cell formation. In atherosclerotic lesions, most lipoproteins are aggregates that are tightly crosslinked to the extracellular matrix, which makes digesting aggregated lipoproteins by endocytosis or phagocytosis difficult. Thus, it has been unclear how the cholesteryl esters in the core of aggregated extracellular LDL (agLDL) are hydrolyzed. Our laboratory's recent studies demonstrate a novel mechanism by which macrophages create tightly sealed compartments that surround portions of the aggregated LDL. These compartments are acidified by secretion of lysosomal enzymes, creating what we have termed a lysosomal synapse. Within the lysosomal synapse, cholesteryl esters are hydrolyzed by secreted lysosomal acid lipase leading to the

production of unesterified cholesterol outside the cell, in a process we have termed digestive exophagy (Reviewed in Maxfield et al., Traffic 2020). We believe that the transport of this cholesterol into macrophages is a primary driver of foam cell formation. However, many gaps remain in our understanding of the signaling and machinery involved in digestive exophagy, especially in the control of lysosome exocytosis.

We have data implicating the phospholipase Cγ1/2 (PLCγ1/2) and protein kinase Cα (PKCα) signaling axis in digestive exophagy based on both pharmacological treatment and genetic manipulation. Both inhibition of PLC using U73122 and siRNA knockdown of PLCγ1 or PLCγ2 results in a sharp reduction of lysosome secretion towards agLDL. PLC cleaves phospholipids into diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). Soluble IP_3 then binds to the IP_3 receptor on a ligand-gated Ca^{2+} channel, leading to the release of Ca^{2+} into the cytoplasm. Chelation of Ca^{2+} using BAPTA-AM leads to a near total loss of lysosome exocytosis towards agLDL. Further downstream, conventional PKC isoforms are regulated by both DAG and Ca^{2+}. Treatment of macrophages with a DAG mimic and PKC activator, PMA, lead to a near 8-fold increase in lysosome exocytosis towards agLDL, while siRNA knockdown of PKCα reduced lysosome secretion upon contact with agLDL. We are in the process of further characterizing this mechanism and are pursuing both targeted and unbiased approaches to identifying novel regulators of this process.

B339/P1329

Rab7-positive late endosomes show rapid responses to lysosomal membrane permeabilization

R. Mulligan, B. Winckler; University of Virginia, Charlottesville, VA

Lysosomes are the main degradative organelles of the cell, responsible for macromolecular turnover and cellular signaling. Maintenance of proper lysosomal function is integral as lysosomal disruption compromises proteostasis, contributes to cellular dysfunction and threatens cellular death. Lysosomal membrane permeabilization (LMP) is one common form of lysosomal disruption that occurs in many pathologies, notably those impacting the central nervous system such as neurodegeneration and stroke. While homoeostatic cellular responses have been described to address LMP at the level of the lysosome, the role of endosomes in LMP have not been elucidated, despite their interconnectedness to lysosomal function. Using LLOMe as a pharmacologic inducer of lysosomal damage in normal rat kidney cells (NRK) and primary mouse embryonic fibroblasts (MEF), we have now found that the late endosomal small GTPase Rab7 is a rapid (<20mins) early responder to lysosomal damage states. Following lysosomal disruption, Rab7 accumulates on enlarged undamaged late endosomal compartments. Endosomal maturation from the trans-Golgi network through *early* late endosomes (Rab7+, cathepsin-B *lo*) is preserved, however maturation beyond this point is arrested. At the molecular level, Rab7 is hyper-activated and binds more GTP following LLOMe-induced LMP. To determine specific mechanisms by which Rab7 is activated and accumulates on late endosomes, we employed a diverse pharmacologic approach to specifically disrupt various aspects of lysosomal function. Indeed, though LMP cumulatively leads to loss of lysosomal degradative capacity and massive efflux of divalent cation stores including Ca^{2+}, it is specifically the loss of luminal lysosomal pH that contributes to Rab7 mediated changes in late endosomes. Together, these results suggest a homeostatic cascade to counteract pH collapse in LMP driven by Rab7 activation, which leads to arrest of endosomal maturation.

Early Endosomes Act as Local Exocytosis Hubs to Repair Endothelial Membrane Damage

N. Raj[1], L. Greune[2], M. Kahms[3], K. Mildner[4], R. Franzkoch[5], O. E. Psathaki[5], T. Zobel[6], D. Zeuschner[4], J. Klingauf[3], V. Gerke[1]; [1]Institute of Medical Biochemistry (IMB), ZMBE, WWU, Muenster, GERMANY, [2]Institute of Infectiology, ZMBE, WWU, Muenster, GERMANY, [3]Institute of Medical Physics and Biophysics, WWU, Muenster, GERMANY, [4]Electron Microscopy Facility, Max Planck Institute for Molecular Biomedicine, Muenster, GERMANY, [5]Integrated Bioimaging Facility (iBiOs), Center of Cellular Nanoanalytics (CellNanO), University of Osnabrück, Osnabrueck, GERMANY, [6]Imaging Network, Cells in Motion Interfaculty Centre, WWU, Muenster, GERMANY.

The plasma membrane of a cell is subject to stresses such as mechanical forces resulting from shear stress and mechanical stretch, causing ruptures that must be repaired immediately to preserve membrane integrity and ensure cell survival. Defective plasma membrane repair can lead to eventual tissue damage and has been linked to numerous disease pathologies. Yet, the spatio-temporal membrane dynamics at the wound site and the source of membrane required for wound repair are poorly understood. Here, we show that early endosomes, previously known to function in the uptake of extracellular material and its endocytic transport, are involved in plasma membrane repair in human endothelial cells. Using live-cell imaging, STED, and correlative light and electron microscopy, we demonstrate that membrane injury triggers a previously unknown exocytosis of early endosomes that is induced by the Ca^{2+} entering through the wound. This novel early endosome exocytosis is spatially restricted to the vicinity of the wound site, occurs immediately upon wounding, and is mediated by the endosomal SNARE VAMP2, which is crucial for efficient membrane repair. Lysosomal exocytosis also occurs upon wounding but is not required to support membrane resealing in endothelial cells, as revealed by different membrane damage assays including two-photon live-cell laser ablation, glass bead rolling, and mechanical scratch-induced wounding. Thus, the specialized Ca^{2+}-triggered and localized exocytosis of early endosomes is an emergency-based process that supplies the membrane material needed for rapid wound closure in endothelial cells. This is essential to prevent wound-induced endothelial leakage and a resulting inflammatory reaction in a mechanically stressed environment.

Does phagocytic receptor dynamics and signalling regulate phagocytic capacity, appetite, and recovery?

S. Soffiaturo[1], R. Botelho[2]; [1]Toronto Metropolitan University, Toronto, ON, CANADA, [2]Ryerson University, Toronto, ON, CANADA.

Within the immune system, there are specialized cells that carry out specific functions to fight infections and maintain health. Phagocytes such as macrophages are specialized cells that perform a critical process known as phagocytosis. Phagocytosis refers to the recognition, uptake, and degradation of particles by phagocytes. Initial stages of phagocytosis include the recognition of particles by receptors on the cell surface such as Fcγ receptors. After recognition, particles are engulfed within an internal compartment referred to as a phagosome. Through an array of signaling events, phagosomes mature and eventually fuse with lysosomes resulting in the degradation of the engulfed material. Although, macrophages uptake particles until they reach their limit and become “full”. This notion is referred to as phagocytic capacity. The limit to the number of particles that can be taken up by macrophages is dependent on size, shape, and composition. Currently, there is a large amount of knowledge

surrounding the role of receptors involved in Fcγ-mediated phagocytosis. Although, we do not know how receptors are involved in terms of phagocytic appetite and capacity, despite the extensive knowledge surrounding phagocytic capacity. Therefore, we hypothesized that depletion of Fcγ receptor levels abates appetite in cells at phagocytic capacity. To test this hypothesis, we chose to examine FcγRIII dynamics as cells reach capacity. We first performed immunofluorescence assays alongside streptavidin-biotin pulldown assays to examine FcγRIII surface levels as cells reach capacity following uptake of synthetic polystyrene beads in RAW 264.7 and primary macrophages. Our primary data suggests that surface levels of FcγRIII in RAW 264.7 and primary macrophages are not largely affected as cells reach capacity. In contrast, preliminary data suggest that total levels are altered potentially indicating a depletion in the cell's reservoir of receptors. Future experiments include examining if engagement of inhibitory signals like ITIM-based FcγRIIb helps reduce phagocytic appetite of macrophages at capacity. As particle recognition is a significant step within the process of phagocytosis, it is critical that we gain a better knowledge of it. Therefore, this work aims to provide insight into the role of phagocytic receptor dynamics and signaling in regulating phagocytic capacity, appetite, and recovery.

Mu opioid receptor-mediated release of endolysosome iron increases levels of mitochondrial iron, reactive oxygen species, and cell death

P. W. Halcrow[1], N. Kumar[1], E. Hao[1], N. Khan[1], O. Meucci[2], J. D. Geiger[1]; [1]Biomedical Sciences, University of North Dakota School of Medicine and Health Sciences, Grand Forks, ND, [2]Physiology and Pharmacology, Drexel University School of Medicine, Philadelphia, PA.

Opioids are widely used analgesics and are prone to abuse due to their euphoric and dependency effects. Functioning through opioid receptors, opioids including morphine and DAMGO activate mu-opioid receptors (MOR), increase intracellular reactive oxygen species (ROS) levels, and induce cell death. Ferrous iron (Fe^{2+}) through Fenton-like chemistry can increase ROS levels and damage DNA and proteins. Endosomes and lysosomes (endolysosomes) are "master regulators of iron metabolism" central to iron trafficking as they contain readily-releasable Fe^{2+} stores and an acidic lumen linked to iron homeostasis. However, the opioid-induced mechanisms influencing endolysosome-iron homeostasis and downstream-signaling events inducing toxicity remain unknown. Here, using SH-SY5Y neuroblastoma cells we found that morphine and DAMGO de-acidified endolysosomes, decreased endolysosome Fe^{2+} levels, increased cytosol and mitochondria Fe^{2+} and ROS levels, depolarized mitochondrial membrane potential, and induced cell death; effects blocked by the nonselective MOR antagonist naloxone and the selective MOR antagonist β-funaltrexamine (β-FNA). Deferoxamine, an endolysosome-iron chelator, inhibited opioid agonist-induced increases in cytosolic and mitochondrial Fe^{2+} and ROS. Opioid-induced efflux of Fe^{2+} from endolysosomes and subsequent accumulation of Fe^{2+} in mitochondria were blocked by the endolysosome-resident two-pore channel inhibitor NED-19 and the mitochondrial permeability transition pore inhibitor TRO. Naloxone and β-FNA by themselves were able to retain Fe^{2+} in endolysosomes and decrease levels of cytosolic and mitochondrial Fe^{2+} and ROS. Opioid agonist-induced increases in cytosolic and mitochondrial Fe^{2+} and ROS as well as cell death appear downstream of endolysosome de-acidification and Fe^{2+} efflux. These findings provide new insight into the pharmacological actions of opioids and demonstrate clearly that the pool of iron in endolysosomes is sufficient to effect changes to other organelles and to affect key cellular functions including cell life and death.

Huntingtin during axonal injury: Evidence for a retrogradely moving Huntingtin-Rab7-LAMP1-containing signaling endosome.

T. J. Krzystek, J. A. White II, R. Rathnayake, L. Thurston, H. Hoffmar-Glennon, Y. Li, **S. Gunawardena**; The State University of New York at Buffalo, Buffalo, NY

Huntingtin (HTT), the protein involved in Huntington's disease is a 350kDa protein of unknown function. Despite more than 350 binding partners identified for HTT across a wide range of cellular processes, including trafficking, the molecular mechanisms by which HTT and its binding partners function remain elusive. Here we provide evidence for a retrogradely moving HTT-Rab7 vesicular complex in Drosophila, mice and human neurons by using *in vivo* imaging in living axons coupled with a custom particle tracking analysis and pharmacological inhibitors. We identify that adaptors HIP1 and RILP aid the retrograde motility of LAMP-1 containing HTT-Rab7 late endosomes, but not autophagosomes. Reduction of Syntaxin17 and Chloroquine/BafilomycinA1-mediated pharmacological inhibition, but not reduction of ATG5, disrupted the *in vivo* motility of these vesicles. The retrogradely moving HTT-Rab7-LAMP1-containing late endosome can traffic long-distance signaling components such as the BMP-receptors TKV/WIT, neurotropic factor BDNF and axonal damage response components WND/DLK and JNK following axonal injury. Taken together, our observations unravel a previously unknown role for HTT in the retrograde movement of a Rab7-LAMP1-containing signaling late endosome, which has functional relevance during axonal injury.

Insights into the Biological Role of the Lysosomal Trafficking Regulator Through Proteomic and Functional Analyses

J. Serra-Vinardell, M. B. Sandler, W. A. Gahl[,1], **P. Sharma**; NHGRI/NIH, Rockville, MD

Variants in the Lysosomal Trafficking Regulator (*LYST*) gene are associated with Chediak-Higashi Syndrome (CHS), a rare autosomal recessive disorder characterized by primary immunodeficiency and a high risk of progressive neurological problems. Enlarged lysosomes/ lysosome-related organelles (LRO) are the cellular hallmark of CHS. Though its name implies LYST in lysosomal trafficking, LYST deficient cells lack primary regulation of lysosome/LRO size and number. Therefore, there is a need to continue delineating the precise role of LYST. The daunting task of expressing large LYST protein (429 kDa) hampered researchers from manipulating LYST levels in the cell of interest. Here, we exploited the piggyBac transposon system to successfully express epitope-tagged LYST in different cell types, including neurons, to gain functional insight. We performed systematic proteomic analysis of affinity-purified samples by liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) and identified several LYST-interacting proteins. We further developed a co-immunoprecipitation strategy to identify endogenous LYST interacting proteins by LC-MS/MS in differentiated macrophages treated with toll-like receptor ligands. Together, our approaches led us to build an inventory of LYST interacting proteins across cell lines of distinct origins. We apply the LYST Proteomic map to functional analyses of candidate protein interactions and illuminate new mechanistic insights into how LYST controls cellular processes dysregulated in CHS.

Intracellular vesicles in B lymphocyte activation

A. Music, S. Hämälistö, **P. Mattila**; University of Turku, Turku, Finland

There is a major lack in our knowledge of the cell biological features of lymphocyte function and activation, critical for understanding the mounting of the immune response both in health and disease. We have focused on characterizing the intracellular vesicle pool in B lymphocytes (B cells), particularly, upon cell activation and antigen processing, which are key steps towards antibody responses against specific antigens. Our research has identified high heterogeneity in the antigen-containing vesicles that direct freshly encountered and internalized antigens towards the compartments processing the antigen into peptide-MHCII complexes (Hernández-Pérez et al, Journal of Cell Science, 2019). Unlike in the general understanding of the early to late endosomal cascade maturation, we also found that vesicles with lysosomal features, such as low pH, capture both the internalized antigen as well as surface-derived MHCII right below the plasma membrane.
Here, we have continued our studies on unveiling the role of the lysosomal vesicle pool in B cells. Our results point towards several distinct vesicle pools, that differ, for instance, by their size, location, and the content of lysosomes associated proteins 1 and 2 (LAMP1 and LAMP2). Furthermore, inhibiting lysosomal function with cationic amphiphilic drugs (CADs) leads to marked changes in the B cell antigen receptor (BCR) -triggered activation of B cells. The cells where lysosomes are inhibited are not able to form normal immunological synapses and they show aberrant activation status of signaling proteins. In our work, we mainly utilize various high-resolution fluorescence microscopy techniques as well as electron microscopy.

B346/P1336

S100A4 regulates lysosomes

N. Dulyaninova, S. Sidoli, A. J. Haimowitz, M. J. Gamble, J. M. Backer, **A. R. Bresnick**; Albert Einstein College of Medicine, Bronx, NY

S100A4, a member of the S100 family of Ca^{2+}-binding proteins, is primarily expressed in fibroblasts and leukocytes. S100A4 is also expressed in cancer cells and is directly involved in tumor metastasis. Biochemical studies have shown that S100A4 binds with high affinity to the nonmuscle myosin-IIA heavy chain and mediates myosin-IIA filament depolymerization. Consistent with S100A4's *in vitro* biochemical activity, the loss of S100A4 in cells results in myosin-IIA filament overassembly, leading to a decrease in the migratory capacity of multiple cell types. We have previously shown that CSF-1-differentiated bone marrow-derived macrophages (BMMs) from S100A4$^{-/-}$ mice show defects in the function of podosomes; actin-rich protrusive structure that degrade the extracellular matrix (ECM). Podosomes in S100A4$^{-/-}$ BMMs are small and the BMMs show an 60% decrease in ECM degradation. To explore the mechanism for this defect, we measured lysosomal exocytosis, which contributes to matrix degradation. In response to A23187, a Ca^{+2} ionophore, S100A4$^{-/-}$ BMMs showed a 1.6-fold decrease in β-hexosaminidase release. Ionophore-stimulated retrograde movement of lysosomes towards the nucleus was also inhibited in S100A4$^{-/-}$ BMMs. To measure the fidelity of lysosomal protein sorting in the endocytic pathways and biosynthetic pathways, we measured CSF-1-stimulated degradation of the CSF-1 receptor, and A23187-stimulated trafficking of Lamp1. CSF-1 receptor internalization and degradation was comparable in wild type and S100A4$^{-/-}$ BMMs. Plasma membrane Lamp1 was low in unstimulated wild type BMMs and increased 2-fold in response to A23187. In contrast, plasma membrane Lamp1 was elevated in S100A4$^{-/-}$

BMMs and was unaffected by A23187. To examine lysosomes in more detail, we performed transmission electron microscopy on wild type and S100A4$^{-/-}$ BMMs. S100A4$^{-/-}$ BMMs showed a 5-fold increase in the number of autophagosomes, and a 3-fold increase in the number of autophagosomes containing lipid droplets. In addition, multilamellar bodies were greatly increased in S100A4$^{-/-}$ BMMs. Taken together, these data show an unexpected role for S100A4 in regulating lysosomal trafficking. Future experiments will use RNAseq and proteomic approaches to define the mechanisms for this surprising phenotype in S100A4$^{-/-}$ BMMs.

B347/P1337

Manipulation of the host cell endo-lysosomal system by the intracellular bacterial pathogen *Legionella pneumophila*

A. Steinbach, S. Mukherjee; University of California, San Francisco, San Francisco, CA

Legionella pneumophila (*L.p.*), an intracellular bacterial pathogen, manipulates eukaryotic host cell membrane trafficking to establish a replicative niche. While the bacterium resides within a phagosome-derived compartment throughout its lifecycle, this compartment, known as the *Legionella*-containing vacuole (LCV), resists trafficking to the lysosome. LCV formation and lysosomal fusion evasion is dependent on the secretion of bacterial proteins, termed effectors, into the host cell cytosol, as a secretion-null isogenic strain is degraded in the lysosome. As the mechanisms of lysosomal trafficking evasion by *L.p.* are poorly understood, the present study aims to address how the bacterium subverts normal endosome maturation at the LCV membrane to block fusion with the lysosome. While previous reports indicated that *L.p.* blocked endosome maturation of the LCV at early stages, application of time-lapse fluorescence imaging in the present study has revealed that both Rab5 and Rab7, the master regulators of early and late endosome identity, respectively, associate with the LCV. This result suggests that endosome maturation of the LCV progresses to a late endosome-like state, while still resisting trafficking to the lysosome. Unexpectedly, we have also found that a class of effector proteins are required for Rab5 association with the LCV, suggesting that Rab5 is actively recruited to the membrane during infection. To determine whether *L.p.* manipulates the function of endosomal regulatory proteins, mass spectrometry analysis was carried out on *L.p.* infected human cell lysates. This dataset and subsequent validation demonstrate that both Rab5 and Rab7 are mono-ubiquitinated during *L.p.* infection. Rab mono-ubiquitination is promoted by two bacterial effectors, SidC and SdcA, and appears to occur upon recruitment of the Rab to the LCV membrane. The mechanism and functional consequences of endosomal Rab mono-ubiquitination during infection, as well as the precise block point in endosome maturation at the LCV membrane, remain active areas of investigation. Taken together, these data suggest that *L.p.* employs a more subtle, multi-pronged approach to blocking trafficking of the LCV to the lysosome than previously proposed and represents progress in understanding of *L.p.*'s interaction with the endo-lysosomal system during infection.

B348/P1338

The Neurobiological Basis of Tourette Syndrome: A Behavioral Assessment of the *Drosophila* gene *Atg8a*

T. Hatfield; SIMMONS UNIVERISTY, Boston, MA

Tourette Syndrome (TS) is a complex, stigmatized, and misunderstood neurological condition primarily characterized by vocal and motor tics. The condition is highly heritable, with many implicated genes,

including *GABARAP.* This gene, whose expression negatively correlates with tic severity in some TS patients, is involved in autophagosome formation and $GABA_a$ receptor trafficking to the cell membrane. By overexpressing an RNAi via the GAL4/UAS system in *Drosophila melanogaster*, we aim to replicate *GABARAP's* decreased expression by knocking down the gene's ortholog, *Atg8a*, in the *Drosophila* nervous system. From these mutants, we aim to understand the origins of TS-like behavioral phenotypes produced in *Atg8a* mutants, and to gain insight into *GABARAP's* potential role in TS development.
Initial screenings of *Atg8a* mutants included over 800 larvae and 200 flies observed across 3 redundant RNAi lines for *Atg8a* of different sequences, reducing the probability of the observed phenotypes being caused by off-target effects. Using Tourette related behavioral traits, like the obsessive grooming and olfactory-learning ability, representative of compulsive motor tics and commonly co-morbid learning disabilities, we evaluate *Atg8a* mutants for Tourette-like phenotypes. In the learning assay, larval mutants of *Atg8a* demonstrate a significant decrease in learning ability across all *Atg8a* mutants compared to their UAS line counterparts, with their average change in LI being -72.42% ($p = 0.0043$). In adults, a similarly significant result is observed during the obsessive grooming assay. Across all RNAi knockdown mutants of *Atg8a*, there is a significant increase in grooming bout frequency and length, with their average percent changes from UAS line to mutants for all RNAi lines being 160.56% ($P = 0.00088$) and 127.50% ($P = 0.01273$) respectively.
These results demonstrate that knocking down *Atg8a* produces behaviors in *D. melanogaster* consistent with human TS patients. Although *GABARAP* plays a role in both autophagy and $GABA_a$ receptor trafficking, *Atg8a*, to our knowledge, has only been studied in the context of autophagy. This makes understanding *Atg8a's* potential GABAergic role as a *GABARAP* ortholog vital to understanding the origins of observed behavioral phenotypes. We intend to determine *Atg8a's* role as a *GABARAP* ortholog both to understand the etiology of these mutant phenotypes, and to shed light on the potential biological mechanisms driving this poorly understood human condition.

Vesicle Tethering, Docking and Fusion

B349/P1339

Role of exocyst phosphorylation in yeast: effect on exocyst structure and function

N. Buwa[1], D. Lepore[2], **L. Martínez-Núñez**[1], M. Feyder[1], B. Reneker[2], P. Opara-Nadi[1], B. Thomas[1], M. Munson[1]; [1]Biochemistry and Molecular Biotechnology, University of Massachusetts Chan Medical School, Worcester, MA, [2]University of Massachusetts Chan Medical School, Worcester, MA.

Membrane trafficking impacts a multitude of physiological phenomena including cell polarization, growth, signaling, and motility. Exocytosis requires vesicle fusion with the plasma membrane followed by cargo release outside the cell. SNARE-mediated vesicle fusion during exocytosis is regulated by the multi-subunit hetero-octameric tethering complex called exocyst. To carry out its functions, exocyst interacts with various players in the exocytic machinery, including SNAREs, the Sec1/Munc18 (SM) protein, small GTPases such as Rab and Rho, and the type V myosin in yeast. In order to control spatial and temporal specificity of fusion, the exocyst must be regulated. We propose that, in addition to the above binding interactions, exocyst is also regulated through phosphorylation of several of its subunits. Mapping of phosphorylation sites on the yeast exocyst cryoEM structure indicates that the majority of its phosphorylation sites are present in intrinsically disordered regions. Other phosphorylation sites are located near regions of inter-subunit interactions, or regions that bind non-exocyst partners. Ongoing mutational analyses in yeast aim to determine how phosphorylated residues affect cell growth, as well

as exocyst assembly, localization and function. We are also determining what structural changes are induced by phosphorylation. These studies will elucidate the role of subunit phosphorylation in exocyst assembly, activation, vesicle tethering and fusion.

The Golgi complex serves as a platform for the DNA damage response pathways

K. Kuodyte[1,2], G. Galea[1], E. Lundberg[3], R. Pepperkok[1]; [1]Cell Biology & Biophysics, EMBL, Heidelberg, GERMANY, [2]Faculty of Biosciences, Heidelberg University, Heidelberg, GERMANY, [3]Science for Life Laboratory, KTH Royal Institute of Technology, Stockholm, SWEDEN.

DNA damage response (DDR) is a well characterized process, however, the majority of studies focus specifically on nuclear events, while cytoplasmic response to DNA damage remains largely unexplored. We have identified 15 DDR proteins that localize to the nucleus and to the Golgi complex. These proteins function in various distinct DNA repair mechanisms (e.g., HR, NHEJ, BER, MMR) and related signaling pathways. The dual-localizing DDR proteins were found to respond to specific DNA lesions through a shift in localization either from the Golgi to the nucleus or from the nucleus to the Golgi, based on their role in the specific DDR pathways.
We have identified several Golgins acting as anchors and regulators of these DDR proteins at the Golgi. More in-depth characterization of one of the dual-localized proteins RAD51C revealed that its Golgi localization is dependent on the golgin Giantin and the depletion of Giantin leads to aberrant DNA repair.Altogether, our data propose that the Golgi complex serves as a regulatory hub for various DNA repair mechanisms.

B351/P1341

A Functional Characterization of Golgi Tethers in*Saccharomyces cerevisiae*

A. Krahn, N. Johnson, B. Glick; Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL.

The Golgi apparatus lies at the heart of the cellular endomembrane system and is responsible for modifying and sorting proteins imported from the endoplasmic reticulum (ER). According to the cisternal maturation model, early Golgi cisternae arise from ER-derived membranes, mature biochemically into late Golgi cisternae through the retrograde vesicular recycling of resident Golgi proteins, and ultimately fragment into secretory carriers. The maturation of individual cisternae is evidenced by the arrival and departure of resident Golgi proteins. This process can be directly observed in the yeast *Saccharomyces cerevisiae*, which possesses non-stacked, optically resolvable cisternae. Although the components that drive cisternal maturation in *S. cerevisiae* have been largely identified, the vesicular recycling pathways at the Golgi and the specific molecular machineries that mediate each pathway are incompletely characterized. Recent work in our lab has identified some of these pathways and has measured the timing of arrival and departure for various membrane traffic components as a cisterna matures. Among these components are Golgi-associated tethers, which are thought to capture incoming vesicles and aid their fusion with cisternae. To identify which tethers act in each traffic pathway, we have developed an *in vivo* vesicle tethering assay. This assay involves ectopically localizing Golgi tethers and testing their abilities to capture transport vesicles containing different resident Golgi proteins. We have functionally characterized the coiled-coil golgins Imh1 and Sgm1 as well as the multi-subunit tether GARP. Our data demonstrate that Imh1 captures vesicles containing late Golgi proteins that recycle either within the Golgi or between the Golgi and the prevacuolar endosome (PVE). Sgm1

captures intra-Golgi vesicles during an intermediate stage of maturation, whereas GARP cooperates with Imh1 to capture intra-Golgi vesicles during a late stage of maturation. Neither Sgm1 nor GARP captures vesicles derived from the PVE. Our results reveal the specificities and interrelationships of these Golgi tethers.

B352/P1342

Kinetic Analysis of Vesicle Tethers that Act Late in Golgi Maturation

N. Johnson, A. H. Krahn, B. S. Glick; Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL.

The Golgi apparatus consists of disk-like membrane cisternae that modify and sort proteins and lipids. Golgi cisternae are transient structures that form *de novo* from the endoplasmic reticulum, then progressively mature by delivering early-acting resident proteins to younger cisternae while receiving late-acting resident proteins from older cisternae, and then finally dissolve into secretory carriers. This cisternal maturation process can be visualized directly in the yeast *Saccharomyces cerevisiae*, in which non-stacked Golgi cisternae appear as optically resolvable spots. During yeast cisternal maturation, many resident Golgi transmembrane proteins recycle within the organelle while some resident Golgi transmembrane proteins travel to prevacuolar endosome (PVE) compartments and back. Multiple membrane traffic pathways transport different classes of resident Golgi transmembrane proteins. 4D confocal microscopy reveals that each class of Golgi proteins has a characteristic kinetic signature, which reflects the timing of arrival and departure of the vesicles involved in the corresponding traffic pathway. A mechanistic understanding of Golgi maturation will require identifying the components that mediate each traffic pathway, including the Golgi-associated tethers that capture transport vesicles. We have focused here on identifying the traffic pathways that employ three late-acting Golgi tethers: the coiled-coil golgins Sgm1 and Imh1, and the multi-subunit tether GARP. Our kinetic and functional data paint the following picture. Sgm1 is recruited by the Rab GTPase Ypt6, and it operates in a traffic pathway that recycles Golgi proteins during an intermediate stage of maturation. This pathway leads to recruitment of the Arf-like GTPase Arl1, which in turn recruits Imh1. Then Imh1 operates in a traffic pathway that captures vesicles originating from the PVE. Imh1 also operates in a traffic pathway that recycles late-acting Golgi proteins. A component that recycles from the PVE apparently promotes the recruitment of GARP, which cooperates with Imh1 to capture vesicles carrying late-acting Golgi proteins. Thus, GARP has a previously unknown role in intra-Golgi recycling. These various tethers and traffic pathways have functional interconnections, and they form part of a molecular logic circuit that controls Golgi maturation.

B353/P1343

Identification of plasma membrane to trans-Golgi Network vesicle fusion machinery in Saccharomyces cerevisiae

J. Grissom, R. Chi; Biological Sciences, The University of North Carolina At Charlotte, Charlotte, NC.

Clathrin-mediated endocytosis (CME) is one of the most important cellular processes for the uptake of nutrients or other cargos at the cell surface. CME is a specialized form of receptor-mediated endocytosis involving clathrin and other endocytic proteins. During CME more than 60 proteins are recruited to plasma membrane (PM) sites for cargo capture, vesicle formation and internalization. Recent studies in budding yeast have shown that yeast have a minimal endomembrane system that is fundamentally

different than that of mammalian cells. In this new model, the trans-Golgi Network (TGN), acts as the primary acceptor of endocytic vesicles, sorting cargo for degradation. Given the vast amount of information obtained using the budding yeast endomembrane system, the field must now come to understand these pathways in the context of this new paradigm. Using a targeted genetic approach, we queried SNARE proteins that are known to localize and mediate vesicle fusion events within specific membranes of the yeast endomembrane system. While all yeast SNAREs have been annotated, interestingly none have been identified to mediate the fusion of plasma membrane-derived vesicles to the TGN. Using this targeted genetic approach screen, we have successfully identified SNARE proteins that mediate PM-TGN vesicle fusion.

B354/P1344

Syntaxin5's flexibility in SNARE pairing supports Golgi function

Z. Dsouza, I. Pokrovskaya, V. Lupashin; University of Arkansas for Medical Sciences, Little Rock, AR.

The Golgi - the central organelle in membrane trafficking, receives, modifies, and sorts secretory and endocytic cargo. Glycosylation, one of the major post-translational modifications are conducted within the Golgi where the majority of the glycosylation machinery resides. Golgi resident proteins are recycled from the late (trans) Golgi compartments to the early compartment (cis) by the trafficking machinery - including small GTPases, vesicular coats, tethers, and SNAREs, which orchestrates the events of vesicle formation, budding, and fusion. Mutations in the Golgi trafficking machinery are known to cause glycosylation defects at the cellular and organismal levels. The Conserved Oligomeric Golgi (COG) complex is the key modulator of vesicular trafficking and glycosylation at the Golgi. It functions upstream of the membrane fusion machinery and stabilizes the Golgi SNARE complex -STX5/GS28 (GOSR1)/GS15 (BET1L)/YKT6. We hypothesized that depletion of Golgi v-SNAREs would mirror defects observed in COG deficient cells. To test this, we created single and double knockouts (KO) of GS28 and GS15 in HEK293T cells and analyzed the resulting mutants using a comprehensive set of biochemical, mass-spectrometry (MS) and microscopy approaches. GS28 KO significantly affected GS15, but not the other two partners, STX5 and YKT6. V-SNARE deletion also did not disrupt Golgi morphology. While glycosylation and retrograde trafficking were unaffected in GS15 KO, GS28 KO showed mild glycosylation abnormalities and a delay in retrograde trafficking of SubAB toxin. Our analysis revealed that COG dysfunction is far more deleterious for Golgi function than double GS28/GS15 KO, indicating adaptation of vesicle fusion machinery in v-SNARE KO cells. Quantitative proteomic analysis of STX5-interacting SNAREs revealed an unexpected flexibility in Golgi SNARE pairing in human cells. We uncovered that two novel non-canonical Golgi SNARE complexes - STX5/SNAP29/VAMP7 and STX5/VTI1B/GS15/YKT6, were increased in GS28 KO cells. Moreover, SNAP29 was relocated to the Golgi area in GS28 KO cells in a STX5-dependent manner. Analysis of triple KO cells depleted for GS28/SNAP29/Vti1b revealed synthetic growth defects. This is the first study to show a remarkable plasticity in the mammalian intra-Golgi SNARE machinery, which is possibly controlled by the COG complex.

B355/P1345

Why are SNARE complexes rod-shaped?

D. An, J. Zeng, Z. A. McDargh, B. O'Shaughnessy; Columbia University, New York, NY.

SNARE proteins are the core components of the cellular machinery that fuses membranes for vital processes such as neurotransmitter or hormone release and intracellular trafficking. In common with

other fusion-catalyzing complexes such as those used by enveloped viruses for cell entry, the 4-helix SNARE complex is extended and rod-shaped, and several complexes fuse membranes cooperatively. Why has nature arrived at the same shape solution to the membrane fusion challenge in such diverse settings? Here we used ultra coarse-grained simulations to show the bulky rod shape is designed to generate entropic forces that drive membrane fusion. As the shape generating maximum excluded volume for a given number of protein residues, the rod is the optimal configuration for fusion-catalyzing entropic force.

The mechanism of SNARE-mediated fusion is controversial. We developed molecularly explicit simulations of synaptic vesicle-plasma membrane fusion on physiological msec timescales for the first time, which showed membrane fusion is driven by entropic forces among the rodlike SNARE complexes (SNAREpins) which pushed SNAREpins outwards, clearing the fusion site and pressing the membranes into an extended contact zone (ECZ). Entropic forces maintained SNAREpins at the outer ECZ edge, catalyzed a hemifusion stalk at the edge, and expanded the stalk into a hemifusion diaphragm (HD) large enough to allow tension to complete the fusion pathway by nucleating a simple pore in the HD. HD expansion was required for the final step since at physiological tensions rupture of the planar HD membrane is via a large diameter hydrophilic pore. The entropic forces originate in the bulky rodlike SNAREpin shape: with hypothetical membrane-spanning complexes lacking rodlike domains, weak entropic forces failed to fuse membranes.

This mechanism radically differs from a common view, that fusion is driven by the ~ 60 kT zippering energy of SNARE complexation. We find no support for this view as complexation occurs after microseconds (Kubelka et al., 2004; Xi et al., 2012), much faster than fusion.

Corroborating the predicted pathway, ECZ and HD intermediates were observed in reconstituted SNARE systems (Diao et al., 2012; Hernandez et al., 2012). Simulated fusion required SNARE complexation zippering forces of order ~ 20 pN or greater, similar to experimental values (Gao et al.,2012).

B356/P1346

Synaptotagmin 7 docks synaptic vesicles for Doc2α-triggered asynchronous neurotransmitter release

G. F. Kusick[1], Z. Wu[2], M. M. M. Berns[3], S. Raychaudhuri[1], K. Itoh[1], A. M. Walter[3], E. R. Chapman[2], S. Watanabe[1]; [1]Johns Hopkins University, School of Medicine, Baltimore, MD, [2]University of Wisconson-Madison, Madison, WI, [3]University of Copenhagen, Copenhagen, Denmark

The molecular basis of asynchronous neurotransmitter release remains enigmatic despite decades of intense study. Synaptotagmin 7 (syt7) and Doc2 have both been proposed as Ca^{2+} sensors that trigger this mode of exocytosis at synapses, but conflicting findings have led to controversy. Furthermore, how these proteins influence synaptic vesicle exocytosis is unknown: do they enhance fusion of synaptic vesicles that are already docked and ready to fuse, or do vesicle dynamics play a role? To address this, we measured glutamate release and activity-dependent ultrastructural changes in neurons lacking each of these proteins. Glutamate release was monitored using the optical reporter iGluSnFR in cultured hippocampal neurons and patch-clamp recordings of acute hippocampal slices from knockout mice, while docking of synaptic vesicles was assayed using time-resolved electron microscopy ('zap-and-freeze'). We found that at excitatory mouse hippocampal synapses, Doc2α is the major Ca^{2+} sensor for asynchronous release, while syt7 supports this process through activity-dependent docking of synaptic vesicles. In synapses lacking Doc2α, asynchronous release after single action potentials is strongly reduced, while deleting syt7 has no effect. However, in the absence of syt7, docked vesicles cannot recover on millisecond timescales. Consequently, both synchronous and asynchronous release depress

from the second pulse on during repetitive activity. By contrast, synapses lacking Doc2α have normal activity-dependent docking, but continue to exhibit decreased asynchronous release after multiple stimuli. Moreover, knocking out both of these Ca^{2+} sensors causes no further decrease in asynchronous release, consisting with them acting in series. These findings result in a new model whereby syt7 drives activity-dependent docking, thus 'feeding' synaptic vesicles to Doc2 for asynchronous release during ongoing transmission.

B357/P1347

A dynamic mechanically stabilized membrane reservoir mediates fast endocytosis

D. An[1], R. Su[1], P. J. Wen[2], C. Chan[2], L. Wu[2], B. O'Shaughnessy[1]; [1]Columbia University, New York, NY, [2]National Institute of Neurological Disorders and Stroke, Bethesda, MD.

We present experimental, data analytic and mathematical modeling results suggesting that repeated exocytic stimulation mechanically stabilizes an internal reservoir of plasma-membrane-attached vesicles that serves as a supply for fast endocytic internalization.

Exocytosis mediates neurotransmission, hormone secretion and other fundamental processes. Following fusion to the plasma membrane (PM), a vesicle releases cargo via a fusion pore and then either merges with the PM, remains in place or grows (Shin et al., 2020). Repeated stimulation delivers large amounts of membrane and other molecules to the PM, whose retrieval is achieved by endocytosis. A major pathway is classical clathrin-mediated endocytosis (CME), when membrane pinches inwards from the PM and is removed by membrane fission (Kaksonen & Roux, 2018). However, the timescale of CME is insufficient to restore PM homeostasis (area, tension) in the face of sufficiently fast repeated stimulation. Alternative ultrafast clathrin-independent modes of endocytosis have been identified, but their molecular origin is unknown.

Here we studied exocytosis of ~400-nm diameter dense-core vesicles in live, primary cultured bovine adrenal chromaffin cells stimulated by whole-cell calcium dialysis. Imaging multiple individual exocytosis events whose statistics were accumulated over 26 movies of 1-2 min each, we catalogued the relative frequency of vesicle-membrane merging, vesicle remaining in place, and vesicle growth events, as well as composite events (grow-merge, stay-merge, merge-stay). The pairwise distribution function revealed that ~ 20% of exocytosis events occurred at hotspots of repeated release.

Over 1-2 min, up to ~70 vesicles fused with the imaged portion of the PM, a huge addition of membrane given the high sensitivity of the tension of a membrane to its area. Part of the added membrane did not merge with the PM, but remained as a reservoir of PM-attached intracellular vesicles that reached steady state after ~ 20s. Cross pairwise distributions showed that membrane reservoirs lie close to hot spots.

To explore the reservoir mechanism and its significance, we developed a mathematical model which showed that repeated exocytosis at a hotspot lowers the local PM tension and the driving force for vesicle-PM merging, up to a threshold where a reservoir stabilizes. The reservoir then constitutes an adjustable supply of rapidly available vesicles for internalization, effectively short-circuiting the slow CME pathway. Thus, our results suggest repeated exocytic stimulation mechanically stabilizes internal reservoirs of PM-attached vesicles ready for fast endocytic internalization.

BAR Domain Proteins and Actomyosin Regulate Fusion Pore Dynamics of Large Secretory Vesicles

T. Biton[1], N. Scher[1], E. Schejter[2], B. Shilo[2], O. Avinoam[1]; [1]Department of Biomolecular Sciences, Weizmann Inst Science, Rehovot, ISRAEL, [2]Department of Molecular Genetics, Weizmann Inst Science, Rehovot, ISRAEL.

Secretion by exocytosis occurs in every living cell, facilitating metabolism, signaling and trafficking. Large secretory vesicles (LSVs), up to 10 µm in diameter, are utilized in exocrine tissues to secrete a high volume of cargo. We recently showed that when LSVs fuse with the apical surface, unlike smaller vesicles such as synaptic or endocrine vesicles, they do not incorporate into or detach from the surface. Instead, LSVs stay connected to the surface through a dynamic fusion pore. While this occurs, the vesicular membrane is folded by an actomyosin meshwork that is recruited to the vesicle after fusion. In such a scenario, the vesicular and apical membranes remain physically and chemically distinct and membrane homeostasis is maintained. We hypothesized that fusion pore regulation plays an important role in this process. To understand how the fusion pore is regulated, I used live, super-resolution microscopy in the Drosophila larval salivary glands. I discovered that the fusion pore of LSVs displays a behavior consisting of three morphologic phases - expansion, stabilization, and constriction. I have shown that pharmacological and genetic perturbations of branched actin polymerization results in pores that fail to expand, leading to LSV detachment from the surface, or pores that fail to stabilize, resulting in a full collapse of the LSV into the surface and actomyosin independent content release. Additionally, inhibiting Myosin-II activity results in stalled vesicles that remain connected to the surface by a wide pore that does not constrict. To better understand the molecular mechanism regulating the fusion pore I performed a candidate-based screen. I identified three conserved Bin-Amphiphysin-Rvs homology (BAR) domain proteins that regulate the pore phases. I found that Missing in metastasis (MIM), is essential for both pore expansion and pore stabilization in a dose-dependent manner. Additionally, I was able to show that MIM localizes to the fusion site before fusion and during the secretory process and that the I-BAR domain of MIM is essential for MIMs localization and function. My experimental evidence suggests that the fusion pore of LSVs is regulated by a dedicated protein machinery involving BAR domain proteins and actin dynamics and that such machinery facilitates content release and membrane homeostasis in exocrine tissues.

Multivesicular Endosome (MVE) Secretion Is Regulated By Temperature

A. Weisgerber[1], Z. Otruba[1], M. Nguyen[2], B. Bills[2], **M. Knowles**[2]; [1]Chemistry & Biochemistry, University of Denver, Denver, CO, [2]Molecular and Cellular Biophysics Program, University of Denver, Denver, CO.

Multivesicular endosomes fuse with the plasma membrane to secrete exosomes into the extracellular space. The regulation of this fusion event is not well understood, however, the recent design of CD63 based, pH sensitive, fluorescent probes, real time dynamics and kinetics of MVE fusion can be measured using TIRF microscopy. In this work, A549 cells, a model lung cancer cell line, expressed fluorescent fusion probes and were observed as the process of MVE membrane fusion occurred spontaneously and slowly in time. The temperature was varied from 23°C to 37°C and fusion happens more frequently at warmer temperatures. Interestingly, the temperature also affected the release kinetics of the fluorescent probes, as noted by the rate of fluorescence decay from the fusion site. Through fitting of

the release kinetics and diffusion-based simulations of exosomes leaving the fusion site, we determined that some exosomes are tethered to the cell surface and these tethers can dissociate slowly in time.

Investigating Annexin and S100A11's role in membrane repair

N. Loew, K. Sonnemann, W. Bement; University of Wisconsin–Madison, Madison, WI.

Every cell is susceptible to stress- or contraction-induced membrane damage which, if left unrepaired, leads to uncontrolled cytoplasmic efflux, ion influx and ultimately cell death. To maintain homeostasis, cells employ a highly conserved membrane repair system characterized by rampant calcium-dependent vesicle-vesicle and vesicle-membrane fusion events around the wound site. Annexins are a family of calcium dependent lipid binding proteins that participate in membrane repair by regulating vesicle fusion events. While annexins are known to promote membrane repair, less is known about how the annexin-binding S100 family of proteins promote or otherwise regulate repair. The objective of this study is to investigate how annexin and S100A11 regulate membrane repair in frog oocytes. We expressed recombinant annexin and S100A11 proteins and injected the purified proteins into oocytes in order to visualize and quantify recruitment of each protein to the site of laser-induced damage. We found that both annexin and S100A11 were rapidly recruited to wounds and co-localized during the repair response. The S100A11 recruitment was calcium dependent; a S100A11 mutant unable to bind calcium was not recruited to wounds. Interestingly, annexin recruitment to wound sites was also diminished in the presence of the S100A11 mutant. Therefore, we conclude that annexin activity during membrane repair is regulated by S100A11. These results advance our understanding of membrane wound repair and identify S100 proteins as potential targets for therapeutic interventions aimed at promoting wound repair.

Membrane remodeling properties of the Parkinson's disease protein LRRK2

X. Wang[1,2,3,4], Y. Wu[1,2,3,4], S. Cai[1,2,3,4], J. Ge[1], S. Lin[1,5], P. De Camilli[1,2,3,5,4]; [1]Yale University School of Medicine, New Haven, CT, [2]Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT, [3]Program in Cellular Neuroscience, Neurodegeneration and Repair, Yale University School of Medicine, New Haven, CT, [4]Aligning Science Across Parkinson's (ASAP) Collaborative Research Network, Chevy Chase, MD, [5]Kavli Institute for Neuroscience, Yale University School of Medicine, New Haven, CT.

Mutations in Leucine-rich repeat kinase 2 (LRRK2) are responsible for late-onset autosomal dominant Parkinson's disease (PD). LRRK2 has been implicated in a wide range of physiological processes including membrane repair in the endolysosomal system. Here, we report that purified LRRK2 directly binds acidic lipid bilayers in a cell-free system and can deform them into narrow tubules in a guanylnucleotide-dependent but ATP-independent way. Moreover, we found that LRRK2 shows preferential assembly on highly curved lipid nanotubes relative to spherical liposomes. We suggest that an interplay between the membrane remodeling and signaling properties of LRRK2 may be key to its physiological function. LRRK2, via its kinase activity, may achieve its signaling role at sites where membrane remodeling occurs.

VPS33B and VPS16B, proteins deficient in ARC syndrome, form a pentameric bilobed complex

R. J. Y. Liu[1], Y. Al-Molieh[1], H. H. Y. Yao[1], R. S. Q. Geng[1], L. Li[2], F. G. Pluthero[2], S. Benlekbir[2], J. L. Rubinstein[2], W. H. A. Kahr[2]; [1]University of Toronto-47731885, Toronto, ON, CANADA, [2]The Hospital For Sick Children, Toronto, ON, CANADA.

Loss of function variants of *VPS33B* and *VIPAS39* (*VPS16B*) are causative for multisystemic arthrogryposis, renal dysfunction and cholestasis (ARC) syndrome, typified by early lethality. This indicates that VPS33B and VPS16B play essential cellular roles, and while these proteins have been shown to associate, little is known about the structure and function of the VPS33B/VPS16B complex. VPS33B is a member of the SEC1/MUNC18 (SM) protein family, and is thus thought to facilitate vesicular fusion like its homolog VPS33A, a component of the homotypic fusion and vacuole sorting (HOPS) complex. While it has been compared to the heterohexameric HOPS complex, the stoichiometry and arrangement of subunits in the VPS33B/VPS16B complex is not known. We show here that endogenous VPS33B and VPS16B from human cells form a large molecular weight complex of similar size to that of affinity-purified human VPS33B/VPS16B expressed in yeast. Circular dichroism confirmed VPS33B/VPS16B has a well-folded α-helical secondary structure. Size exclusion chromatography-multi angle light scattering, quantitative immunoblotting, small angle X-ray scattering and negative staining electron microscopy indicate the complex has a VPS33B:VPS16B ratio of 2:3, and a distinctive two-lobed shape. Examination of truncated and arthrogryposis, renal dysfunction and cholestasis (ARC) syndrome-causing variants of VPS33B and VPS16B expressed in yeast identified a VPS16B truncation that did not affect binding to VPS33B, as well as an ARC-associated VPS33B missense variant that disrupts complex formation. The demonstration that VPS33B and VPS16B form a unique bilobed complex containing only these proteins will facilitate future studies into their structure and function.

B363/P1353

Intersectin-1 condensates control replacement site vesicles

T. H. Ogunmowo[1], R. E. Pepper[1], A. Ho[1], S. Raychaudhuri[1], H. Wang[2], C. Hoffmann[2], I. Milosevic[3], D. Milovanovic[2], S. Watanabe[1]; [1]Cell Biology, Johns Hopkins University Sch Med, Baltimore, MD, [2]German Center for Neurodegenerative Diseases, Berlin, GERMANY, [3]University of Oxford, Oxford, UNITED KINGDOM.

Vesicles docked at release sites are used for synaptic transmission and quickly replaced by new vesicles. Replacement vesicles can rapidly toggle between undocked and docked states on a millisecond time scale during synaptic activity, and this dynamic transition controls the plastic nature of synaptic transmission. Thus, these vesicles must be held in the region close to the release sites. However, the precise location of replacement vesicles and how their transition to release sites is controlled remains mysterious. The objective of this study is to determine the mechanisms regulating replacement vesicles, and their physiological relevance. Here, we show that the multimodal scaffolding protein Intersectin-1 forms condensates to maintain vesicles near the active zone where release sites are located, and its interaction with Endophilin A1 mobilizes the vesicles to release sites. Specifically, heterologous expression of Intersectin-1 in HEK293 cells suggests that Intersectin-1 forms liquid-like condensates with Synapsin-1 and Synaptophysin-containing vesicles, indicating a potential role in vesicle sequestration by Intersectin-1. Intersectin-1 condensates can be dispersed by co-expression of Endophilin A1 or Ca^{2+} influx in HEK293 cells, suggesting that both Endophilin A1 and Ca2+ may free vesicles from Intersectin-1

condensates. Consistent with this notion, Intersectin-1 forms distinct spherical puncta just above release sites, between Rim1 and Synapin1 condensates, when mouse hippocampal synapses are observed by superresolution microscopy. These clusters are likely liquid molecular condensates since they are dispersed by an aliphatic alcohol which disrupts weak hydrophobic interactions and display diffusion-limited kinetics by internal FRAP. Our time-resolved ultrastructural analysis, zap-and-freeze electron microscopy, shows that vesicles within 30 nanometers of release sites are scarce when lacking Intersectin-1, suggesting that Intersectin-1 likely keeps vesicles in this region. After stimulation, new vesicles cannot dock immediately to replenish the release sites. Consequently, these synapses fail to facilitate synaptic transmission. Interestingly, in Endophilin A1 knockout neurons, the number of vesicles in replacement sites is normal, yet release sites are not rapidly replenished after stimulation. This defect is also observed in neurons expressing mutant Intersectin-1, which cannot interact with Endophilin A1. Taken together, these data suggest that Intersectin-1 localizes replacement vesicles near the active zone, and its interaction with Endophilin A1 promotes replenishment of release sites.

B364/P1354

investigations of annular gap junctions as delivery vehicles to cellular organelles

A. Cooper[1], S. Cetin-Ferra[1], B. S. Jones[1], A. O. Hinton, Jr.[2], S. A. Murray[1]; [1]Cell Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA, [2]Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN.

Gap junction channels facilitate the transfer of molecules between adjacent cells and regulate multiple cellular processes. These channels are composed of proteins, connexins. Connexin assembly into gap junction channels, and channel aggregation into gap junction plaques has been well characterized. However, the channel removal from the cell surface by a gap junction plaque internalization process that results in annular gap junction formation is less understood. The central dogma is that annular gap junctions are degraded however the fate of these annular gap junctions and their proteins is controversial. We hypothesize that annular gap junctions, in addition to being degraded, deliver their connexins to other cellular compartments. To characterize annular gap junction fate, we used SW-13 adrenal cells that express connexin 43 (Cx43), the most abundant connexin family member. Annular gap junction contact sites with lysosomes and mitochondria were characterized with transmission electron microscopy (TEM). Immunocytochemical colocalization with 3D computer-assisted reconstruction was used to analyze annular gap junction associations with lysosomal (LAMP), recycling (Rab 11, VPS35), and mitochondrial (TOM20) markers. With TEM, lysosomal annular gap junction membrane fusion was seen such that the lysosomal membrane and annular membranes appeared to be continuous with one another. There was no space intervening between annular gap junction and lysosomal membranes at these contact sites. In contrast, annular gap junction/mitochondrial membranes were never seen to be continuous with one another and at their contact sites there was an average 18.4 ± 0.7nm space (range 0-25nm). Even in the cases where no space was measured between annular gap junction and mitochondria membranes, the integrity of each organelle's membrane remained intact. With immunocytochemistry annular gap junctions colocalized with lysosomes. However, the percent colocalization of annular gap junctions with the recycling (Rab 11, VPS35), and with mitochondria markers was statistically greater than that for lysosomes/annular gap junctions. We suggest that while some annular gap junctions are degraded, others form close contacts that may allow connexin delivery to the plasma membrane via recycling endosomes, or to mitochondria for possible regulation of mitochondrial function. B365/P1355

Composition and Structure of the VPS33B/VPS16B Complex

Y. AL-MOLIEH[1], R. J. Y. Liu[1], F. G. Pluthero[2], L. Li[2], S. Benlekbir[2], J. L. Rubinstein[2], W. H. A. Kahr[2]; [1]University of Toronto-47731885, Toronto, ON, Canada, [2]Hospital for Sick Children, Toronto, ON, Canada

Loss of VPS33B and/or VPS16B protein expression causes the multisystem neonatal lethal condition arthrogryposis, renal dysfunction, and cholestasis (ARC) syndrome, where symptoms include the failure of platelet precursor megakaryocytes to produce secretory α-granules. VPS33B is a member of the SEC1/MUNC18 (SM) protein family, and is proposed to facilitate vesicular fusion like its homolog VPS33A, a component of the homotypic fusion and vacuole sorting (HOPS) complex. We have determined that VPS33B and VPS16B form a large molecular weight complex in cells that contains only these proteins (unlike the heterohexameric HOPS complex). We have gained insights into the structure and composition of the VPS33B/VPS16B complex using a range of biochemical and biophysical techniques, including circular dichroism, size exclusion chromatography-multi angle light scattering (SEC-MALS), quantitative immunoblotting, small angle X-ray scattering and negative staining electron microscopy (EM). We have determined that the VPS33B/VPS16B complex contains 2 copies of VPS33B and 3 of VPS16B, and that it has a distinctive two-lobed structure. We investigated the relationship of components within the complex by adding a biotinylation signal to the C-terminus of VPS33B and binding avidin to the complex prior to EM analysis. This revealed that the VPS33B subunits occur in a *trans* conformation at either end of the complex, with VPS16B occupying the central region. Our findings represent the most detailed structural determination of the VPS33B/VPS16B complex to date.

B366/P1356

Plasma membrane disruption induce macropinocytosis and lysosome fusion after membrane repair

M. Konishi[1], Y. Egami[2], K. Kawai[3], N. Araki[3], **K. Miyake**[1]; [1]Int. Univ. Health & Welfare, Narita, Japan, [2]Kagawa Univ., Miki, Kagawa, Japan, [3]Kagawa, Miki, Kagawa, Japan

Plasma membrane is repaired within seconds after damage. It has been reported that lysosomes supply cell membranes to the damaged area for repair. In this study, how lysosomes fuse to the membrane was confirmed by live imaging. We also observed morphologically how contaminated cytoplasm is repaired over time after plasma membrane disruption. FITC-Lys-Dextran, 10 kD (Fdx) was injected into mice flexor digitorum brevis muscle, followed by electroporation. After a few days, fibroblasts, macrophages and muscle fibers with many sequestered vesicles were identified, and when these cells were subjected to membrane damage with a two-photon laser, active exocytosis of Fdx was observed from the fibroblasts and macropages. However, sequestered vesicles of muscle fibers were not secreted. We also observed Lgp120-GFP transfection-labelled lysosomes or LC3-GFP transfection-labelled autophagosomes in cultured cells such as BS-C-1 or muscle fibers, but exoxcytosis were not obserbed by membrane damage or ionomycin. Therefore, scratch loading was performed in HRP (10 mg/ml, D-PBS+) and fixed after recovery times of 15 s, 3 min, 30 min, 1 h, 6 h, 24 h, 36 h and 72 h after injury. HRPs were sequestered by the membrane 30-24 h after injury, with an increase in large lysosomal-like sequestered

vesicles surrounded by the sequestered membrane at 36 h and 72 h. Electron microscopic images of repaired cells at 30 min post-injury showed that they extended cell surface ruffling and intensely engulfed extracellular fluid and their own cytoplasm. Therefore, Rab35-GFP was transfected and LIVE imaging during damage repair using FM4-64 showed macropinocytosis. Furthermore, Fdx was introduced into the cells by scratch loading and changes over time were observed for 72 hours. As a result, as time progressed from 24 to 72 hours, more sequestered vesicles were observed in the cells. When cells with these sequestered vesicles were subjected to membrane repair again with two-photon laser, many of the sequestered vesicles fused to the nearby plasma membrane, which was not damaged, and the fluorescent material in them was found to be expelled by exocytosis. When these cells were transfected with Lgp120-GFP, many of the sequestered vesicles were considered to be secretory lysosomes. These findings indicate that macropinocytosis is induced by plasma membrane disruption and that there is a mechanism by which damaged cytoplasm is sequestered and expelled from the contaminated cytoplasm by exocytosis occurd by plasma membrane disruption.

B367/P1357

Dynamics of dysferlin and t-tubles during sarcolemma repair

T. Matsuda, **K. Miyake**; International University of Health and Welfare, Narita, Japan

5-30% of skeletal muscle fibers are constantly damaged by exercise and undergo membrane repair. We found that limb muscular dystrophies unable to produce dysferlin are unable to repair cell membranes, suggesting that dysferlin localises to intracellular vesicles of sarcoplasmic reticulum, muscle plasma membrane transverse tubule(t- tubule) or other origin and that sarcolemma repair is mediated by vesicles fusion. The detailed localisation of dysferlin and its kinetics during sarcolemma repair remain unclear. In this study, live imaging of dysferlin and t-tubules during sarcolemma repair was performed to morphologically analyse how the sarcolemma is repaired. Electroporation was used to introduce dysferlin-GFP and the t-tubule marker BIN1 (Amphiphysin-2)-GFP into the mouse flexor digitorum brevis muscle. 10-30 days later, multiphoton microscopy and Airyscan live imaging was performed. Using isolated mouse skeletal muscle, two-photon laser damage to sarcolemma visualised by FM reagents showed many vesicles forming longitudinal columns along t-tubules and many vesicles accumulating in the damaged area. Dysferlin was also localised in vesicles just below the plasma membrane and in the sarcoplasmic reticulum between myofibrils, but most of them were strongly localised in the t-tubules, as was BIN1. When the sarcolemma was injured, both dysferlin and BIN1 were observed to collect in the injured area. However, BIN1 was observed to collect inside the injured area earlier than dysferlin. This movement may be due to the fact that BIN1, which stabilises the t-tubules, first changes and prepares the t-tubule membrane for vesicle formation, from where dysferlin forms vesicles and transports them one after the other to the injured area. Thus, it was speculated that dysferlin localises predominantly in t-tubules. It is also possible that dysferlin and BIN1 both work to sarcolemma repair, but that their roles are different.

Neuronal Signaling and Metabolism

B369/P1358

Potential regulation of SYD-2 Liprin α; protein abundance by the Anaphase Promoting Complex (APC) and UNC-43 CaM Kinase II in C. elegans

A. Pressel, T. Prechtel, L. Campagnoli, K. Rush, D. Lester, J. R. Kowalski; Butler University, Indianapolis, IN.

Neuronal signaling makes up the basis of every thought, action, and movement; misregulation of neurological signaling contributes to neurological diseases. Specifically, a crucial balance of excitatory to inhibitory neuronal signaling (E:I balance) is controlled by synaptic proteins; yet details are incompletely understood. Prior studies used *Caenorhabditis elegans* as a model to study a conserved synaptic scaffolding protein, SYD-2 Liprin α, which acts in inhibitory GABA neurons to control signaling at the *C. elegans* neuromuscular junction (NMJ). However, regulation of SYD-2 Liprin α itself is incompletely understood. We tested whether two hypothesized regulators of SYD-2 Liprin α from mammalian systems, the anaphase-promoting complex (APC) ubiquitin ligase and the calcium-dependent UNC-43 CaM Kinase II (CaMKII), control SYD-2 Liprin α abundance in C. elegans GABA neurons. We previously showed the synaptic abundance of SYD-2 is regulated by the APC, which is present in GABA neurons to regulate NMJ inhibitory signaling. Like the APC, CaMKII negatively regulates Liprin α levels in mammalian cells, and *unc-43* loss-of-function *(lf)* C. elegans have increased muscle contraction similar to *apc(lf)* mutants, also consistent with negative regulation of SYD-2 Liprin α. Here, we provide preliminary evidence of SYD-2's direct regulation via APC ubiquitination, while its regulation by UNC-43 may happen locally, if at all. We found *C. elegans apc (lf)* mutants have decreased GABA release and more muscle contraction, and *syd-2(lf)* mutants have less muscle contraction that suppresses increased contraction of *apc(lf)* mutants. Imaging experiments demonstrated GFP::SYD-2, but not a GFP::SYD-2(**Δ**;;Dbox) mutant lacking APC recognition sites, accumulates at GABA neuron presynapses in *apc(lf)* mutants, consistent with negative regulation of SYD-2 by the APC. Double immunoprecipitation analyses support potential ubiquitination of GFP::SYD-2 Liprin α in *C. elegans*; tests to confirm APC dependence are underway. Initial Western blots of total protein lysates from *unc-43(lf)* mutants suggest little effect of *unc-43* on total GFP::SYD-2 levels; however, current experiments are testing local synaptic regulation. Future studies will continue both aspects of this project in efforts to understand SYD-2 regulation as a mediator of inhibitory signaling, a crucial component of neuronal balance.

B370/P1359

Investigation of cell autonomous and nonautonomous signaling of the G protein-coupled receptor, FSHR-1, in controlling neuromuscular structure and function in C. elegans

M. Buckley, A. Ritter, **M. McClain**, W. Jacob, D. Emch, J. Kowalski; Butler University, Indianapolis, IN.

Regulation of neuronal signaling balance is critical for nervous system function. At neuromuscular junctions (NMJs), this occurs via regulation of excitatory and/or inhibitory signaling events. The G protein-coupled receptor (GPCR), FSHR-1, is a key regulator of NMJ signaling, as well as germline differentiation, and stress responses. Prior research showed that *C. elegans* with *fshr-1* deletion exhibit decreased muscle excitation along with accumulation of fluorescently labeled synaptic vesicles in excitatory cholinergic motor neuron presynapses. We used paralysis, swimming assays, and quantitative imaging of the fluorescently-tagged synaptic vesicle protein SNB-1::GFP to confirm the NMJ defects of

fshr-1 loss-of-function *(lf)* mutants. Along with synaptic vesicle accumulation and reduced muscle contraction, *fshr-1(lf)* mutants exhibited build-up of the active zone proteins UNC-10/RIM and SYD-2/Liprinα in cholinergic motor neurons. However, where *fshr-1* acts to control NMJ function is unknown. Expression of *fshr-1* in all neurons, and in excitatory cholinergic or inhibitory GABAergic neurons alone, restored NMJ activity to these animals. Yet, the same *fshr-1* re-expression in cholinergic or GABAergic neurons failed to restore wild type synaptic vesicle localization. Endogenous *fshr-1* expression was detected in several head cells, along with its known intestinal expression, but not in body wall motor neurons, suggesting a complex site of action. Experiments in which re-expression of *fshr-1* under intestinal, neuronal, and glial promoters rescued the NMJ behaviors of *fshr-1* mutants further support non-motor neuron sites of action. Currently, we are imaging SNB-1::GFP to quantify the abundance and localization of synaptic vesicles in cholinergic NMJs of animals with *fshr-1* re-expressed under these non-motor neuron-specific promoters to determine if the rescue of NMJ function with these promoters correlates with expected changes in SNB-1::GFP accumulation. Future work will include use of tissue-specific deletions to identify where *fshr-1* is required for NMJ structure and function in diverse physiological conditions. Together these data should provide a more complete picture of the cell autonomous and non-autonomous mechanisms by which FSHR-1 controls NMJ function that may be relevant to mammalian FSHR, which has been implicated in neurological dysfunction.

B371/P1360

Investigation of FSHR-1 and its putative α;; and β;; glycopeptide ligands in the cell non-autonomous regulation of neuromuscular function

L. Bortey, W. Jacob, J. Kowalksi; Butler University, Indianapolis, IN.

Normal neuronal signaling regulates the balance of chemical messages to the postsynaptic cell. FSHR-1 is the sole *C. elegans* homolog to a family of glycopeptide hormone receptors involved in gonad function and required for normal neuromuscular activity. Previous studies show *fshr-1* mutants exhibit decreased muscle contraction and our preliminary data indicate these effects on muscle contraction can be caused through cell non-autonomous activity of FSHR-1 in distal tissues. However, the ligands that activate FSHR-1 signaling, as well as the mechanisms by which FSHR-1 promotes muscle excitation are unknown. Possible ligands for FSHR-1 may be the **α**;; glycopeptide FLR-2, the closest homolog to the human FSHR ligand, and *T23B12.8*, which encodes the **β**; glycopeptide homolog. We hypothesized FLR-2 and the **β**; glycopeptide work in a ligand-receptor relationship with FSHR-1 in *C. elegans* to control neuromuscular function. In swimming assays measuring neuromuscular function, *flr-2* **α**;; glycopeptide loss of function (lf) mutants showed the same deficits in motility as *fshr-1*(lf) mutants, demonstrating *flr-2* is required for neuromuscular signaling. The *T23B12.8* **β**; mutants also showed a decrease in motility, and swimming defects in **α**;;**β**; double mutants are non-additive, supporting a role for the two peptides in co-regulating muscle excitation. *fshr-1;flr-2* double mutants also showed similar decreases in motility as either of the fshr-1 and flr-2 mutants alone, suggesting *fshr-1* and *flr-2* **α**; glycopeptide work within the same pathway and supporting a model in which FLR-2 is an FSHR-1 ligand. Studies with *fshr-1*;**β**; mutants are planned. In addition to identifying FSHR-1 ligands, we are exploring the mechanisms by which FSHR-1 cell non-autonomously regulates signaling for muscle contraction. Current experiments are using RNAi interference to knock down a panel of secretory genes in worms overexpressing FSHR-1 in distal tissues (e.g., intestine, glia, head neurons) to test the hypothesis that FSHR-1 activation induces secretion of peptide or other factors required for muscle excitation. Together, our findings will contribute to understanding the role of a conserved GPCR, its glycopeptide ligands, and how its interaction with

multiple different pathways promotes neuronal signaling balance, which may provide insight important in approaching treatments for neurological diseases.

B372/P1361

Cannabinoid Receptor-Mediated Synaptic Signaling and Neural Plasticity in Central Olfactory Neurons

T. Heinbockel, Z.-J. Wang; Howard University College of Medicine, Washington, DC

Our studies aim to understand integrative and computational mechanisms that allow main olfactory bulb neurons to respond to afferent input and synaptic or feedback signals. The endocannabinoid (eCB) signaling system has been functionally implicated in many brain regions but our understanding of the role of cannabinoid receptor type 1 (CB1R) in olfactory processing remains limited. Endocannabinoids are known to mediate retrograde signaling at synapses in several brain regions through a form of short-term neural plasticity. Endocannabinoids are released from depolarized principal neurons and rapidly diffuse to presynaptic inhibitory interneurons to transiently reduce presynaptic firing and neurotransmitter (GABA) release (Depolarization-Induced Suppression of Inhibition, DSI). We study the function of the endocannabinoid system in regulating neural activity at synapses in the main olfactory bulb, the first central relay station in the brain for the processing of olfactory information coming from the nose. Our experimental approach uses electrophysiological recording techniques, specifically whole cell patch-clamp recordings. Previously, using anatomical approaches, we showed that CB1R is present in periglomerular processes of a GAD65-positive population of interneurons but not in mitral cells, key output neurons. We detected eCBs in the mouse main olfactory bulb as well as the expression of CB1R and other genes associated with the cannabinoid signaling system. Output neurons such as mitral cells and tufted cells in the olfactory bulb are computational elements in brain circuits that integrate incoming signals with membrane properties to generate behaviorally relevant synaptic output. Our data support the notion that retrograde signaling is present in neural circuits involving mitral and tufted cells. Mitral and tufted cells release endocannabinoids and, through retrograde signaling, inhibit presynaptic interneurons such as periglomerular cells, which controls the GABA release of these presynaptic neurons. This, in turn, allows mitral and tufted cells to temporarily regulate their synaptic input and relieve them from synaptic inhibition. Endocannabinoids function as retrograde messengers to regulate neural signaling and mediate plasticity at olfactory bulb synapses with potential effects on olfactory threshold and behavior. This publication resulted in part from research support to T.H. from NSF (IOS-1355034), NIH (P30AI117970), and Howard University College of Medicine.

Synaptic deficits of fragile X syndrome in patient-derived isogenic induced neurons

C. MacKenzie, E. Rao, C. Arnold, J. Chrisman, J. Knopp, K. Hutson, C. Patzke; University of Notre Dame, Notre Dame, IN.

Fragile X syndrome (FXS) is one of the main forms of inherited intellectual disability and the most common monogenic cause of autism spectrum disorder. FXS is caused by loss of expression of the gene *FMR1*, most often via epigenetic silencing secondary to a pathogenic expansion of trinucleotide repeats in the 5' untranslated region of the gene. Excision of the repeat expansion can induce promoter demethylation and restore *FMR1* expression in patient-derived induced pluripotent stem cells (iPSCs). We used FXS patient-derived iPSCs, corrected the mutation by CRISPR/Cas9-mediated repeat deletion, and generated induced neurons (iNs) by overexpression of neurogenin-2. Lack of *FMR1* expression

results in irregular morphology, overabundance of synapses, synaptic vesicle pool dysregulation, and endocannabinoid signaling impairment in FXS iNs, compared to isogenic controls. Our findings highlight molecular deficits which may contribute to irregular brain development in FXS patients and might provide new avenues for future treatments of the condition.

Multimeric and monomeric α-synuclein induce distinct effects on vesicle trafficking and mitochondria at synapses.

C. Roman-Vendrell[1], G. E. Fisher[2], M. Celikag[3], T. Bartels[3], J. R. Morgan[1]; [1]Marine Biological Laboratory, Woods Hole, MA, [2]University of Chicago, Chicago, IL, [3]UK Dementia Research Institute & University College London, London, UNITED KINGDOM.

Multimeric and monomeric α-synuclein induce distinct effects on vesicle trafficking and mitochondria at synapses.

Parkinson's disease and Dementia with Lewy Bodies are neurodegenerative diseases characterized by the abnormal aggregation of α-synuclein throughout neurons. Under physiological conditions, neurons express multimeric α-synuclein (60-100 kDa oligomers) and monomeric α-synuclein (14 kDa). Altering the balance between these molecular species leads to aggregation, synaptic dysfunction, and neurotoxicity. Moreover, accumulation of α-synuclein at synapses leads to synaptic deficits that precede or co-occur with other signs of neurodegeneration. However, the precise effects of distinct molecular species of α-synuclein at synapses, including synaptic vesicle trafficking and mitochondria morphology, remain unclear. Lamprey reticulospinal synapses provide an excellent model for these studies because we can acutely introduce precise amounts of different α-synuclein species directly to presynapses followed by detailed ultrastructural analysis using electron microscopy. Previously, we showed that excess brain-derived α-synuclein (mixed multimeric and monomeric), moderately impaired intracellular vesicle trafficking without effects on clathrin mediated endocytosis (CME). Currently, our goal is to determine which aspects of this phenotype are due to α-synuclein multimers or to monomers, by introducing them to synapses isolated in purified form. We found that excess purified multimeric α-synuclein partially phenocopies the effects of brain-derived α-synuclein, particularly, causing a decrease in the SV cluster, an increase in the size and number of cisternae/endosomes, without effects on plasma membrane or CME. In contrast, excess purified monomeric α-synuclein induced atypical fusion/fission events at the active zone and moderately impaired CME. We also analyzed mitochondria morphology and found that multimeric α-synuclein decreases the number of mitochondria at the synapse and that the remaining mitochondria are swollen and closer to the active zone. In contrast, monomeric α-synuclein decreased the number of mitochondria with no significant effects on their location or morphology. These data provide further evidence that the impacts of α-synuclein on synapses and mitochondria depend on which molecular species is accumulated. These results provide insight into the cellular mechanisms by which distinct α-synuclein contributes to synaptic pathology in neurodegenerative diseases.

How does the DAF-7 TGF-beta signaling pathway affect the dense core vesicle protein IDA-1?

D. Zheng Fung, A. McGehee; Suffolk University, Boston, MA

Environmental factors influence behavioral responses in many organisms. We are interested in understanding the molecular changes in the nervous system that influence these changes. In *C. elegans*, overcrowding, scarce food supply, and high temperatures affect the DAF-7 TGF-beta signaling pathway. According to previous studies, mutation in the *daf-7* gene or other parts of the DAF-7 TGF-beta signaling pathway results in increased expression of the glutamate receptor GLR-1. Therefore, the DAF-7 TGF-beta signaling pathway regulates protein levels of GLR-1, and data from our lab suggests that IDA-1 might be involved. IDA-1 is a protein found on the surface of dense core vesicles (DCVs) and levels of IDA-1 are correlated with dense core vesicle signaling. In order to test whether a *daf-7* mutation affects IDA-1 levels we used quantitative fluorescence microscopy to measure GFP levels in reporter strains. An IDA-1-GFP protein fusion was imaged and measured in a *daf-7* mutant strain and a wildtype strain. Intensity measurements of IDA1-GFP fluorescence indicate that the abundance of IDA-1-GFP is significantly higher in the *daf-7* mutant strain compared to the wildtype strain. We found this same result in the ALA neuron and in cells around the vulva in *C. elegans.* Furthermore, in order to determine whether regulation was transcriptional or post-transcriptional, a reporter construct where *ida-1* promoter drives GFP was used (P*ida-1*::GFP). Fluorescence microscopy was employed to image and measure the GFP intensity in a *daf-7* mutant strain and a wildtype strain. Quantification of GFP fluorescence showed that there was no significant GFP difference between the *daf-7* and the wildtype strains. Together these results suggest that the DAF-7 TGF-beta signaling pathway is important in regulating levels of the dense core vesicle protein IDA-1, and that this regulation may be post-transcriptional.

Investigating the relationship of the DAF-7/TGF- β signaling pathway, IDA-1 and GLR-1 through behavioral assays

F. Lampitiello, A. M. McGehee; Suffolk University, Boston, MA

Abstract

The nematode *C. elegans* responds to changes in its environment by regulating neurotransmission through several signal transduction pathways. These alterations regulate the transcription and levels of various proteins on the surface of neurons, which in turn influence behavior as well as adaptive strategies to this new environment. When environmental conditions are not favorable (such as a lack of food, extreme temperatures, or overcrowding), the DAF-7/TGF-β signaling pathway gets deactivated. It allows *C. elegans* to enter the Dauer stage by promoting the expression of genes associated with this stage. Previous research has shown that the DAF-7/TGF-β signaling pathway negatively controls the levels of the GLR-1 glutamate receptor expressed in the synapses of *C. elegans*. When a loss of function mutation is present in one of the components of the pathway GLR-1 levels increase. High levels of functional GLR-1 glutamate receptor are associated with an increased frequency of spontaneous reversals; this behavior was therefore used as an indicator for active GLR-1. How exactly the DAF-7/TGF-β pathway affects the levels of GLR-1 is unknown. We studied whether IDA-1 is involved in this regulation. IDA-1 is a transmembrane protein located on dense core vesicles (DCV) that contain neuropeptides. To investigate the role of IDA-1 spontaneous reversal assays coupled with locomotion assays were performed using the wild type strain, *daf-7* loss of function mutants, *ida-1* loss of function

mutants and *ida-1 daf-7* double mutants. The reversals assays highlighted a significant increase in spontaneous reversals in the *daf-7* mutants compared to the wild type, which is consistent with previous research. A difference, however, was not found between the *ida-1* single mutants and *ida-1 daf-7* double mutants. This outcome suggests that IDA-1 is required for the increase in reversals observed in the *daf-7* strain. To confirm that the change in reversals is due to a change in GLR-1 protein we imaged a GLR-1-GFP fusion protein in these same mutant strains. Similar to the behavioral results we saw increased GLR-1-GFP in the *daf-7* mutants as compared to wild type, but no difference in GLR-1-GFP levels between the *ida-1* and *ida-1 daf-7* double mutants. Together these results suggest that IDA-1 is required for regulation of GLR-1 levels through the DAF-7/TGF-β signaling pathway.

Autism and schizophrenia-associated Shank3 mutants regulate the nuclear localization of the Par polarity complex

E. N. Ozsen, M. M. Voglewede, H. Zhang; Rutgers Robert Wood Johnson Medical School, Piscataway, NJ

The Shank family of scaffolding proteins are involved in neuronal development and synaptic plasticity. Mutations in Shank family members have been linked to neurodevelopmental disorders including autism spectrum disorders (ASD) and schizophrenia (SCZ). In particular, *Shank3* is one of the most common monogenic ASD genes and is associated with schizophrenia. However, the mechanisms underlying disrupted synapse formation and function in the Shank3 mutants remain unclear. Previous studies have shown Shank2 interacting with atypical protein kinase C (aPKC), a component of the partitioning-defective protein (Par) complex along with Par3 and Par6, which regulates tight junction formation in epithelial cells. However, it is still unclear whether Shank proteins display similar mechanistic properties in regulating synaptic function. We hypothesize that Shank3 regulates synaptic development through interactions with the Par3/Par6/aPKC complex, and that Shank3 mutants will show altered activities of the Par complex. To examine this hypothesis, we utilize two mutated forms of the *Shank3* gene, *Shank3* InsG3680 and *Shank3* R1117X, which are linked to ASD and SCZ, respectively. Overexpression of Par3, aPKC, and Shank3 in Rat2 cells reveals an increase in aPKC co-localization with the ASD and SCZ-associated Shank3 mutants as compared with wildtype Shank3. Furthermore, there is decreased co-localization between Par3 and aPKC in the Shank3 mutants, suggesting that Shank3 alters Par3-aPKC association. This co-localization of mutant Shank3 and aPKC is concentrated in the nuclei, with no changes in Par3 localization, suggesting that aPKC preferentially interacts with Shank3, leading to its dissociation from Par3 and redistribution into the nucleus. To further examine these findings, we are performing subcellular fractionations of Shank3 mutant mice brains to investigate the cellular localization of Par3, Shank3, and aPKC *in vivo*. Overall, this study can give insight into the interaction of Shank3 with the Par3/Par6/aPKC complex in autism spectrum disorder and schizophrenia, and how Shank3 mutations dysregulate proper synapse development and plasticity.

Development of Expression and Purification Protocols for Characterizing Members of the Ly6 Protein

R. Sung, V. Vaganov, **Y. Hallman**, A. Michii, M. Felland; Carleton College, Northfield, MN.

The Ly6 proteins are a family of novel regulatory proteins conserved among multiple species that share significant structural homology with alpha neurotoxins commonly found in snake venoms, such as α-bungarotoxin. Previous work studying Ly6 function has relied on in vivo monitoring of endogenous

protein levels/behaviors; however, the ability to biochemically characterize and study Ly6 function using purified protein has been limited. Ly6 proteins share a conserved motif known as the Ly-6/uPAR (LU) domain, in which 10 cysteines form five disulphide bonds that maintain the highly flexible three-fingered structure of the LU domain. These predicted structural elements make the expression of Ly6 proteins in their soluble form challenging. In this study, optimal recombinant expression in E. coli and purification conditions for the ODR-2, a membrane-associated protein related to the Ly6 superfamily of GPI-linked signaling proteins found in C. elegans, were elucidated. ODR-2 has two predicted signal sequences, an N-terminal signal sequence for export to the plasma membrane and a C-terminal signal sequence for GPI attachment. We chose to test expression for constructs that were full length or had both signal sequences removed (to mimic the predicted sequence for the mature protein). We examined the impact of using a variety of solubility tags to support expression of soluble ODR-2; we found that use of N-terminal GST, MBP, and pelB leader sequence tags did not improve soluble expression while an N-terminal SUMO-tag did promote soluble expression in the supernatant. All constructs showed significant insoluble expression in the pellet. These conclusions were consistent across multiple expression strains, including BL21 DE3, Origami-2, Rosetta-gami, and SHuffle. Surprisingly, we found that optimal expression yield occurred at 30 or 35°C and a 3-hour inoculation time. We are in the process of scaling up expression and developing protocols for purification of both soluble and insoluble ODR-2.

B379/P1368

Epileptic activity in Drosophila melanogaster with a knockdown of Ube3a in different neuronal populations as a model of Angelman Syndrome

M. Moore, D. T. Taylor; Utah Valley University, Orem, UT

Angelman Syndrome is a rare inherited neurogenetic disease resulting in a neurodevelopmental disorder. This disorder stems from a mutation or deletion of the *Ube3a* (E3 ubiquitin ligase) gene leading to a loss of function of Ube3a. This loss of function interferes with the proteosome-mediated pathway. Some characteristics of this disease are developmental delay, recurring seizures, and severe intellectual disabilities. We studied seizure activity in male *Drosophila melanogaster* (fruit flies) with knockdowns of *Ube3a* in different subtypes of neurons. Epileptic activity was monitored in individual fruit flies using imaging chambers and mechanically induced seizures using a vortex assay. We hypothesized that there will be fewer seizures and a decrease in time to return to normal activity in crosses when valproate, an anticonvulsant, is administered. Mechanically induced seizure activity was recorded in three treatments groups which have *Ube3a* knocked down in glutamatergic, GABA-ergic, or all neurons. A positive control was also used: eas (easily shocked seizure phenotype). The seizure activity was tested in individual male *Drosophila* 3-5 days post-eclosion. They were tested 1-2 hours post-CO2 anesthesia, and transferred into their imaging chambers following the mechanical seizure induction via a vortex. Seizure activity was recorded for 4 minutes, providing enough time for the *Drosophila* to regain normal function post-seizure induction. Epileptic activity was analyzed and included total seizure duration, number of seizures, and total time to return to normal activity.

Developing Behavioral Assays to Study Ly6 Protein Function in C. elegans

R. Sung, **I. Pozzi**, M. Shen, A. Dujsikova, K. Mali; Carleton College, Northfield, MN.

The Ly6 protein family is an understudied conserved family of proteins that is of interest due to their structural similarities to alpha neurotoxins. Alpha neurotoxins target nicotinic acetylcholine receptors; interestingly, Ly6 proteins such as lynx1 have also been shown to regulate nicotinic acetylcholine receptor function. In C. elegans, the Ly6 protein family consists of odr-2 and its nine homologs known as hot genes. Odr-2 has been implicated in functions relating to chemotaxis and pheromone sensing, while the function of the remaining hot genes remains unknown. Our long term goal is to determine the function of hot genes by creating knockout mutants, running behavioral assays, and comparing wild type behavior to our hot gene mutant behavior. We are in the process of generating and obtaining those hot gene mutants, and in preparation, we are establishing protocols for behavioral assays that may serve as methods for mutant characterization. be relevant to mutant characterization. We are using GFP transcriptional reporters for each hot gene to determine where those genes are expressed. We then use this expression pattern as a guide for identifying potential behaviors that may be impeded in a knockout mutant. Here, we focus on developing assays that could be beneficial for studying hot-3 function. Using a GFP transcriptional reporter for hot-3, we see hot-3 expression in the worm olfactory system and the vulval muscles. Based on these expression patterns, we hypothesized that an egg laying assay and a chemotaxis assay were most likely to reflect changes in behavior. To establish the validity of each assay, we compare N2 behavior to a mutant line with known defects in the observed activity. Chemotaxis assays with wild type (N2) worms as a negative control and odr-2 knockout mutants (CX2304) as a positive control for altered chemotaxis due to impaired Ly6 protein function show behavior consistent with previously reported findings. Egg laying assays with N2 worms as a negative control and egl-4 worms as a positive control for egg-laying deficiencies show behavior that aligns with previously reported results. We are in the process of using NeuroPAL to identify additional hot-3 expressing cells in order to identify additional behavioral assays. We anticipate this workflow will be useful for evaluating the function of other members of the Ly6 protein family in C. elegans.

Dynamics of Proteins and Organelles in Neurons

Non-autonomous Signaling from Hypodermal cells Instructs the Formation of Neuronal Glycolytic Condensates *in vivo*

M. Singh, A. Wolfe, D. A. Colón-Ramos; Yale University, New Haven, CT.

Glycolysis, a glucose-consuming pathway required for cellular energy production, is well conserved and has been extensively characterized biochemically. Less is understood regarding how it is subcellularly organized, or coordinated across tissues *in vivo*. Previous work from our lab found that during transient hypoxia or neuronal stimulation, the rate-limiting glycolytic enzyme phosphofructokinase-1(PFK-1.1) dynamically re-localizes from the cytoplasm to condensates near synapses in *C. elegans* neurons. PFK-1.1 is also required at the synapse for the synaptic vesicle cycle(Jang, Nelson et al. 2016, Jang, Xuan et al. 2020). Here we demonstrate that PFK-1.1 condensate formation in neurons is regulated by a non-cell-autonomous signal derived from hypodermal(epidermal) cells. Via cell-specific rescues *in vivo*, we determine that non-autonomous disruption of glycolysis in hypodermal cells affects condensate

formation in neurons. Hypodermal cells in *C. elegans* are rich in metabolic genes and known to regulate metabolic processes(Clark, Meade et al. 2018, Kaletsky, Yao et al. 2018). Our data suggest that the state of glycolysis in the hypodermis signals, non-autonomously, to the neurons to regulate PFK-1.1 clustering, and metabolic state, during transient hypoxia, and reveal mechanisms that are involved in cross-tissue metabolic state communication and cell biological organization of glycolytic proteins.

B382/P1371

Metabolic compartmentalization supports synaptic function during hypoxia in *C. elegans*

S. Ravikumar[1], A. D. Wolfe[1], R. H. Goodman[2], D. A. Colón-Ramos[1]; [1]Department of Neuroscience, Yale University, New Haven, CT, [2]Vollum Institute, Oregon Health & Science University, Portland, OR.

The biochemical reactions required to generate energy for a cell have been well-characterized, yet less is known about how such metabolism is spatially organized and regulated. In specialized cells such as neurons, their unique polarization can result in subcellular changes in metabolic demand far from the cell body. In neurons of the nematode *C. elegans*, transient energy stress by hypoxia causes glycolytic enzymes to dynamically re-localize within the cytoplasm into liquid-like condensates at neuronal connections called synapses. This provides *in vivo* evidence for the existence of a metabolic complex and the intriguing possibility that these metabolic complexes can regulate local metabolic flux.
We identified a **G**lycerol-3-**P**hoshphate **D**e**H**ydrogenase (GPDH-2) required for synaptic vesicle recycling and localization of a glycolytic protein PFK-1.1 during hypoxia. To infer PFK-1.1 enzymatic activity in time and space, we used a fluorescent biosensor to measure concentration changes of its product, fructose 1,6-bisphosphate (FBP). Hypoxia causes a surge and subsequent drop in FBP concentration, presumably increasing overall rates of glycolysis. Interestingly, in *gpdh-2(-)* mutants FBP levels remain high. The reaction GPDH-2 catalyzes is coupled with the redox transfer of electrons from NADH, subsequently regenerating NAD+, an essential cofactor for many cellular reactions. We aim to explore the role of GPDH-2 and NADH/NAD+ ratios on glycolytic flux and synaptic function at single cell resolution. Finally, we observe that GPDH-2 forms accumulations preferentially in synaptic regions and future work will elucidate how it interacts with synaptic proteins and other cellular compartments in neurons.

Energy Matters: Resetting synaptoenergetics is a new mechanistic target for the anti-bipolar actions of lithium

S. Li, G. Xiong, Z. Li, Z. Sheng; National Institutes of Health, Bethesda, MD.

Synaptic transmission imposes large energy demands that are met by local ATP synthesis, which is consumed to initiate action potentials and fuel synaptic vesicle refilling and recycling. Neurons face challenges in maintaining presynaptic bioenergetics or 'synaptoenergetics' during sustained synaptic activity (Li and Sheng, ***Nat Rev Neurosci*** 2022). Bipolar disorder (BD) is a manic-depressive illness characterized by unusual shifts in mood, energy, and concentration. Lithium is a widely used drug for treating BD patients with recurring manic and depressive episodes. However, its cellular target and mechanism of action for alleviating BD symptoms is not yet completely understood. A growing body of evidence suggests that brain bioenergetic failure and mitochondrial dysfunction are pathological hallmarks of BD. Our previous study demonstrated that mitochondria are recruited to presynapses through a crosstalk between AMPK signaling and syntaphilin (SNPH)-mediated mitochondrial anchoring; impaired mitochondrial maintenance fails to maintain sustained synaptic transmission (Li et al., ***Nat***

Metab 2020). This raises a fundamental question of whether impaired presynaptic energetics contributes to BD pathology. In this unpublished work, we address this question using *Snph* KO mice, which display defective presynaptic mitochondrial anchoring and synaptoenergetic deficits. Intriguingly, *Snph* KO mice recapitulate human mania-like behavioral traits, including hyperactive locomotion, anxiety- and depressive-like behaviors, and impaired sensorimotor gating, which are responsive to lithium. Treating *Snph* KO cortical neurons with lithium chloride restores synaptoenergetics by recruiting mitochondria through TRAK O-GlcNAcylation, thus rescuing synaptic efficacy and synaptic depression recovery after prolonged synaptic activity. We further establish human BD-linked iPSC-derived excitatory neuron models, which recapitulate synaptoenergetic deficits during sustained synaptic activity. More strikingly, human BD neurons show reduced SNPH expression. Altogether, using both human iPSC-derived BD neuronal models and *Snph* KO mice, we establish two emerging concepts: (1) defective synaptoenergetics is one risk factor for BD; and (2) restoring synaptoenergetics is a novel target underlying the anti-BD actions of lithium. (Supported by the Intramural Research Program of NINDS, NIH).

Redox-dependent membrane trafficking of neurotransmitter transporters

S. Radhakrishnan[1], S. Amara[2]; [1]National Institute of Mental Health, Bethesda, MD, [2]National Institutes of Mental Health, Bethesda, MD.

Plasma membrane neurotransmitter transporters clear neurotransmitters from the extracellular space and play a key role in regulating neuronal signaling. The neuronal excitatory amino acid transporter 3, EAAT3, is essential for glutamate clearance and modulation of glutamatergic tone. However, EAAT3 also transports cysteine into the cell where it serves as a rate-limiting substrate for the synthesis of glutathione, a key neuronal antioxidant. EAAT3 mutations are associated with several neuropsychiatric disorders such as schizophrenia and obsessive-compulsive disorders that may be due to its role in glutamate or cysteine transport. The activity of plasma membrane transporters can be altered by changes in transport kinetics, expression levels and trafficking to and from the plasma membrane. Using radiolabeled neurotransmitter uptake assays and surface biotinylation assays in Neuro2A cells we showed that activation of protein kinase C (PKC) can increase cell surface localization of EAAT3, as previously reported in other cell lines. There is evidence that redox-triggered mechanisms can influence signaling through PKC by altering the catalytic properties or the subcellular compartmentalization of various PKC isoforms. This suggests a mechanism whereby EAAT3 trafficking could be modulated by cellular redox stress and PKC activation to increase cysteine import and stimulate glutathione biosynthesis. To study this, we examined whether oxidizing agents such as hydrogen peroxide can enhance PKC activation and increase EAAT3 plasma membrane localization. Using a genetically encoded PKC activity sensor, CKAR, we found that application of oxidizing agent, hydrogen peroxide increased PKC activation and enhanced surface expression of EAAT3 in both EAAT3-transfected Neuro2A cells and in primary cultures of mouse cortical neurons that express EAAT3 endogenously. Additional studies have addressed another potential mechanism for redox regulation of neurotransmitter transporters—the direct redox modification of cysteine residues. The dopamine transporter (DAT) contains highly conserved internal lysine and cysteine residues that could trigger a redox-dependent internalization mechanism where the electrophilic modification of a cytosolic cysteine facilitates a conformation change and ubiquitylation of an adjacent lysine residue. We have examined this possibility by assessing DAT trafficking with surface biotinylation, TIRF microscopy and dopamine uptake assays. Taken together

our observations suggest multiple mechanisms though which changes in cellular redox states can regulate the activity of neurotransmitter transport systems.

B385/P1374

Functional characterization of iPSC-derived astrocytes in monoculture

A. Bhattarai, 1st[1], E. Nickoloff-Bybel[2], R. Abedalthaqafi[3], K. Jordan-Sciutto[4]; [1]Life Sciences, Soka University of America, Aliso Viejo, CA, [2]Department of Pathology, University of Pennsylvania, Philadelphia, PA, [3]Department of Periodontics, University of Pennsylvania, Philadelphia, PA, [4]Department of Oral Medicine, University of Pennsylvania, Philadelphia, PA.

Astrocytes are important brain regulatory cells and are essential in supporting physiological processes in the healthy brain. A number of studies have shown astrocytic dysfunction plays a role in many neurological diseases. Much of what is known comes from animal models as obtaining primary human astrocytes is challenging, and beyond the reach of many labs. Recent studies suggest these cells may differ in their response to stressors compared to animal astrocytes. Therefore, there is a need for reliable humanized astrocyte models. Our lab is working towards optimizing a new experimental approach using induced pluripotent stem cell-derived (iPSC) astrocytes (iAst) to model human astrocytes *in vitro*. Preliminary studies suggest iAst in monoculture do not take up glutamate, a critical astrocyte function, to the same degree as when cultured with neurons, suggesting a less mature phenotype. Therefore, we investigated whether different culturing conditions and treatments could induce a more mature phenotype in monoculture. We cultured increasing numbers of iAst in the presence of different concentrations of neuron conditioned media (NCM), or db-cAMP, an agent used to mimic neuronal factors, for 7 days to understand if they changed their phenotype, as has been described for rodent astrocytes. We performed glutamate uptake assays to quantify astrocyte function and used immunofluorescence staining to look at changes in morphology. For glutamate assays, media was removed after 7 days and media containing 100uM glutamate was added. Supernatants were collected at 5, 60, 120, and 180 minute timepoints. Our results show that iAst at 20k-40k cells per well, but not 10k, show modest glutamate uptake ability. Our data also indicates treatment with 50% and 75% NCM, but not db-cAMP, may further increase glutamate uptake in iAst. We are now assessing whether this treatment also alters astrocyte morphology and activation, using the astrocyte specific markers S100b and GFAP. These changes could indicate a more mature or reactive astrocyte phenotype, which would alter the response of the astrocytes to disease relevant stimuli, such as inflammatory cytokines. These data are important as they suggest that while iAst in monoculture do not mimic *in vivo* astrocytes, the use of exogenous neuronal media and/or factors could be used to make them a better *in vitro* model system.

Relationship between mitochondrial transport and neuronal architecture *in vivo*

E. Donovan, N. Bell, E. Sarkar, E. Barnhart; Biological Sciences, Columbia University, New York, NY.

In developing neurons, mitochondrial motility is critical for the growth and stabilization of axonal and dendritic arbors. Mitochondrial movement decreases as neurons mature, and it is unclear whether mitochondrial transport is required to maintain neuronal form and function in adults. To elucidate the physiological significance of mitochondrial transport in adult neurons, we measured and manipulated mitochondrial motility in adult horizontal system (HS) neurons in the *Drosophila* visual system. First, we

used *in vivo* confocal microscopy to measure mitochondrial exchange rates, the volume of mitochondria moving across the primary dendrite, in young (day 4) and old (day 28) flies. We found mitochondrial exchange rate decreases from ~1 μm^3 per min to ~0.25 μm^3 per min from young to old flies. Therefore, as flies age mitochondrial transport decreases, but even in old flies there remains significant mitochondrial transport. Next, we used *Drosophila* genetic tools to selectively perturb mitochondrial motility in adult HS neurons. We selectively up- or down-regulated expression of Milton, a conserved adapter protein essential for mitochondrial transport, in HS neurons. Overexpression had no significant effect on mitochondrial exchange rates in young flies, but mitochondrial exchange increased by 50% in older flies; RNAi knockdown eliminated mitochondrial exchange rates in both young and old flies. RNAi knockdown of Milton reduced mitochondrial localization in distal dendrites and increased mitochondrial localization in the soma. Strikingly, this decrease in mitochondrial localization in the distal dendrites was correlated with reduced neuron branching, and smaller dendrite arbors. Although RNAi knockdown of Milton neurons developed normally, since RNAi was restricted only to the adult, alterations in adult mitochondrial transport perturbed the morphology of the adult neuron. These results demonstrate that mitochondrial motility is necessary to maintain proper mitochondrial localization and dendrite integrity in adult neurons.

Mitophagy receptor function in *Drosophila* neurons is mediated by *kenny*, homolog of mammalian optineurin

L. Randolph[1], Z. Haupt[2], **R. Insolera**[2]; [1]Molecular, Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI, [2]Ophthalmology, Visual and Anatomical Sciences, Wayne State University, Detroit, MI.

The maintenance of a healthy pool of mitochondria is essential to long-term neuronal health. Mitophagy acts as a critical mechanism to degrade damaged mitochondria in neurons, and disruption of this process is tightly associated with neurodegenerative disease. Previous work has shown that mammalian optineurin (OPTN), a gene mutated in familial forms of amyotrophic lateral sclerosis (ALS) and glaucoma, functions as a mitophagy receptor in cultured cells. However, OPTN's role in neuronal mitophagy *in vivo* and how its dysfunction perturbs neuronal physiology remains largely unknown. Here, we demonstrate that the *Drosophila* homolog of optineurin, *kenny (key)*, directly mediates the recruitment of the phagophore to mitochondria undergoing mitophagy. In larval motoneurons, endogenous kenny protein localizes to polyubiquitinated mitochondria. We find that kenny's domain structure mediates its function as a mitophagy receptor: its ubiquitin-associating (UBA) domain localizes the protein to polyubiquitinated mitochondria, and kenny's LC3-interacting region (LIR) domain enables recruitment of the phagophore. Loss of *kenny* in basal conditions, or in conditions of mitochondrial stress, stalls the progression of mitophagy and leads to the accumulation of polyubiquitinated mitochondria in neuronal cell bodies. Interestingly, despite putative autophagy receptor domain structure and tight localization to mitochondria undergoing mitophagy, we observe that the *Drosophila* homolog of mammalian p62, Ref(2)p, is not required for the recruitment of the phagophore in neuronal mitophagy. Physiologically, the absence of *kenny* causes age-dependent locomotor defects under basal conditions, and sensitizes animals to genetic and pharmacological mitochondrial stress manipulations. Overall, this work establishes *kenny* as an essential component of neuronal mitophagy in *Drosophila,* and sets the foundation to further understand the potential cellular and physiological consequences of disease mutations associated human OPTN in an *in vivo* system.

Exceptionally long-lived mitochondrial proteins in mammalian brains

E. Bomba-Warczak, J. Savas; Northwestern University, Chicago, IL.

Mitochondria are critical for maintaining neuronal homeostasis and decreased mitochondria quality and impaired function is a point of convergence for many neurological disorders. Mitochondria are rejuvenated through several processes including mitogenesis, fission-fusion, and multiple quality-control mechanisms. Consistently, the average half-life of mitochondrial proteins in the brain is less than 3 weeks. Efficient surveillance and the continual renewal of mitochondrial components are thought to be essential for maintaining high-quality organelles. and impairments to these mechanisms are thought to lead to the progressive functional and structural degeneration of neurons. However, I recently discovered that a discrete subset of the mitochondrial proteome escapes the classical first-order degradation kinetics and persists for at least 4 months in the mouse brain. Using whole animal dynamic metabolic stable isotope with labeling and mass spectrometry (MS)-based proteomic analysis, I found that these mitochondrial long-lived proteins (mt-LLPs) are (1) present in tissues enriched with long-lived postmitotic cells, (2) are enriched within and near mitochondrial cristae invaginations, and (3) are spatially restricted within the same mitochondria. However, the mechanisms governing the persistence, maintenance, and potential contribution of mt-LLPs to mitochondrial function are currently unknown. We hypothesized that akin to other long-lived proteins, the exceptional longevity of mt-LLPs could play an essential role in the long-term stabilization of the mitochondrial cristae in long-lived, post-mitotic cells. Therefore, the ongoing research efforts are centered on the investigation of the spatio-temporal distribution of mt-LLP within mitochondrial networks using optical pulse-chase techniques and super-resolution microscopy in primary neurons. Further, we hypothesize that the ultrastructure of cristae invaginations physically separates mt-LLPs from degradation, which we examine using genetic manipulations targeting cristae integrity and QC-pathways. Together, investigating the localization of long-lived proteins and characterizing their relationship to cristae structure will increase our understanding of mitochondrial biology and of the role of mitochondrial dysfunction in neurons.

CED-3 caspase and opposing kinesins direct mitochondrial confinement to govern Compartmentalized Cell Elimination

R. Sharmin[1], S. P. Carmona[2], G. Clark[1], K. Juanez[1], A. Elkhalil[1], M. W. Pellegrino[1], S. Shaham[2], P. Ghose[1]; [1]University of Texas at Arlington, Arlington, TX, [2]The Rockefeller University, New York, NY.

Morphologically complex cells, defined by their elaborate processes, such as neurons bearing axons and dendrites, are commonplace in the metazoan body. How morphologically complex cells are eliminated is poorly understood. Intracellular transport is especially important for morphologically complex cells yet its role in cell elimination is underexplored. We discovered a novel 'tripartite' killing program that dismantles the sex-specific CEM neurons and the morphologically complex tail-spike epithelial cell (TSC) during *C. elegans* embryonic development. This program, we term Compartmentalized Cell Elimination, or CCE, is distinguished by three cell regions dying in three different ways. Remarkably, the single process/dendrite of these cells shows two disparate elimination morphologies in two subcellular domains, morphologically similar to different types of developmental pruning, retraction and fragmentation, as well as injury-induced Wallerian degeneration and pathological neurodegeneration.

We present CCE as a powerful *in vivo* model for region-specific cell elimination. We report that mitochondrial retrograde transport, mediated by the Kinesin-1 homolog UNC-116, and soma sequestration of mitochondria are a pre-requisite for CCE. Our genetic evidence suggests that soma confinement of mitochondria is accomplished by the targeting of the anterograde motor UNC-104/Kinesin-3 by CED-3/Caspase. Our findings present a regulatory mechanism for the novel phenomenon of CCE, introduce a novel, *in vivo*, caspase target and provide insight into regulation of pruning/localized cell elimination as well as neurodegenerative diseases.

Single particle tracking reveals the distinct motility patterns of different ER proteins and the overall morphology of ER in dendritic processes of mature neurons

L. Benedetti[1], C. J. Obara[1], P. De Camilli[2], T. A. Ryan[3], J. Lippincott-Schwartz[1]; [1]4D Cellular Physiology, HHMI Janelia Research Campus, Ashburn, VA, [2]Cell Biology and Neuroscience, Yale University School of Medicine, New Haven, CT, [3]Biochemistry, Weill Cornell Medicine, New York, NY.

Neurons are polarized cells whose function is to collect, integrate and relay electrical signals for communication with target cells. The development and maintenance of neurons is accompanied by a high degree of spatial and morphological specialization of intracellular membrane-bound organelles. Neuronal endoplasmic reticulum (ER), for example, extends from cell body to peripheral axon and dendritic elements over hundreds of microns. Since the size of ER tubules in neurons is extremely narrow, diffraction-limited, optical microscopy does not allow visualization of the intricate mesh of ER tubules. Consequently, little is known about the mobility, spatial distributions, and dynamic regulation of intrinsic ER proteins. To gain insight into these questions, we applied single particle tracking analysis combined with super-resolution imaging in dendrites from mature neurons. Summing up diffusion-trajectories of different ER proteins, we could visualize ER morphology across entire dendrites. We found the ER consisted of long, longitudinal tubules extending along dendritic processes. The tubules were interconnected by short perpendicular connections spaced ~1 µm apart, resembling the ladder-like organization of axonal ER in immature neurons reported recently by Voeltz and colleagues. ER proteins diffused throughout this system, but different proteins exhibited a unique motility pattern correlating with the protein's topology and ensemble of functional interactions.

B391/P1380

PDZD8 promotes autophagy at ER-Lysosome contact sites to regulate synaptic growth

R. Thakur[1], K. O'Connor-Giles[1,2]; [1]Neuroscience, Brown University, Providence, RI, [2]Carney Institute for Brain Science, Providence, RI.

Sites of apposition between organelles, referred to as membrane contact sites (MCSs), are hotspots for intracellular signaling, lipid metabolism, and organelle biogenesis/dynamics in eukaryotic cells. The endoplasmic reticulum (ER) forms an extensive and dynamic network of MCSs with almost all organelles. MCSs between the ER and endo-lysosomes are particularly abundant, suggesting important physiological roles.PDZD8 is an intrinsic ER transmembrane protein with a synaptotagmin-like mitochondrial lipid-binding protein (SMP) domain that has been reported to localize to ER-late endosome (LE)/lysosome and ER-mitochondria MCSs. PDZD8 is enriched in neurons. However, its role in the nervous system remains poorly understood. We identified Drosophila PDZD8 as a candidate regulator of synapse formation and function, and used CRISPR-Cas9 editing to generate null and

endogenously tagged alleles. We find that PDZD8 is expressed at synapses throughout the central nervous system and the larval neuromuscular junction (NMJ), where it localizes to ER-LE/lysosome MCSs. Activity-induced synaptic growth, neurotransmission, and locomotion are dysregulated in PDZD8 mutants, indicating key roles in nervous system development and function. Through genetic and in vivo cell biological studies, we have found that PDZD8 regulates synaptic growth via autophagy. Our analyses suggest that PDZD8 promotes autolysosome maturation to maintain autophagic flux in neurons. We further show that the C1-CC domain of PDZD8 functions to tether ER and LE/lysosomes membranes through lipid binding and is required to promote autophagy and synaptic growth. SMP-domain mediated lipid transfer activity at ER- LE/lysosome MCSs is also required to promote synaptic growth. Finally we show that autophagy negatively regulates the Wingless signaling pathway to promote PDZD8-mediated synaptic growth. Overall, we find that PDZD8-mediated ER-lysosome membrane interactions promote autophagy to regulate synaptic growth, revealing an important role for lipid transfer proteins in promoting communication in the brain.

B392/P1381

AP-1 recruits KIF13B to dendrite-selective vesicles at the trans-Golgi network

A. C. Montgomery, M. Bentley; Rensselaer Polytechnic Institute, Troy, NY

Neurons are the fundamental unit of the nervous system and mediate electrochemical signaling. To fulfill their signaling function, neurons are polarized and maintain two distinct compartments: axons that primarily send signals and dendrites that receive signals. Each compartment requires a specific complement of membrane proteins that is maintained by vesicle trafficking. At the Golgi, dendritically polarized membrane proteins are sorted into vesicles by the heterotetrameric adaptor protein complex AP-1. Nascent Golgi-derived vesicles undergo KIF13B-mediated transport and exclusively move in the somatodendritic region without entering the axon. Because cargo sorting and vesicle transport are necessarily sequential, they must be connected. To date, the molecular link between these trafficking events remains undefined. We performed live-cell microscopy of KIF13B in cultured hippocampal neurons to determine at what stage of the secretory pathway KIF13B is recruited to dendrite-selective vesicles. We found that neurons maintained a stable population of KIF13B at the Golgi. Immunocytochemistry showed that this population specifically localized to the trans-Golgi network and colocalized with AP-1. To test the hypothesis that AP-1 retains KIF13B at the Golgi, we used a novel assay to probe for protein-protein interactions in the native cytoplasmic environment of intact neurons. We found that AP-1 specifically bound KIF13B, but not other related members of the Kinesin-3 family. Specific disruption of the interaction between KIF13B and AP-1 perturbed dendrite-selective transport, indicating the requirement of this interaction for polarized trafficking. We propose the model that AP-1 connects the sorting of dendritically polarized membrane proteins into Golgi-derived vesicles to the recruitment of KIF13B to confer dendrite-selective transport. This is the first instance in which a mechanistic link between sorting and transport has been defined and it is likely that similar mechanisms participate in many other trafficking events, both in neurons and non-neuronal cells.

Endocytosis in the axon initial segment maintains neuronal polarity

K. Eichel[1], V. Belapurkar[2], D. Perrais[2], K. Shen[1]; [1]Stanford University, Stanford, CA, [2]University of Bordeaux, Bordeaux, France

Neurons are highly polarized cells with distinct axonal and dendritic domains that send and receive signals, respectively. To achieve this polarization, neurons extensively use membrane trafficking mechanisms to compartmentalize a vast and diverse repertoire of proteins to each domain. The axon initial segment (AIS) is a critical boundary zone separating these domains and is known to function in neuronal polarity by sorting intracellular vesicles and slowing protein diffusion on the plasma membrane. However, it remains unclear how the AIS maintains stringent polarity over the decades-long lifetime of the neuron. We identified a conserved mechanism in which polarized membrane proteins are endocytosed in the AIS and subsequently degraded to maintain neuronal polarity. Using *C. elegans* to study AIS function in intact living animals, we find that dendritically and axonally polarized membrane proteins are endocytosed at the axon-dendrite boundary zone of the AIS. Endocytic removal prevents both the further diffusion of dendritic membrane proteins into the axon and the diffusion of axonal membrane proteins into the dendrite after their initial vesicular delivery to the axon. Engineering receptor interaction with the AIS master organizer, ankyrinG, antagonizes receptor endocytosis in the AIS and causes polarity deficits with subsequent morphological and behavioral defects. We then extend these finding to cultured rodent and induced human neurons. By measuring receptor endocytic rates in live rat hippocampal neurons, we find that the dendritically polarized transferrin receptor is endocytosed at the same rate in the AIS as in the dendrite. However, the post-endocytic targeting of receptors differs: receptors endocytosed in the AIS are targeted for degradation whereas those endocytosed in the dendrite are recycled back to the plasma membrane. We propose that robust receptor endocytosis in the AIS when coupled to degradation functions to clear axonal and dendritic membrane proteins from the AIS to maintain their compartmentalization. Our results reveal a conserved and essential endocytic clearance mechanism in the AIS that contributes to maintaining polarity over the long lifespan of the neuron. Through the study of one of the most polarized cell types, we have identified strategies by which cells achieve compartmentalization along a contiguous membrane.

B394/P1383

Plasticity of prefrontal projections mapped by axonal transport

E. L. Bearer[1], T. W. Uselman[1], C. S. Medina[1], R. E. Jacobs[2]; [1]University of New Mexico Sch Med, Albuquerque, NM, [2]Physiology, Keck School of Medicine, Los Angeles, CA.

The anterior cingulate area (ACA), located in the medial prefrontal cortex (mPFC), regulates flexibility and is implicated in decision-making. Loss of volume in mPFC of cocaine users correlates with decreased executive function and compulsive drug use. We previously reported that ACA projections are plastic, with destinations altered by genetic manipulations of monoamine systems. We now test whether a single experience of ethological threat during adulthood can influence ACA projection functional anatomy. Mice were exposed for 30 min to synthetic predator odor (2,3,5-Trimethyl-3-thiazoline, TMT). Three weeks later tracers were stereotactically injected into the ACA and their projections in the living mouse imaged, first with MEMRI (manganese-enhanced magnetic resonance imaging), and then after fixation, by optical microscopy. Mn(II), a contrast agent for MRI, enters active neurons through voltage-gated calcium channels, is packeged into transport vesicles and trafficked down axons by kinesin-based

fast axonal transport. MEMRI detects brain-wide projections in the living mouse at 100 μm resolution. MR images were captured before and at successive time points after ACA injection (0.5, 6, 24h). Analysis of MEMRI with voxel-wise SPM comparisons between time points revealed progression of Mn(II) distally. Application of our new *In Vivo* digital mouse brain atlas allowed automated quantification of Mn(II) accumulation, which detected dramatic differences in locations of projections between animals experiencing acute threat and those without. Regional segmentation of these projection maps showed decreases in anterior and basolateral amygdala, preoptic hypothalamus and superior central raphe, and increases in posterior and cortical amygdala, periaqueductal gray and dorsal raphe in threat-exposed versus no-threat groups. These changes best correlated with redirection of projections after NET disruption, which increases the amount of noradrenaline in the synaptic cleft similar to an effect of cocaine and may also mimic stress. No ACA volume loss was detected in non-threat exposed, NET-deleted mice by SPM of DTI ($p<0.005$ FDR). Thus a single experience of acute threat redirects ACA distal connections independent of volume loss, which may explain one aspect for how life-threatening experiences pose long lasting risks for anxiety and substance use disorders

B395/P1384

Coordinated Signaling of Laminin and BDNF Stimulates Local Translation and Point Contact Density in Neuronal Growth Cones

N. K. Kirkise, K. Welshhans; Biological Sciences, University of South Carolina, Columbia, SC.

Accurate neural wiring in the developing brain is mediated by growth cones, which are the pathfinding tips of growing axons that respond to environmental cues to find and connect with their synaptic partners. One mechanism initiated by these cues that regulates axon guidance is the local translation of mRNAs, such as *β-actin*, within growth cones. Although it is well-established that neurotrophic factors, such as brain-derived neurotrophic factor (BDNF), stimulate local translation, the contribution of extracellular matrix (ECM) proteins, such as laminins, to this process is not well understood. Our lab has previously shown that local translation of *β-actin* mRNA occurs at point contacts, which are growth cone adhesions that link the ECM to the intracellular cytoskeleton. Thus, we hypothesized that laminin may stimulate local translation in axonal growth cones. Embryonic day 17 mouse cortical neurons were acutely stimulated with laminin 111 ± BDNF by bath application and used in (1) a puromycin assay to label all nascent protein synthesis and (2) a puromycin-proximity ligation assay (Puro-PLA) to label only newly translated β-actin. We found that brief stimulation with laminin 111 and BDNF together results in an increase in overall local protein synthesis and local translation of *β-actin* mRNA in growth cones. Stimulation with laminin 111 and BDNF together also results in an increase in axon length and point contact density. Interestingly, stimulation with either BDNF alone or laminin alone does not result in a significant increase in β-actin local translation, axon length, or point contact density, suggesting that coordinated signaling of these two factors is needed for axon development. However, there are many isoforms of laminin, each with differing temporal and spatial distributions. Thus, we repeated the puromycin assay using BDNF and either Laminin 111, 511, 211, or 221. Neurons cultured on Laminin 111 show increased local protein synthesis and axon length, whereas Laminin 221 results in a remarkable decrease in both local protein synthesis and axon length. Local translation regulates growth cone turning in response to external stimuli. Thus, these results suggest that laminin and BDNF have a synergistic effect on local translation and point contact density, thereby facilitating the movement and directionality of growth cones during axon pathfinding.

Neuronal lysosomes intrinsically regulate site-specific mRNA translation

M. S. Fernandopulle, V. Ryan, F. Almsned, H. Yuan, A. Qi, S. Meydan, C. Drerup, M. Ward; NINDS, National Institutes of Health, Bethesda, MD.

Lysosomes are metabolic and signaling organelles whose dysfunction often leads to neurological disease. Long known as sites of nutrient sensing and recycling, lysosomes have recently been recognized as vehicles for mRNA transport in neurons, enabling translation of proteins far from the cell body. This phenomenon of "local translation" is critical for proper neuronal function; however, how cells regulate this process in space and time remains unclear. Using electron and live cell microscopy, we found that distal lysosomes in neurons were associated with both mRNAs and ribosomes, implicating lysosomes in jointly regulating RNA transport and translation. SunTag translation experiments revealed that lysosomes actively engaged in translation show decreased motility, suggesting a coordinated signaling mechanism for site-specific translation. To uncover the mechanistic basis of lysosome-associated translation, we developed a suite of functional proximity labeling approaches in iPSC-derived neurons that characterize translation on the lysosome surface. We catalog the landscape of mRNA binding to neuronal lysosomes, showing that these mRNAs are functionally diverse and predominantly localized to distal processes. We identify TRPML1, a lysosomal cation channel, as a major binding partner of lysosome-proximal ribosomes. TRPML1 is known to efflux Zn^{2+} in neurites, which halts lysosomal transport by direct motor protein inhibition. Activation of TRPML1 also dramatically stimulated lysosome-associated translation, mechanistically linking lysosome-mediated mRNA localization with site-specific translation. These results shed light on the neuronal function of TRPML1, in which recessive mutations cause the neurodegenerative disease mucolipidosis IV. More broadly, our work suggests a mechanism through which lysosomes disseminate and translate mRNAs in a locally regulated fashion.

B397/P1386

Locally Translated β-actin Associates with Both Adhesions and Filopodia in Growth Cones

K. Rygel, K. Welshhans; Department of Biological Sciences, University of South Carolina, Columbia, SC.

Local translation is the process by which specific mRNAs are localized and translated in subcellular regions. Numerous studies have demonstrated that local translation of *β-actin* mRNA in neuronal growth cones is required for appropriate axon guidance during nervous system development. However, where this newly translated β-actin is incorporated into the growth cone to functionally impact axon guidance has yet to be studied. The prevailing hypothesis in the field states that locally translated β-actin is important for filopodial dynamics since rapid extension and retraction of filopodia is necessary for growth cone turning, but this has not been directly tested. We recently demonstrated that *β-actin* mRNA is locally translated at adhesion sites, called point contacts, in growth cones. Point contacts are highly dynamic structures in motile growth cones that link the extracellular matrix to the intracellular actin cytoskeleton, and generate the force needed for growth cone motility. Based on our finding that *β-actin* mRNA is locally translated at point contacts, we hypothesized that nascent β-actin is needed for both filopodia and point contacts to regulate axon guidance. Using embryonic mouse cortical neurons, we performed fluorescent noncanonical amino acid tagging-proximity ligation assay (FUNCAT-PLA) to label newly translated β-actin and visualize where it is integrated within growth cones. We have found that nascent β-actin is localized in all regions of the growth cone including filopodia, lamellipodia, and the central domain. We also demonstrate that about 34% of newly translated β-actin colocalizes with

point contacts, suggesting that nascent β-actin may contribute to axon guidance, in part, by regulating adhesions. Using axon-specific β-actin siRNAs, we are investigating whether locally translated β-actin is required for both point contact and filopodial dynamics. Taken together, this work describes a novel role for nascent β-actin in growth cones and increases our understanding of the molecular mechanisms that regulate axon pathfinding, a process that is critical for nervous system development.

B398/P1387

Injury Signaling Kinases DLK and LZK Regulate Cell Death in Vincristine-treated Human Neurons

M. Nebiyou, J. Gomez-Deza, C. E. Le Pichon; NIH/NICHD, Bethesda, MD

Vincristine is a drug used to treat solid tumors in cancer patients and is known to cause chemotherapy induced peripheral neuropathy. We found that vincristine is toxic to iPSC-derived human neurons. Dual Leucine Zipper Kinase (DLK) and Leucine Zipper Kinase (LZK) are homologous, stress-sensing and injury-signaling proteins that can regulate neuron death. We tested whether DLK and/or LZK were necessary for vincristine-induced neuron death. We generated single and double CRISPR knockout lines for DLK and/or LZK and found that DLK or LZK single knockouts were partially protected from vincristine-induced toxicity while the DLK/LZK double knockouts were wholly protected compared to wild type. Blocking transcription in wild type neurons also prevented vincristine-induced toxicity. Using RNA seq, we confirmed that vincristine treatment induces a diverse transcriptional response. In each of the single knockout lines the transcriptional response to vincristine was blunted while in the double knockout line it was essentially abolished. We are currently collecting proteomic data to complement our transcriptomic data and examining which transcriptionally dependent pathways are necessary for toxicity.

B399/P1388

Temperature adaptation shapes the calcium response and morphology of a thermosensory neuron to drive temperature seeking behavior

J. R. McVay[1], J. A. Beagan[1], D. A. Colón-Ramos[1,2]; [1]Yale University, New Haven, CT, [2]Universidad de Puerto Rico, San Juan, PR

Sensory neurons across the evolutionary spectrum adapt their responses when chronically exposed to environmental stimuli, thereby altering behavior. AFD, the thermosensory neuron of the nematode *Caenorhabditis elegans,* represents an information-rich, genetically tractable model system with which we can study the molecular interface of sensation and behavior. *C. elegans* do not have an innate temperature at which they live, rather they form memories of preferred habitation temperatures and perform goal-directed behavior to return to this temperature, a behavior called thermotaxis. By quantifying single-neuron calcium activity and tracking the behavior of animals trained to have different habitation temperature preferences we find, consistent with previous studies, that AFD exhibits a limited 'perceptive range' of temperatures that it responds to which adapts on the same timescale as behavioral plasticity. Intriguingly we find that AFD's sensory tip, comprised of a primary cilium and a network of microvilli, exhibits structural remodeling which occurs on the same timescale as perceptive range adaptation, and as has been previously observed (Singhvi et al. 2016, Cohn et al. 2020). Similar to the mammalian retina, activity of a set of phosphodiesterases (PDEs) is required for proper adaptation of both the structural- and activity-based signatures of AFD's perceptive range.

B400/P1389

The conserved kinase NEKL-4/NEK10 orchestrates ciliary microtubule integrity and mitochondrial dynamics to modulate hyperglutamylation-induced neurodegeneration

K. M. Power, J. Shivas, C. Rongo, M. M. Barr; Rutgers University, Piscataway, NJ

Neurodegenerative diseases present a severe and significant medical concern that has historically proven difficult to study. The health of neurons depends in large part on mitochondrial localization and metabolic function. Microtubule-based transport is important for proper mitochondrial localization and function, and thus to neuron health. Consequently, proteins that affect microtubule stability play indirect yet important roles in the regulation of mitochondria function. A loss-of-function mutation of the deglutamylase CCP1 causes infantile-onset neurodegeneration and leads to excessive glutamylation of microtubules and defects in transport of mitochondria in neurons. CCP1 is evolutionarily conserved; its ortholog in *Caenorhabditis elegans*, *ccpp-1*, also functions in a subset of neurons where it affects microtubule stability of neuronal cilia. We performed a forward genetic screen to identify suppressors of *ccpp-1* age-related ciliary degradation. We identified a mutation in the NIMA-related kinase *nekl-4*, an ortholog of mammalian NEK10. NEK10 is associated with both cilia dysfunction and disrupted mitochondrial homeostasis in mammalian cells. We found that NEKL-4 did not play a role in regulating microtubule glutamylation and acted via an unknown mechanism. To uncover the NEKL-4 mechanism of action and to determine the role of NEKL-4 and CCPP-1 in mitochondrial dynamics, we generated CRISPR-tagged fluorescent wild type, constituently active, and kinase dead forms of NEKL-4. Wild-type and kinase-dead NEKL-4 did not localize to cilia, but was associated with mitochondria. In *ccpp-1* mutants, kinase-dead NEKL-4 translocated to cilia and suppressed ciliary degeneration. Time lapse microscopy showed that NEKL-4 and mitochondria are co-transported, which suggests that NEKL-4 may regulate mitochondria transport in the ciliated neurons. Additionally, our imaging showed that both *nekl-4* and *ccpp-1* affect mitochondrial morphology and localization in these neurons. We are currently testing the hypothesis that CCPP-1 and NEKL-4 affect mitochondrial function, which may impact cilia structure and function. Our work adds to a growing body of evidence suggesting a connection between cilia stability and mitochondrial function that, when perturbed, could instigate neuronal degeneration.

B401/P1390

Are organelle contacts the key to neuron and astrocyte resilience as well as their demise during neurodegeneration?

S. Rhoads, S. Hsu, V. Dong, T. Cohen, S. Cohen; University of North Carolina, Chapel Hill, NC

Organelle contacts are sites of close apposition between two or more membrane-bound organelles. They facilitate critical lipid, protein, and metabolite transfer for proper cell function. Recently, organelle contact dysregulation has been implicated in several neurodegenerative diseases, including amyotrophic lateral sclerosis (ALS). However, the extent of organelle contact dysfunction in ALS is not fully understood. Here, we use multispectral imaging, a fluorescence microscopy technique that can be used to simultaneously visualize six fluorescent structures (i.e., organelles) in live cells, to quantify the type and extent of organelle contacts. First, we investigated organelle contacts in live primary neurons and astrocytes at baseline. Our results showed that both cell types have distinct sets of organelle contacts that reflect cell-specific functions. Particularly, mitochondria content and contacts were more extensive in neurons likely reflecting their higher oxidative phosphorylation rates compared to astrocytes. Then, we examined the extent of organelle reorganization during acute pharmacological perturbations,

including oxidative stress and ER stress. Surprisingly, organelle contacts were not significantly altered. Our results could suggest that these cell types maintain specific organelle contacts because they are integral to proper cell function and survival. In future experiments, we will analyze if this resilience is maintained during ALS-related genetic perturbations and whether contact dysregulation is a prominent pathomechanism in ALS.

B402/P1391

Drosophila* motion vision neurons exhibit diverse ER calcium signals *in vivo

K. C. Delgado, E. L. Barnhart; Columbia University, New York, NY

Calcium gates synaptic vesicle release in neurons and is therefore a crucial regulator of neurotransmission. Neuron activation drives calcium influx across voltage gated calcium channels, but it is unclear how calcium handling by the endoplasmic reticulum (ER) contributes to cytosolic calcium concentrations and therefore neurotransmission *in vivo*. In this work we used *in vivo* two photon calcium imaging to measure stimulus-evoked calcium signals in the cytosol and ER in *Drosophila* neurons. In the cytosol, the sign of the calcium response is always the same — calcium concentrations always increase in response to preferred visual stimuli — regardless of cell type or compartment (i.e. axons versus dendrites). Response kinetics, on the other hand, vary across cell types: whereas some neurons response to visual stimuli quickly and transiently, others response more slowly and in a sustained fashion. In the ER, both the sign and timing of stimulus-evoked calcium signals differed across cell types and compartments. For example, in the axon terminals of second-order interneurons Mi1, the ER took up calcium during neuron activation but released calcium in the dendrites of the same cell. In Tm1 neurons, the ER took up calcium immediately after neuron activation in both axons and dendrites. Additionally, the addition of SERCA inhibitor thapsigargin to the brains of flies greatly decreased ER calcium signaling and altered cytosolic calcium signals, indicating that ER calcium dynamics during neuron activation can alter cytosolic calcium signals. The *Drosophila* visual system is an ideal model for investigating how ER calcium signals tune neuronal response kinetics, and how those responses shape cell and circuit function *in vivo*.

B403/P1392

Investigating pleiotropic roles of PINK1 and Parkin in neuronal homeostasis

A. M. Lamper; Columbia University, New York City, NY

PINK1 and Parkin are well established initiators of mitophagy, but can also modulate the activity of several mitochondrial fission, fusion, and motility factors. In Drosophila, PINK1 and Parkin induce the degradation of the major mitochondrial fusion factor, Marf, and a mitochondrial motility factor, Miro. Degradation of these proteins is hypothesized to arrest and isolate mitochondria, thereby facilitating mitophagy. However, it is unclear how PINK1 and Parkin regulate mitochondrial morphology and localization in vivo. Using confocal microscopy to image adult Drosophila neurons in vivo, we measured increased mitophagy levels in flies overexpressing either PINK1 or Parkin. These flies also exhibited extreme fragmentation of the mitochondrial network, consistent with PINK1/Parkin-dependent degradation of Marf and subsequent downregulation of fusion. Additionally, PINK1 or Parkin overexpression increased the amount of mitochondrial mass in the somata of these neurons, indicating modulation of mitochondrial trafficking or biogenesis. Interestingly, the average mitolysosome volume significantly increased in neurons expressing RNAi against Parkin, suggesting that mitolysosome size may

vary by mitochondrial degradation mechanism. These results support the idea of pleiotropic roles for PINK1 and Parkin in mitochondrial homeostasis, and suggest that defects in mitophagy may not be sufficient to fully describe the neurodegeneration seen in Parkinson's disease.

B404/P1393

Illuminating organelle dynamics during neuronal differentiation

M. C. Zanellati[1], R. Basundra[2], V. Dong[1], V. Williams[1], S. Hsu[1], M. Deshmukh[2], S. Cohen[1]; [1]UNC-Sarah Cohen Lab, Chapel Hill, NC, [2]UNC-Mohanish Deshmukh Lab, Chapel Hill, NC

Organelles undergo dramatic changes in shape, position, dynamics, and interactions with other organelles (together termed morphodynamics) to fine tune the metabolic state of a cell.
Until recently, scientists lacked the tools to study organelle organization in living cells at a systems level. We have developed a method for multispectral imaging of up to seven organelles simultaneously in live cells. We used this method to study organelle dynamics along the differentiation of induced pluripotent stem cells (iPSCs) into cortical neurons (iNeurons). We transfected iPSCs and iNeurons with organelle markers using custom piggyBac vectors 24 hours prior to imaging and collected multispectral images at five timepoints throughout neuronal differentiation, maturation, and *in vitro* aging: iPSCs, and iNeurons at day 7, day 14, day 21, and day 30. At each timepoint, >30 Z-stacks and >30 timelapse images were collected, from at least three biological replicates. Raw images were then subjected to linear unmixing and run through a Cell Profiler image analysis pipeline for segmentation and analysis of approximately 400 morpho-metrics including organelle area, size, shape, and number; number and area of the contacts (2 to 6-way). We found that the cell body (soma) contracts during differentiation from an iPSC to an iNeuron. Interestingly, some organelles scale with the soma, while others do not. We also observed changes in organelle morphology. For example, tubulation of mitochondria increased as iPSCs differentiated into cortical neurons and decreased again when the neurons aged. These data are consistent with increased oxidative phosphorylation as cells differentiate. We noted that organelle communication networks dramatically rewire throughout iNeuron differentiation. At early stages of differentiation, we observed rearrangement of mitochondria-organelle contacts. Mitochondria-ER and mitochondria-ER-Golgi contacts were high in iPSCs, and significantly decreased at early stages of neuronal differentiation. These contacts are consistent with glycolytic metabolism in stem cells being lost as they differentiate to iNeurons. Moreover, we found an increase in higher order contacts (4- and 5-way contacts) when neurons became mature, compared to young neurons and undifferentiated iPSCs. Finally, these high-order contacts were subsequently lost with *in vitro* aging. Our results suggest that extensive rewiring of organelle contacts is necessary to support metabolic changes throughout differentiation, and that the resulting organelle signature is required to sustain neurological functions.

B405/P1394

Interrogating how local axonal microtubule dynamics impact motor activity and synaptogenesis

J. Aiken, E. L. F. Holzbaur; University of Pennsylvania, Philadelphia, PA

Neurons rely on sustained, long-range trafficking of components to maintain the complex synaptic networks that encode the human experience. With a single neuron capable of forming thousands of distinct synapses, spatially precise delivery of the necessary synaptic components is paramount. Here, we explore how local regulation of microtubules, the track upon which neuronal cargos are transported, and long-range microtubule motors, the proteins responsible for cargo movement, influence synapse

distribution and delivery of essential synaptic cargos. We previously demonstrated that synaptic vesicle precursors (SVPs) are retained at presynaptic regions in rat primary neurons. These *en passant* presynaptic zones are enriched for dynamic microtubule ends, which promote detachment of the neuronal kinesin-3 motor KIF1A. Using live-imaging of human neurons derived from induced pluripotent stem cells (iPSCs), we reveal that even in the absence of robust synaptic connections, "protosynaptic" sites are hotspots for dynamic microtubules rich in GTP-tubulin, with a 5-fold increase in microtubule growth events observed in regions containing stable SVPs compared to non-synaptic regions. In the human i3Neuron system, SVPs demonstrate increased pause frequency at the protosynapses in both the anterograde and retrograde directions. Further, we have developed a novel heterologous synapse protocol utilizing microfluidic chamber technology to isolate human i3Neuron axons and the addition of neuroligin-expressing HEK cells to rapidly induce robust presynapse formation. We find that neuroligin-1 (NL1) expression in non-neuronal cells is sufficient to instigate presynapse formation in human i3Neuron axons within an hour of NL1+ cell addition. This method provides unique spatial and temporal control over presynapse formation, making exclusive presynaptic genetic and pharmacological manipulation possible and providing a convenient time scale upon which to observe/probe axonal synaptogenesis. Using this system, we find that axonal nocodazole treatment leads to a significant decrease in Synapsin I/II coverage over NL1+ HEK cells. Interestingly, while less Synapsin by volume is detected, the average intensity of accumulated Synapsin is not altered by nocodazole treatment. We propose a model where local microtubule modulation and cargo-specific motor behavior directs axonal traffic to help direct synaptogenesis and guide synaptic cargo delivery.

B406/P1395

Investigating competing constraints on dendrite architecture in Drosophila motion vision neurons

J. I. Kalai, E. J. Donovan, G. Napoleone, E. L. Barnhart; Columbia University, New York, NY

Form and function are inextricably linked in elaborately branched neurons. In particular, theoretical work suggests that specific parent-daughter power rules, which describe the relative widths of parent and daughter dendrites at branch points, are important for neuronal signal processing and stability. In theory, scaling according to Rall's Law, in which total dendrite cross-sectional area narrows across branch points, facilitates the efficient propagation of electrical signals in dendritic arbors. In contrast, our previous work suggests that scaling according to Da Vinci's Rule for Trees, in which cross-sectional area is conserved across branch points, facilitates intracellular transport and the reliable distribution of mitochondria throughout the neuron (Donovan and Agrawal et. al., 2022). To investigate how neurons balance these competing constraints on dendritic architecture, we measured mitochondrial motility and localization patterns in different types of *Drosophila* lobula plate tangential cells (LPTCs). Using in vivo confocal microscopy, we measured significant mitochondrial motility in several types of LPTCs, including CH, VS, and V1 neurons. In addition, by reconstructing mitochondria in ssTEM images of the Drosophila brain, we found that mitochondria are densely distributed throughout these same cell types. Finally, our preliminary measurements of dendrite architecture suggest that different types of LPTCs obey different forms of parent-daughter scaling rules, including Rall's Law and Da Vinci's Rule for Trees. In future studies, we will exploit this morphological diversity, along with in vivo measurements of mitochondrial dynamics and dendritic signal processing, to better understand how systems-level maintenance and intracellular homeostasis give rise to different dendritic architectures in neurons.

Visual Input Synergizes With the Wnt/B-Catenin Pathway to Promote Proliferation in the Zebrafish Optic Tectum

J. Yue[1], O. L. Hagen[1], Y. Kim[1], E. Kushkowski[1], C. Roberts[1], H. Rouse[2], M. Varga[3], S. W. Wilson[2], K. L. Cerveny[1]; [1]Reed College, Portland, OR, [2]University College London, London, United Kingdom, [3]Eotvos Lorand University, Budapest, Hungary

Specialized stem cell niches arrayed throughout the zebrafish body support life-long growth. In the visual system, coordinated growth of the retina and optic tectum (OT) promotes accurate retinotopic mapping as new neurons are added throughout life. Studies of adult fishes have provided evidence that survival, proliferation, and differentiation of cells in the OT are correlated with retinal innervation, raising the possibility that retinal axons provide crucial information to control stem and progenitor cell behaviors in the optic tectum. To explore how retinal innervation influences OT growth in larval zebrafish, we examined brains lacking innervation from (i) both eyes as a result of the lakritz mutation and (ii) one eye as a result of surgical eye removal, and then compared them with wild-type larvae with two eyes. We observed elevated cell death in non-innervated and denervated OT lobes. In addition, we found fewer sox2+ stem cells and a smaller proportion of proliferating progenitors in lakritz and denervated OT lobes. To test the extent to which light-evoked retinal activity contributes to proliferation and survival in the optic tectum, we reared fish from 1-9 dpf in the dark and then asked how OT cells in innervated and non-innervated tecta behave. We found that innervation was still able to promote survival and proliferation, albeit to a lesser extent, when fish were reared in the dark. These data, combined with preliminary RNA-Sequencing data, led us to investigate whether the Wnt/B-catenin pathway was acting as an innervation-dependent trophic factor. Expression of wnt3a and Wnt/B-catenin target genes, lef1 and axin2, appears to be innervation dependent as in situ hybridization and RT-qPCR show decreased levels of these genes in non-innervated and denervated tectal lobes. Further supporting an innervation-dependent role for Wnt activation, we found that lakritz mutants treated with a Wnt-pathway agonist, 6-bromoindirubin-3-oxim (BIO), exhibited increased levels of OT cell proliferation that was indistinguishable from wild-type OT proliferation. Together our data provide new insight into how sensory organs and the brain regions they innervate coordinate their growth and development.

Mitochondria are not discrete organelles. On the contrary, mitochondrial fission and fusion facilitate mixing of mitochondrial proteins throughout a dynamic, interconnected mitochondrial network. Defects in fission and fusion are associated with a host of neurodegenerative disorders. However, it is unclear how specific perturbations affect the rate and spatial pattern of mitochondrial mixing in neurons in vivo. In this work, we used a mitochondrially-targeted photoconvertible fluorescent protein, Mito-Dendra2, to measure mitochondrial mixing rates in wild-type Drosophila neurons in vivo. We photoconverted Mito-Dendra2 from green to red fluorescence in selected regions of Horizontal System (HS) neurons (e.g. in the primary or distal dendrites) and measured the rate of recovery of green fluorescence over time. Fluorescence recovery occurs more rapidly in primary dendrites than in the distal dendrite: three hours after photoconversion, recovery was 54+/-6% in primary dendrite and 39+/-4% in the distal dendrites. In addition, whereas more than 50% of mitochondria in the primary dendrite had mixed

mitochondrial content (i.e. both green and red fluorescence) three hours post photoconversion, only ~25% of mitochondria in the distal dendrites were both green and red. Altogether, these results suggest that the rate of mitochondrial mixing is higher in primary dendrite than in the distal dendrites. In future studies, we will investigate how specific perturbations of fission and fusion affect the spatiotemporal pattern of mitochondrial mixing, as well as mitochondrial health and neuronal function in vivo.

Lipids and Membrane Microdomains

Rafting in a RUSH: membrane microdomains in secretory trafficking

I. Castello Serrano, R. Ippolito, K. R. Levental, I. Levental; Molecular Physiology and Biological Physics, University of Virginia, Charlottesville, VA.

The determinants of sub-cellular distribution are not known for most membrane proteins. Although a variety of specific motifs responsible for cargo integration into coat/adapter mediated sorting schemes have been identified, many membrane proteins have no known motifs. A potential parallel mechanism for organizing membrane protein traffic is sorting by membrane microdomains known as lipid rafts. Such domains are small, dynamic assemblies of preferentially interacting lipids and proteins that have been widely implicated in signaling at the plasma membrane (PM) but are likely also present in various endo-membranes. Our lab has recently defined the structural determinants of preferential protein partitioning into these ordered membrane domains and shown that raft affinity is required for PM localization of a subset of membrane proteins. These observations suggested that sorting and trafficking of membrane proteins can be directed by their affinity for a particular membrane environment. To directly assess the role of membrane microdomains in the secretory pathway, we have taken advantage of a robust tool for synchronized protein traffic, known as RUSH (Retention Using Selective Hooks). Here, tagged proteins are retained in specific organelles by a resident “hook”, where they can be quickly released upon introduction of biotin, allowing direct and quantitative analysis of trafficking rates and destinations by fluorescence microscopy. We applied this system to a library of transmembrane domain (TMD) constructs to evaluate the role of raft affinity in secretory traffic, and the machinery involved therein. We find that while TMD-encoded raft affinity is fully sufficient for PM sorting, it is not sufficient for rapid exit from the endoplasmic reticulum (ER), which requires a specific cytosolic sorting motif. However, we find that Golgi exit rates are highly raft-dependent, with raft preferring proteins exiting ~2.5-fold faster than mutants with perturbed raft affinity. By super-resolution microscopy, we directly observe segregation of proteins in the Golgi apparatus based on their affinity for ordered membrane rafts. We rationalize these observations with a kinetic model of trafficking through the secretory pathway that implicates phase separation of organellar membranes in the kinetics of inter-organellar transport. These observations highlight a central role for lipid rafts in sorting in the secretory pathway and establish the core machinery for raft-mediated cellular trafficking from Golgi. The proposed kinetic model provides quantitative insights into the dynamics of TMD protein migration from ER to their final post-Golgi destination.

ORP9 controls the abundance of accessible cholesterol in cell membranes by inhibiting OSBP at ER-TGN contacts

T. Naito[1], H. Yang[1], D. Koh[1], Y. Saheki[1,2]; [1]Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, SINGAPORE, [2]Department of Molecular Physiology, Faculty of Life Sciences, Kumamoto University, Kumamoto, JAPAN.

Sterol is an essential structural component of cell membranes in eukaryotes. The dominant form of sterol in mammals is cholesterol, which is particularly enriched in the plasma membrane (PM), where it plays a critical role in cell signaling. The majority of cholesterol is transported inside the cell via vesicular transport. However, growing evidence suggests that non-vesicular lipid transport facilitated by lipid transfer proteins maintains cellular cholesterol distribution by transporting a biochemically distinct pool of cholesterol, known as accessible cholesterol, between various organelles and cell membranes. Previous studies from our group and others showed that evolutionarily conserved lipid transfer proteins, including GRAMD1s (GRAMD1a/1b/1c) and oxysterol binding protein (OSBP), contribute to this process. GRAMD1s transport accessible cholesterol from the PM to the endoplasmic reticulum (ER) when the levels of accessible PM cholesterol are elevated, while OSBP transports such cholesterol from the ER to the trans-Golgi network (TGN) via phosphatidylinositol 4-phosphate (PI4P)-driven countertransport. However, how the activities of these proteins are coordinated by the cell remains unclear. Here, we performed a mini-screen, using a novel cholesterol biosensor derived from the cholesterol sensing domain of GRAMD1s (GRAM-H), and identified ORP9, a member of OSBP-related proteins (ORPs), as a critical regulator of OSBP function. We generated HeLa cells lacking ORP9 and GRAMD1s and found that these quadruple knock-out cells showed massive accumulation of accessible cholesterol in the PM and the TGN membrane. Strikingly, inhibition of OSBP function in these cells was sufficient to remove accessible cholesterol from these membranes. Mechanistically, ORP9 extracts PI4P from the TGN and inhibits OSBP-mediated cholesterol transport at ER-TGN contacts. In the absence of ORP9, PI4P accumulates in the TGN, causing hyperactivation of OSBP-mediated cholesterol transport to the TGN as well as to the post-TGN membranes, including the PM. Furthermore, GRAMD1 aberrantly populates at ER-TGN contacts in cells lacking ORP9, suggesting its additional role in extracting cholesterol from the TGN. Our results show that ORP9 controls PI4P levels in the TGN, thereby coordinating the activities of OSBP and GRAMD1s at ER-TGN contacts to maintain cellular cholesterol distribution.

Cholesterol-enriched domains contribute to myoblast migration by controlling focal adhesions

J. Vanderroost[1], N. Avalosse[1], D. Mohammed[2], P. Van der Smissen[1], D. Hoffmann[1], D. Alsteens[2], D. Tyteca[1]; [1]UCLouvain, Brussels, BELGIUM, [2]UCLouvain, Louvain-la-Neuve, BELGIUM.

Myoblast migration is crucial for myogenesis and muscle regeneration and requires membrane deformation, calcium ion exchanges and cytoskeleton rearrangements, a.o. However, the spatiotemporal control of myoblast migration remains elusive. This study tests whether and how plasma membrane (PM) cholesterol (chol) and/or sphingolipids can perform this role using mouse C2C12 myoblasts. Multiple lipid labeling and high-resolution confocal microscopy evidenced two types of lipid domains at the outer PM leaflet of resting myoblasts: sphingomyelin/chol/ganglioside GM1 (SM/chol/GM1)- and chol-enriched domains. Both domains showed a lower membrane stiffness than the bulk membrane as evidenced by atomic force microscopy. Super-resolution confocal microscopy

showed that upon migration, chol and SM polarized at the front whereas GM1 polarized at the rear. Spontaneous migration (IBIDI chambers) and oriented migration towards a specific gradient (transwell assays) were both reduced after chol depletion by methyl-beta-cyclodextrin (mβCD) but not after sphingolipid depletion by fumonisin B1. The effect of mβCD on myoblast migration could be related to sphingolipid opposite polarization and/or to the abundance of chol-enriched domains as both parameters were specifically reduced by mβCD treatment. To discriminate between those two possibilities, the effects of actin cytoskeleton disruption by cytochalasin D (cytoD) on myoblast migration, sphingolipid polarization and lipid domains abundance were evaluated in parallel. Compared to mβCD, this treatment induced a similar or even lower decrease of sphingolipid polarization contrasting with a stronger decrease of spontaneous migration and chol-enriched abundance, suggesting the specific implication of chol-enriched domains for myoblast spontaneous migration. To understand the mechanism behind, membrane lipid lateral diffusion and focal adhesions (FAs) abundance, size and distribution were respectively evaluated by fluorescence recovery after photobleaching (FRAP) and immunolabeling. Whereas a lipid mobility-based mechanism can be excluded, both mβCD and cytoD decreased the number of FAs in perfect correlation with the chol-enriched domain abundance and spontaneous migration. In addition, inhibition of actin polymerization abrogated the mβCD-induced impaired FAs and chol-enriched domains, supporting their interplay. This study reveals the contribution of chol-enriched domains in myoblast spontaneous migration possibly by controlling FAs.

APOE Targets Astrocyte Lipid Droplets to Modulate Triglyceride Saturation and Droplet Size

I. Windham, E. D. Wallace, C. Wagner, S. Cohen; University of North Carolina-Chapel Hill, Chapel Hill, NC

APOE is the strongest genetic risk factor for late-onset Alzheimer's Disease (AD). Individuals with one or two copies of the *APOE4* variant are at an increased risk of developing AD compared to those homozygous for the *APOE3* variant. In the central nervous system, apolipoprotein E (APOE) is highly expressed in astrocytes. Astrocytes secrete APOE-containing lipoproteins, which mediate bidirectional lipid transport between astrocytes and neurons. However, the role of APOE in intracellular lipid metabolism is not understood, nor is the mechanism by which the *E4* variant predisposes individuals to AD.

Surprisingly, we discovered that a subset of APOE diverts from the secretory pathway and instead targets cytoplasmic lipid droplets (LDs) during lipogenesis. This raises the possibility that APOE plays previously unrecognized roles in cellular lipid metabolism by acting directly on LDs. Using immunogold electron microscopy and live-cell imaging, we found that APOE translocates onto LDs via membrane bridges at ER-LD contact sites. Expression of APOE truncation mutants indicates that both the N and C terminal domains of APOE play a role in LD targeting; the N-terminus is required for trafficking to LDs while the C-terminus is required for LD binding. Lipidomics studies demonstrate that *APOE* knockdown increases unsaturated triglycerides. Increased unsaturation of triglycerides stored in LDs has previously been shown to promote larger LDs. Consistent with this idea, knockdown of *APOE* causes fewer, larger LDs. Expression of a chimeric construct targeted only to LDs rescues the LD size of the knockdown, indicating that LD-localized APOE is responsible for the droplet phenotype. Like *APOE* knockdown cells, we observed that *APOE4* cells have fewer and larger LDs and more unsaturated triglyceride than APOE3-expressing or *APOE* knockdown cells. The larger LDs observed in E4 cells are more sensitive to lipid peroxidation than E3 LDs. Our data indicate that APOE can localize to cytoplasmic LDs in astrocytes,

where it promotes triglyceride saturation and modulates LD size. Loss of APOE reduces triglyceride saturation, while APOE4 is a toxic gain of function variant that causes increased triglyceride unsaturation and larger LDs. We propose that astrocytes with large, unsaturated LDs caused by *APOE4* are sensitized to lipid peroxidation or lipotoxicity, which could contribute to AD risk.

Chronic Ethanol Exposure Induces an Increase in the LD Surface Enzyme HSD17B13 via a Disruption of the Ubiquitin-Proteasome Transporter Protein VCP

R. Schulze[1], S. Weller[1], S. Sen[1], C. Casey[2], P. Thomes[2], **M. McNiven**[1]; [1]Mayo Clinic, Rochester, MN, [2]University of Nebraska Medical Center, Omaha, NE.

BACKGROUND: Steatotic hepatocytes store and catabolize substantial numbers of large neutral lipid-storage organelles termed lipid droplets (LDs) upon which associate scores of enzymes and adapter proteins that regulate LD dynamics. The process by which the synthesis or utilization of these organelles is perturbed during alcohol-induced fatty liver of steatohepatitis AFLD/ASH is poorly defined. METHODS**:** Mass Spectrometry of LDs isolated from EtOH damaged rat livers, combined with immunofluorescence microscopy of cultured hepatocytes, and Western blot analysis demonstrated a substantial number of LD-associated proteins with a marked increase in ubiquitination in response to chronic EtOH exposure. From this initial finding we predict that this alteration in the LD-proteome can lead to a disruption of LD catabolism and hepatocellular steatosis. RESULTS**:** Further analysis of our Mass Spec results revealed a substantial 10- fold reduction in the Valosin Containing Protein (VCP) from the LD surface in EtOH damaged hepatocytes. VCP is a well-studied “protein segregase” that is known to remove ubiquitinated proteins from cell membranes for transport to the proteosome. Western blot analysis of LDs isolated from control or EtOH-damaged hepatocytes confirmed this loss of VCP while high resolution confocal imaging of EtOH-treated cells expressing GFP-VCP showed a dramatic 5-fold reduction in LD-association. To define how changes in VCP might lead to alteration in the ubiquitinated-LD proteome and hepatocellular steatosis we tested for changes in the LD enzyme HSD17B13, known to play an important role in hepatic steatosis. We find that HSD17B13 is a ubiquitinated protein that exhibits an increased association with LDs from EtOH-damaged cells. Importantly, disruption of VCP function by a well characterized chemical inhibitor (DBeQ), or siRNA knock down, leads to an increase in HSD17B13 association with LDs and a doubling in hepatocellular LD content. In CONCLUSION, this study demonstrates that chronic EtOH exposure disrupts the association of a known ubiquitin segregase from the LD surface leading to a marked increase in the ubiquitination of LD-surface proteins such as HSD17B13 and that this increase is concomitant with hepatocellular steatosis. These findings provide new insights into the cellular mechanisms by which EtOH exposure disrupts normal hepatic lipid catabolism.

Visualizing & dissecting mechanisms driving liquid-crystalline lipid droplet (LD) biogenesis

S. Rogers[1], L. Gui[1], A. Kovalenko[1], V. Zoni[2], M. Carpentier[3], K. Ramji[3], K. Ben Mbarek[3], A. Bacle[3], P. Fuchs[3], P. Campomanes[2], E. Reetz[1], N. Ortiz Speer[1], E. Reynolds[1], A. Thiam[3], S. Vanni[2], D. Nicastro[1], **M. Henne**[1]; [1]UT Southwestern Medical Center, Dallas, TX, [2]University of Fribourg, Fribourg, SWITZERLAND, [3]Laboratoire de Physique de l'École Normale Supérieure, Paris, FRANCE.

Lipid droplets (LDs) are the primary energy storage organelles of cells, and serve as reservoirs for triglycerides (TGs) and sterol-esters (SEs). These lipids typically exist as isotropic liquids, but recent findings indicate that SEs including cholesterol-ester can transition from amorphous states into so-called smectic liquid-crystalline phases within LDs. Liquid-crystalline SE deposits are commonly observed in metabolic diseases such as atherosclerosis, obesity, NAFLD, and coronary heart disease, but the metabolic cues that trigger their formation are poorly understood. A key knowledge gap is also how changes in the phase properties of LD lipids influence the LD proteome, which ultimately gives LDs their cellular function. In this multi-disciplinary study, we combine *in situ* cryo-electron tomography, molecular dynamics simulations, cell biology, and biochemistry to reveal that TG lipolysis is a major driver in the formation of liquid-crystalline lattice LDs (LCL-LDs). Furthermore, we find that LDL-LD biogenesis selectively alters the LD proteome, with a sub-set of resident LD proteins translocating to the ER network, whereas others remain LD-associated. Mechanistically, we find that TG lipolysis alters the TG:SE ratio within LDs, promoting SE accumulation and its transition from an isotropic to liquid-crystalline phase. Molecular dynamics simulations reveal that TG depletion promotes spontaneous TG and SE de-mixing, additionally altering the lipid packing of the LD phospholipid monolayer surface. Fluorescence imaging and proteomics further reveal that liquid-crystalline phases are associated with selective remodeling of the LD proteome. A sub-set of canonical LD proteins including Erg6 re-localize to the ER network, whereas others remain LD-associated. Model Type I (ERTOLD) protein LiveDrop also redistributes from LDs to the ER, suggesting liquid-crystalline phases influence ER-LD inter-organelle transport, and may affect Type I (ERTOLD) LD protein localization. Proteomics data using isolated LDs also indicates that non-canonical proteins not normally targeted to LDs can associate with LCL-LDs, suggesting liquid-crystalline LDs may interact with non-LD protein machinery. Collectively, we propose that TG mobilization alters the TG:SE neutral lipid ratio of LDs, driving lipid demixing within the LD interior and ultimately the phase transition of LD SEs into a liquid-crystalline phase, which selectively alters the LD surface proteome.

B416/P1404

The role of lipid droplets in muscle hypertrophy

S. Hayashi, S. Yonekura; Shinshu University, Nagano, JAPAN.

Muscle hypertrophy is caused by various external factors, including exercise and the intake of some nutrients, for example vitamin D, zinc and source of protein. Recently, there has been a great deal of effort in promoting skeletal muscle hypertrophy, and *in vitro* and *in vivo* reports have shown that appropriate heat stimulation is beneficial to the hypertrophy of skeletal muscle. It was reported that C2C12 mice myoblast cultured under mild heat stimulation (39℃) show muscle hypertrophy compared to standard temperature (37℃). However, the detailed mechanisms that mild heat stimulation promotes hypertrophy are unknown. We observed heat-stimulated myoblasts form a lot of lipid droplets (LD) in inside. Therefore, we hypothesized that mild heat stimulation contributes to

hypertrophy through promoting LD formation. The aim of this study was to demonstrate whether heat-induced LD formation facilitates C2C12 skeletal muscle hypertrophy or not. Firstly, in order to track changes over time, we observed LD in muscle cell at day1, 3, 5 after differentiation using fluorescent immuno-staining. We found that LD number in heat-stimulated cell significantly increased compared to non-heat cell at day1. In addition, *Plin2*, *Plin3*, *Plin5*, which are LD membrane localized proteins, those gene expression in heat-stimulated cell also significantly increased compared to non-heat cell at 12 hours after differentiation. However, almost LD in heat-stimulated cell disappeared after day3 when myotube forms. These results suggest that LD formation at early differentiation stage is crucial event in order to promote hypertrophy by mild heat stimulation. Finally, we evaluated whether muscle hypertrophy attenuate or not by inhibiting LD formation. We confirmed that LD number under mild heat stimulation didn't increase at day1 by *Plin2* siRNA transfection, which molecule is LD membrane localized protein and essential for LD formation. Interestingly, we observed that myotube formation significantly decreases in *Plin2* siRNA group at day3 compared to non-heat cell. These results indicated that LD formation is essential for mild heat-induced muscle hypertrophy.Taken together, these findings provide evidence that mild heat stimulation contributes to hypertrophy through promoting LD formation. Currently, we investigate how mild heat stimulation promotes LD formation and how LD affects hypertrophy.

Modeling Congenital Generalized Lipodystrophy in C. elegans

X. Bai[1], L. Huang[2], S. Chen[3], B. Nebenfuehr[1], B. Wysolmerski[4], J. Wu[5], S. Olson[4], A. Golden[1], C. Wang[3]; [1]National Institutes of Health, Bethesda, MD, [2]Institute of Plant and Microbial Biology, Academia Sinica, Nankang, Taipei, TAIWAN, [3]Institute of Plant and Microbial Biology, Academia Sinica, Taipei, TAIWAN, [4]Department of Biology and Program in Molecular Biology, Pomona College, Claremont, CA, [5]Department of Clinical Laboratory Science and Medical Biotechnology, National Taiwan University, Taipei, TAIWAN.

The metabolic homeostasis of fatty acids is important for human health. The lipid droplets (LDs) serve as the major energy reservoirs to maintain fat homeostasis in nearly all cell types. Seipin, a conserved endoplasmic reticulum protein, plays pivotal roles during LDs biogenesis. Clinical studies demonstrated that SEIPIN contributes to congenital generalized lipodystrophy, which is a disorder with the excessive absence of adipose tissue and muscular dystrophy. Dysfunction of SEIPIN also affects both adipocyte development and lipid storage in non-adipose tissues. However, the mechanisms of Seipin associated diseases are poorly understood. Here, we functionally characterized *seip-1*, the sole ortholog of SEIPIN in the nematode model *Caenorhabditis elegans*, using CRISPR/Cas9 gene editing, transcriptional assay, lipidomic analyses, and other genetic tools. We observed that SEIP-1 is associated with LDs and is crucial for controlling LDs size and lipid homeostasis. The depletion of seip-1 disrupted fatty acid synthesis, and particularly reduced the ratio of polyunsaturated fatty acids (PUFAs) in the *C. elegans* embryonic fatty acid pool, suggesting an important role of SEIP-1 in maintaining fatty acid homeostasis. Homozygous *seip-1* mutants displayed penetrant embryonic lethality, which is caused by the disruption of the lipid-rich permeability barrier, the innermost layer of the *C. elegans* embryonic eggshell. Intriguingly, dietary supplementation of selected n-6 PUFAs rescued the embryonic lethality and defective permeability barrier in *seip-1* deletion mutants. Accordingly, we propose that SEIP-1 may maternally regulate LD biogenesis and lipid homeostasis to orchestrate the formation of the permeability barrier for eggshell synthesis during embryogenesis. We then edited the gene to mimic an orthologous lipodystrophy

patient variant *seip-1(A185P)* in *C. elegans*, which also resulted in embryonic lethality and could be rescued by PUFA supplementation. The expression pattern indicated that *seip-1(A185P)* may only compromise SEIP-1 protein function instead of affecting trafficking and cellular localization of SEIP-1 *in vivo*. The penetrant phenotype allowed us to perform a chemical mutagen-based suppressor screen to revert or suppress the embryonic lethality in the *seip-1(A185P)* mutant. A total of five suppressor candidate lines were isolated in a small trial screen by screening for a significant restoration of the embryonic viability. We identified a set of candidate suppressor alleles in each suppressor line from our genomic mapping and whole-genome sequencing studies. These newly identified suppressing factors may lead to the new direction of LD biology, and shed light on future therapies for lipodystrophies.

B418/P1406

New chemical genetic tools selectively illuminate choline phospholipid distribution in organelle membranes

W. Moore[1], R. J. Brea-Fernandez[2], N. K. Devaraj[1], I. Budin[1]; [1]University of California, San Diego, San Diego, CA, [2]Universidade da Coruña, Coruña, Spain

The membrane bilayer is a defining feature of cells and contains complex mixtures of individual lipid building blocks. While early models for membrane structure assumed a homogeneous distribution of lipid species within the bilayer, mounting evidence has illustrated that both lateral heterogeneity and interleaflet lipid asymmetry are key features of membrane architecture and function. However, there is still a poor understanding of how lipids are organized and transversely distributed between bilayers in eukaryotic cells. In large this has been due to a lack of non-destructive tools capable of imaging lipids in an organelle-specific manner and resolving their transbilayer orientation. Here we have developed a chemical genetic tool capable of quantitatively imaging lipid subpopulations in living cells. The method utilizes bioorthogonal click chemistry to label phospholipid headgroups with a fluorogenic dye, whose fluorescent emission in genetically controllable through the expression of a fluorogen-activating protein. As a test case we show that bioorthoganol incorporation of azido choline into cellular membranes can be used to selectively image and measure subcellular choline phospholipid (CPL) pools in live cells. Moving forward, we use this tool to investigate how lipid biosynthesis and trafficking influence CPL content and organization in specific membrane compartments.

B419/P1407

Surface Cholesterol-Enriched Domains Specifically Promote Invasion of Breast Cancer Cell Lines by Controlling Invadopodia and Extracellular Matrix Degradation

M. Maja[1], D. Mohammed[2], A. C. Dumitru[2], S. Verstraeten[3], M. Lingurski[4], M. Mingeot-Leclercq[3], D. Alsteens[2], D. Tyteca[1]; [1]de Duve Institute, UCLouvain, Brussels, BELGIUM, [2]Louvain Institute of Biomolecular Science and Technology, UCLouvain, Louvain-la-Neuve, BELGIUM, [3]Cellular and Molecular Pharmacology Unit, UCLouvain, Brussels, BELGIUM, [4]Institut de Duve, UCLouvain, Brussels, BELGIUM.

Breast cancer is the most common neoplasm and the primary cause of cancer death in women. Mortality is almost exclusively due to metastatic disease. Better molecular characterization of the primary tumor is therefore crucial for a good prediction of the clinical outcome. Although breast cancer cells present an altered cholesterol content, how this change influences plasma membrane biophysical properties and cancer cell invasion is unknown, mainly due to difficulties to investigate cholesterol both quantitatively and qualitatively and to compare isogenic cell models. In this study, we benefited from

endogenous cholesterol probes, confocal vital imaging and atomic force microscopy to investigate if and how plasma membrane cholesterol content and distribution contribute to breast cancer cell invasion. We started with the MCF10A cell line series (non-tumorigenic MCF10A, pre-malignant MCF10AT and malignant MCF10CAIa cells) as an isogenic model of breast cancer progression and showed that, compared to A and AT cells, malignant CAIa cells exhibit (i) a decreased cytocortex stiffness, (ii) an increased plasma membrane stiffness, (iii) a high cholesterol content at the dorsal cell surface and its distribution in submicrometric domains and (iv) a high invasive potential. To explore the involvement of cholesterol in cell invasion, cells were partially cholesterol-depleted with methyl-β-cyclodextrin (mβCD) and tested for Matrigel invasion assay. We found a specific and reversible inhibition of the malignant cell invasion, in perfect correlation with the residual cholesterol content. Mechanistically, dorsal cholesterol-enriched domains can be endocytosed and reach the cell ventral face where they participate in invadopodia formation and extracellular matrix (ECM) degradation, as revealed by the mβCD-induced decreased abundance and size of cortactin-positive invadopodia structures and of fluorescent gelatin degradation areas. We then extended our research to MDA-MB-231, Hs578T and BT549, 3 invasive triple-negative breast cancer cell lines, and found similar cholesterol-enriched domains and dependence of invadopodia outgrowth, ECM degradation and cell invasion to cholesterol. Our data provide new clues on the molecular mechanisms of breast cancer invasion and open the way for the development of new therapies based on specific membrane cholesterol targeting in cancer cells.

B420/P1408

Coupling of protein condensates to ordered lipid domains determines functional membrane organization

I. Levental[1], H. Wang[1], S. H. Chan[1], M. K. Rosen[2], J. Ditlev[3], K. R. Levental[1]; [1]Molecular Physiology and Biophysics, University of Virginia, Charlottesville, VA, [2]Department of Biophysics, University of Texas Southwestern Medical Center, Dallas, TX, [3]Department of Biochemistry, University of Toronto, Toronto, ON, CANADA.

During T-cell activation, the transmembrane adaptor Linker of Activation of T-cells (LAT) forms biomolecular condensates with Grb2 and Sos1, facilitating signaling. LAT has also been associated with cholesterol-rich condensed lipid domains. However, the potential coupling between protein condensation and lipid phase separation and its role in organizing T-cell signaling were unknown. Using a combination of reconstitution and live cell imaging, we report that LAT/Grb2/Sos1 condensates reconstituted on model membranes can induce and template lipid domains, indicating strong coupling between lipid- and protein-based phase separation. Correspondingly, activation of T-cells induces protein condensates that associate with and stabilize raft-like membrane domains. Inversely, lipid domains nucleate and stabilize LAT protein condensates in both reconstituted and living systems. This coupling of lipid and protein assembly is functionally important, since uncoupling of lipid domains from cytoplasmic protein condensates abrogates T-cell activation. Thus, thermodynamic coupling between protein condensates and ordered lipid domains regulates the functional organization of living membranes.

B421/P1409

Membrane tension gradients induce membrane mechanical lysis in living bacteria

D. Gomez[1], G. Hocky[1,2], E. Rojas[1]; [1]Biology, New York University, New York, NY, [2]Chemistry, NYU, New York, NY.

Environmental fluctuations represent a continuous thread for single-celled organisms, increasing lysis probability, the phenomenon of cell membrane rupture that leads to cell death. To survive, bacteria adapt their plasma membrane mechanical properties and activate their tension-sensing mechanosensitive (MS) channels. While the mechanisms of cell survival using MS channels are well known, critical features of membrane biology linked to cell survival have been largely overlooked. Here we demonstrate that mechanical lysis in living cells is supported by tension gradients, experiencing a maximum at the heterogeneously distributed protein-lipid interface. Furthermore, changes in membrane fluidity affect the protein distribution within the membrane, which induces a more homogeneous protein distribution and higher survival probabilities. Our work highlights lipid fluidity and membrane protein's vital role in cell lysis, a potentially vulnerable feature that could be used in future antibiotic designs.

B422/P1410

Investigating the organisation of the asymmetric plasma membrane using a novel solvatochromic reporter

C. Patra[1], M. Singh[2], T. V. Zanten[1], P. P. Singh[2], R. Vishwakarma[2], S. Mayor[1]; [1]National Centre for Biological Sciences, TIFR, Bangalore, INDIA, [2]CSIR-IIIM, Jammu, INDIA.

The plasma membrane of an animal cell is a heterogenous mixture of lipids and proteins that exhibits both lateral heterogeneity and transverse asymmetry in composition with Phosphatidylserine(PS) and Phosphatidylethanolamine(PE) being predominantly in the inner leaflet and Sphingomyelin(SM) and Phosphatidylcholine(PC) in the outer leaflet[1]. The membrane is a complex mixture of lipid species with a range of headgroups and degrees of acyl-chain unsaturation, influencing the properties of the bilayer such as fluidity and ordering and consequently the function of embedded membrane proteins[2] . The outcome of particularly the leaflet composition asymmetry on membrane organisation, local physical properties and function has been explored in limited ways[3]. In this study, we have probed the presence of liquid-ordered (l_o) domains in each leaflet and their transbilayer registry that can regulate information transfer, in live cells by designing a membrane localised probe that is sensitive to lipid order. This fluorescent probe, C3L, uses the solvatochromic reporter Laurdan as a template and reports on changes in membrane lipid order of complex compositions such as Giant Plasma Membrane Vesicles(GPMVs), while exhibiting a preference for l_o-domains. C3L distributes across both leaflets in the live cell membrane, regulated by flippases and scramblases and may be selectively and robustly confined to the inner leaflet after back extraction. Using this reporter we find that depletion of SM has a more outer-leaflet restricted effect, PS depletion leads to effects on both leaflets with the inner leaflet being more affected. This suggests that PS and SM play important roles in building and maintaining domains as well as coupling them across the bilayer. The organisation of the active composite membrane is hypothesised to be driven by the activity of the juxtaposed cortical cytoskeleton along with composition[4]. Using C3L, we see preliminary evidence for this hypothesis. We find that the lipid order distribution in live cells exhibits domains of much smaller scale and broader order distribution in the membrane, whereas it is rather homogenously disordered at the same temperature in GPMVs derived from the same cells. This

provides support for active de-mixing in membranes of living cells[5]. Using this tool we intend to explore the fundamental principles of regulation of membrane properties by the membrane composition and cytoskeletal activity and its impact in tuning cellular function.

Sphingolipids protect ergosterol in the *Leishmania major* membrane from sterol-binding toxins

C. Haram[1], S. Moitra[1], R. Keane[1], M. Kuhlmann[2], C. Frankfater[2], F. Hsu[2], S. M. Beverley[2], K. Zhang[1], P. Keyel[1]; [1]Department of Biology, Texas Tech University, Lubbock, TX, [2]Washington University, St. Louis, MO.

Leishmaniasis causes 1.5-2 million cases and 70,000 deaths annually worldwide, and is caused by protozoan parasites in the genus *Leishmania*. One key treatment is amphotericin B. Amphotericin B suffers from drawbacks like renal toxicity and drug resistance. It targets ergosterol, which maintains *Leishmania* membrane integrity and interacts with other lipids in the membrane, including Inositol Phosphorylceramide (IPC), the major sphingolipid in *Leishmania*. Sphingolipids protect sterols from toxin accessibility in mammalian cells, but it is unclear if this is conserved in *Leishmania*. Here, we used the cholesterol-dependent cytolysins (CDCs) streptolysin O and perfringolysin O to test the hypothesis that sphingolipids restrict ergosterol plasma membrane accessibility. Using flow cytometry, we showed that CDCs bound equally well to *L. major* genetically lacking IPC synthesis enzymes compared to wild type, indicating IPC does not restrict ergosterol accessibility. While CDC binding was IPC and ceramide independent, CDC cytotoxicity was enhanced in the absence of IPC. Ceramide reduced perfringolysin O, but not streptolysin O, dependent cytotoxicity. This difference was due to membrane binding determinants in the toxin lipid binding L3 loop. We conclude that the L3 loop can sense ceramide. Ceramide was sufficient to protect *L. major* promastigotes from amphotericin B. Thus, *L. major* serves as a genetically tractable model organism for understanding toxin-membrane interactions. Furthermore, our findings suggest removing ceramide may enhance ergosterol-targeting drug efficacy.

Cytoplasmic tail of the fission yeast polycystin Pkd2 regulates its clustering in the eisosomes

M. Malla, P. Chowdhury, D. Sinha, B. T. Bisesi, Q. Chen; The University of Toledo, TOLEDO, OH.

Cytoplasmic tail of the fission yeast polycystin Pkd2 regulates its clustering in the eisosomes Mamata Malla, Pritha Chowdhury, Debatrayee Sinha, Benjamin Thomas Bisesi, and Qian Chen*Department of Biological Sciences, The University of Toledo, Toledo, OH, 43606
Polycystins are a family of evolutionarily conserved ion channels. Mutations of either human polycystins, PC1 or PC2, lead to a common genetic disorder Autosomal Dominant Polycystic Kidney Disease. The unicellular model organism *Schizosacchromyces pombe* possesses a single polycystin homolog Pkd2 which localizes to the plasma membrane and regulates cytokinesis, the last step of cell division. Here, we carried out a functional analysis of Pkd2 based on its Alphafold predicted tripartite structure consisting of N-terminal lipid-binding (LBD), central transmembrane (TMD) and C-terminal cytoplasmic (CCD) domains. LBD assumes a unique immunoglobulin-fold, while TMD contains nine transmembrane

helices. Both were essential, but CCD was not. However, without CCD, Pkd2 clustered on the cell surface in eisosomes, a furrowing microdomain on the plasma membrane. Inhibiting eisosome assembly prevented the clustering, while disrupting ER-PM contacts further increased it. This eisosome-clustering of Pkd2 was further supported by the negative genetic interaction between mutants of *pkd2* and the eisosome gene *pil1*. The tripartite structure of Pkd2 is also preserved in the *S. japonicus* Pkd2 ortholog which can fully replace Pkd2. Our discovery suggests a potential mechanism of regulating polycystin function through clustering in the microdomains of the plasma membrane.

Perilipin facilitates lipophagy in yeast

J. R. Monala, B. Folger, J. M. Goodman; Pharmacology, UTSW Dallas, Dallas, TX.

Lipid droplets (LDs) are ubiquitous cell organelles that are vital for energy homeostasis for which they constantly undergo anabolic and catabolic processes based on cellular metabolic need. The mechanism of LD biosynthesis is becoming understood but the molecular mechanism of LD degradation is far less clear. Since the discovery of lipophagy in liver in 2009, many studies have attempted to understand the underlying mechanism. In yeast, the predominant form of lipophagy is microlipophagy (µlipophagy), in which LDs are directly engulphed by the vacuole. We have been trying to identify LD surface proteins that mediate µlipophagy in yeast, and report here the involvement of Pln1, a protein we previously identified in yeast as a member of the perilipin family, important for LD biogenesis, morphology and stability. Perilipins have three known domains, PAT, Hydrophobic, and Repeats. We find that lipophagy, measured by fluorescence microscopy and by vacuolar release of GFP from Erg6, is delayed or blocked in the pln1 null strain under nitrogen starvation or glucose restriction. Deletions of Pln1 were generated to identify regions necessary and sufficient for lipophagy. The PAT and Hydrophobic domains were necessary for LD targeting and stability and are not easily assessed for lipophagy, while the Repeats domain could be deleted with no apparent loss of function. However, a region of ~120 residues (which we term GAP2) after Repeats lost significant lipophagy function while not interfering with LD targeting or stability. Yeast µlipophagy can be dissected into LD binding to vacuoles, engulfment, and internalization. Fluorescence microscopy suggest that Pln1 is not required for binding but is required for a subsequent step such as engulfment. Lipophagy is inhibited but not fully blocked in the absence of Ypt7 (Rab7), a known factor in vacuolar fusion events, suggesting it is important but not absolutely necessary for this lipophagy. Our studies suggest that Pln1 controls an intermediate but essential step in µlipophagy and that GAP2 is important for this function. We hope to identify the binding partner to Pln1 on the vacuolar surface.

Regulation of mitochondrial derived compartments by unsaturated fatty acids

S. Wong, A. Hughes; University of Utah, Salt Lake City, UT

Unsaturated fatty acid levels in cells must be tightly regulated, as too much or too little both have adverse effects on cellular health and animal physiology. The deregulation of cellular lipids is a major cause of metabolic diseases, a hallmark of metabolic syndrome, and a risk factor for other diseases including diabetes and heart disease. However, the regulatory mechanisms that maintain unsaturated fatty acid levels are not completely understood, nor are the full extent of their impacts on the function of organelles, including mitochondria. Our lab discovered a new mitochondrial remodeling pathway that

responds to nutrient stress in yeast and mammals. In response to various metabolic stressors, cells generate mitochondrial-derived compartments (MDCs). MDCs form at ER-mitochondria contact sites and are cargo selective, only incorporating select mitochondrial outer membrane proteins. Upon formation, MDCs remove membrane proteins and lipid bilayers from mitochondria, and thus play a role in regulating both mitochondrial lipid and protein homeostasis. To date, it remains unclear as to what is the cellular function of MDCs, and whether MDCs are strictly responsive to alterations in amino acid metabolism or if other metabolic stressors, such as lipids, trigger MDC formation. Our recent studies are uncovering a role for unsaturated fatty acids and triglycerides in the MDC pathway. Overexpression or constitutive activation of *OLE1*, the yeast stearoyl-CoA desaturase, results in constitutive MDC formation, as well as elevated unsaturated fatty acids and triglycerides. Interestingly, heterozygous deletion of *OLE1* also results in constitutive MDC formation. These data suggest that MDCs may respond to an imbalance of lipids that affects metabolic pathways and/or membrane composition. Overall, these studies raise the exciting possibility that MDCs may form as a response to deregulated cellular lipids.

Understanding the mechanisms of accessible plasma membrane cholesterol maintenance using a novel cholesterol biosensor

D. Koh[1], T. Naito[1], P. Rozario[1], F. Zhong[1,2], Y. Saheki[1,3]; [1]Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore, [2]Skin Research Institute of Singapore (SRIS), Singapore, Singapore, [3]Department of Molecular Physiology, Faculty of Life Sciences, Kumamoto University, Kumamoto, Japan

Cholesterol is an essential component of eukaryotic cell membranes, where it plays crucial roles in membrane integrity and cell signaling. While vesicular transport contributes to bulk transport of cholesterol in cells, this mode of transport is often slow and non-selective. Recent evidence suggests that non-vesicular lipid transport facilitated by lipid transfer proteins (LTPs) controls the transport of a biochemically defined fraction of cholesterol, termed “accessible” cholesterol, between the plasma membrane (PM) and other organelles, including the endoplasmic reticulum (ER) (where cholesterol is synthesized) to maintain cholesterol homeostasis. However, the molecular basis of accessible cholesterol transport remains poorly understood. A family of evolutionarily conserved sterol-binding LTPs known as GRAMD1s (GRAMD1a/1b/1c) plays an important role in transporting accessible cholesterol from the PM to the ER. Here, we engineered the N-terminal cholesterol sensing domain of GRAMD1b (i.e., the GRAM domain) to a highly sensitive cholesterol biosensor and successfully visualized the distribution of accessible cholesterol in several cell types in live. To elucidate the mechanisms that are responsible for transporting accessible cholesterol to the PM, we performed a mini-screen using HeLa cells and keratinocytes and identified oxysterol binding protein (OSBP) as a critical player for maintaining the levels of accessible cholesterol in the PM. OSBP is another evolutionarily conserved LTP, which transports cholesterol from the ER to the *trans*-Golgi network (TGN) against its concentration gradients in exchange for TGN-enriched phosphatidylinositol 4-phosphate (PI4P) at ER-TGN contacts. Using live cell imaging approaches, we found that drug-induced formation of aberrant enlarged vesicles induces OSBP-dependent accumulation of accessible cholesterol on these vesicles, which is accompanied by reduction of accessible PM cholesterol. Our findings provide important insights into how the cellular distribution of cholesterol is maintained by LTPs at membrane contact sites.

B431/P1416

Coupling*de novo*lipid synthesis to ER and nuclear membrane biogenesis

J. W. Carrasquillo Rodriguez[1], S. Gao[2], O. Uche[1], M. V. Airola[2], S. Bahmanyar[1]; [1]Yale University, New Haven, CT, [2]Stony Brook University, Stony Brook, NY

The endoplasmic reticulum (ER) is the largest membrane bound organelle in cells. The ER is made up of distinct structural and functional domains, which include the nuclear envelope and peripheral ER sheets and tubules. The nuclear envelope surrounds and protects the genome, while the peripheral ER is essential for protein and *de novo* lipid synthesis. The membrane architecture of the peripheral ER is generated and maintained by membrane shaping proteins and interactions with the cytoskeleton; however, it remains unclear how the *de novo* synthesis of bilayer lipids is regulated to control the organization of the ER and nuclear envelope. Here, we focus on CTDNEP1 *(Sc Nem1)* and its regulatory binding partner NEP1R1 *(Sc Spo7)* that control the activity of a key enzyme necessary for *de novo* glycerolipid synthesis, lipin 1 (*Sc Pah1*), in human cells. Regulation of lipin 1 by the CTDNEP1/NEP1R1 complex limits *de novo* glycerophospholipid synthesis throughout the cell cycle to restrict ER size and maintain NE shape. Using a combination of protein modeling, structure-function analyses, and live cell microscopy, we show that CTDNEP1 contains an amphipathic helix necessary for its targeting to ER/nuclear envelope membranes. Deletion of the amphipathic helix of CTDNEP1 reduces its interaction with NEP1R1, impairs its ability to regulate lipin 1 and decreases its protein stability. We identify a key residue in NEP1R1 essential for binding to CTDNEP1 and for regulating its protein half-life. Our data suggest a model in which the subcellular localization of CTDNEP1 controlled by its amphipathic helix and its protein stability, which depends on its interaction with NEP1R1, regulates the synthesis of bilayer lipids that generate ER/nuclear membranes. Future work will determine whether CTDNEP1's amphipathic helix senses specific types of bilayer lipids or bulk membrane properties of the ER/nuclear envelope. Together, these data suggest a model in which regulation of *de novo* lipid synthesis is coupled to the specific lipid content of ER/nuclear envelope membranes through direct lipid sensing.

Intracellular Organization by Biomolecular Condensation

B432/P1417

Metastable Phase-separated Membraneless Organelles (MLOs) of Human Myxovirus-resistance (MxA) GTPase: Rapid Reversible Osmosensing

P. B. Sehgal; Cell Biology & Anatomy, and Medicine, New York Medical College, Valhalla, NY.

Liquid-liquid phase-separation (LLPS) leads to the formation of biomolecular condensates [also called membraneless organelles (MLOs)] in the cytoplasm and nucleus of eukaryotic cells. MLOs provide a scaffold for diverse cellular functions. The replication of many viruses in mammalian cells also involves LLPS condensates [e.g. vesicular stomatitis (VSV), rabies (Negri bodies), influenza A, Ebola, measles, Epstein-Barr, and SARS-CoV-2 viruses]. Four years ago, in studies involving the interferon-α2-induced human myxovirus-resistance protein (MxA), a dynamin-family large GTPase, we made the discovery that GFP-MxA as well as IFN-induced endogenous MxA formed biomolecular condensates in the cytoplasm. As background, MxA is a major antiviral effector of IFNs-α/β against diverse RNA- and DNA-viruses. Heterogenously sized and shaped cytoplasmic MxA condensates were observed in intact human Huh7 and A549 cells, showed homotypic fusion, were membraneless by CLEM, had a gel-like consistency by FRAP, evidenced a shell and core organization by dissection using 0.03% saponin, were often tethered to

intermediate filaments, and displayed spheroid to filament metastability in response physical pressure on live cells. Functionally, cells with cytoplasmic MxA condensates showed an antiviral phenotype against VSV and SARS-CoV2-mCherry viruses. VSV nucleocapsid protein associated with MxA condensates. Previous mutational studies had shown that GTPase activity was required for this antiviral activity but not for condensate formation. Mutants that had lost oligomerization properties also lost antiviral activity. Thus, the ability to form condensates was necessary but not sufficient for antiviral activity. Unexpectedly, MxA condensates were exquisitely sensitive to hypotonic stress similar to tissue edema. Condensates of GFP-MxA or IFN-induced endogenous MxA disassembled within 1-2 min of exposing cells to hypotonic medium (in the range ¼ to ½ tonicity), but then spontaneously reassembled 10-15 min later into new structures. Antiviral activity of MxA survived hypo-osmotic stress despite a cycle of disassembly and reassembly of MxA condensates during VSV infection. The data point to (a) cell integrity and cytoplasmic "crowding" as a critical regulator of MxA condensate structure, and (b) a complex relationship between MxA condensate dynamics and antiviral activity.

B433/P1418

Constructing Synthetic Organelles for Mammalian Cellular Engineering

W. Wang, M. Garabedian, R. Welles, M. Good; Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA.

Intrinsic disordered proteins (IDPs) form macromolecular membraneless compartments through phase separation to regulate cellular process. Our goal is to explore the potential of synthetic organelles in modulating cellular signaling and behaviors through targeting and sequestering endogenous proteins. These organelles offer a powerful and generalizable approach to modularly control cell decision-making with broad applications for human cellular engineering. Genes encoded synthetic scaffolds were cloned into either pcDNA3.1 vector (Addgene) for transient expression or 3rd gen lentiviral vector pLJM1 (Addgene) for lentiviral transduction. The inducible versions of scaffold were generated by swapping the constitutive promoter to either Tet-on 3G promoter (Takara Bio). Transient transfections were performed through lipofection. Cell lines with CRISPR tagged dimerization motifs at C-terminus of endogenous Rac1, Erk1 and Par6. Evaluation of condensates formation, recruitment, enrichment, and client partitioning were primarily done by data acquisition from confocal microscopy. For evaluating efficiency of inducible systems, induced and uninduced cells were run through flow cytometry. Optogenetic release of client were done by 10 sec 405nm light pulse in a 40 sec acquisition cycle for consecutively 11 cycles. We observed up to 80% of scaffold proteins and up to 60% of endogenous client ended up in the synthetic organelles via cognate recruitment motifs and no recruitment with non-matching recruitment motifs, demonstrating efficient and specific client recruitment. Lentiviral generated cells showed slightly weaker scaffold and client partitioning with greater consistency compared to transient transfection. The optogenetic controlled scaffold shows more than 50% of client release within the first 10 minutes, showing robust reversibility of the system controlled by light. We observed similar scaffold and client partitioning in the Erk1 and Par6 double knock-in cell lines generated by CRSPR with indications of phenotypical changes. Our synthetic organelles have shown highly specific and efficient recruitment of endogenous clients with optogenetic controlled reversibility, reveals its potentials as a generic tool kit for cellular engineering. Furthermore, we successfully implement our platform with lentivirus, broadening its application to therapeutic development involving primary cells and stem cells. The future direction for this project will be continuing to enhance client

partitioning, evaluating and improving its safety profile as a therapeutic approach and validating its efficacy in pre-clinical model.

B434/P1419

Amphiphilic proteins coassemble into multiphasic condensates and act as biomolecular surfactants

B. Favetta[1], F. Kelley[1], R. Regy[2], J. Mittal[2], B. Schuster[1]; [1]Rutgers University, New Brunswick, New Brunswick, NJ, [2]Texas A&M University, College Station, TX.

Membraneless organelles that form due to liquid-liquid phase separation have emerged as a mechanism for cellular organization. Such organelles may have complex morphologies, including multiphasic systems and core-shell structures, that enable complex functions. For instance, Ape1 condensates are coated by a layer of Atg19 that is required for selective autophagy in yeast. Also, the nucleolus is composed of nested liquid phases of distinct compositions and functions which are required for ribosome biogenesis. Importantly, the size and structure of such condensates must be regulated for proper biological function. We leveraged a bioengineering approach to study how amphiphilic, surfactant-like proteins may contribute to the structure of membraneless organelles. We designed and examined families of amphiphilic proteins comprising one phase-separating domain and one non-phase separating domain. Proteins included the soluble structured domain glutathione S-transferase (GST) or maltose binding protein (MBP), fused to the intrinsically disordered RGG domain from P granule protein LAF-1. When one amphiphilic protein is mixed in vitro with RGG-RGG, the proteins assemble into enveloped structures, with RGG-RGG at the core and the amphiphilic protein forming the surface film layer. Interestingly, MBP-based amphiphiles are surfactants and influence droplet size, with increasing surfactant concentration resulting in smaller droplet radii. In contrast, GST-based amphiphiles at increased concentrations co-assemble with RGG-RGG into multiphasic structures. Our in vitro and computational results support a mechanism explaining these observations based on the strength of domain-domain interactions. Varying this interaction strength by modifying the environment (e.g., salt concentration, redox state) allows us to tune the behavior of the system. We speculate that surfactant proteins may be widespread in cells. Modification of the intracellular environment may be leveraged by cells to regulate how surfactant proteins and biomolecular condensates assemble, thus affecting their structure and function.

Membrane surfaces regulate assembly of a ribonucleoprotein condensate

W. T. Snead, A. P. Jalihal, T. M. Gerbich, I. Seim, Z. Hu, A. S. Gladfelter; Department of Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Biomolecular condensates compartmentalize diverse biological processes, but little is known about how cells control the spatial organization and sizes of these structures. In cells, condensates often appear as relatively small assemblies that do not grow (coarsen) into a single droplet despite their propensity to fuse, suggesting that condensate function is closely linked with size. Here we find that ribonucleoprotein condensates, composed of the Q-rich protein Whi3 and mRNA, are tethered to the endoplasmic reticulum, prompting us to examine how membrane association impacts condensate assembly and size. Recruitment of Whi3 to synthetic membrane surfaces promotes condensate formation under physiological buffer conditions and protein concentrations. However, the growth of membrane-associated assemblies rapidly arrests within minutes of formation, resulting in size distributions that

resemble native assemblies in cells. We find that condensate size can be controlled by the temporal ordering of interactions among Whi3 and mRNAs on membrane surfaces. Moreover, the slow diffusion of membrane-bound complexes limits condensate size by reducing the probability of encounter between molecular binding partners. Thus, our experiments reveal a tradeoff between locally-enhanced protein concentration at membranes, favoring condensation, and an accompanying reduction in diffusion, restricting coarsening. Given that many condensates are tethered to endomembranes, we predict that the biophysical properties of lipid bilayers are key for controlling condensate size and function in diverse biological contexts.

Dr.
A. Dall'Agnese[1], J. Platt[1], M. Zheng[1], M. Friesen[1], G. Dall'Agnese[1], E. Tevonian[2], R. Jaenisch[1], L. Griffith[2], I. Cisse[2], J. Jeppesen[3], T. Lee[1], R. Young[1]; [1]Whitehead Institute, Cambridge, MA, [2]MIT, Cambridge, MA, [3]Novo Nordisk, Copenhagen, DENMARK.

Insulin receptor (IR) signaling is central to normal metabolic control and is dysregulated in metabolic diseases such as type 2 diabetes. We have found that, in insulin-sensitive hepatocytes and adipocytes, IR is incorporated into biomolecular condensates that exert liquid-like properties and that insulin stimulation further promotes IR incorporation into condensates wherein IR is functional. In insulin-resistant cells, IR condensate dynamics, insulin-induced incorporation of IR in condensates and IR activity are all attenuated, suggesting a physico-mechanical link between insulin response and the dynamic molecular behavior of IR condensates. The observed defects in IR condensate behaviors are caused, at least in part, by an increase in oxidative stress in insulin-resistant cells, which is known to interfere with normal condensate dynamics. Treatment of insulin-resistant cells with metformin, a first-line drug used to treat type 2 diabetes, can rescue accumulation and dynamic behavior of IR condensates. This rescue corresponds with metformin's effect of reducing the levels of reactive oxygen species. The observation that IR is incorporated into biomolecular condensates during the normal response to insulin stimulation, and evidence that changes in the physico-mechanical features of IR condensates contribute to insulin resistance, have implications for improved therapeutic approaches for patients.

Principles Determining Coacervation Specificity of Intrinsically Disordered Domains

R. M. Welles, M. V. Garabedian, M. C. Good; Cell & Molecular Biology, University of Pennsylvania, Philadelphia, PA.

Intrinsically disordered protein (IDP) sequences lack secondary structure and often self-assemble via liquid-liquid phase separation (LLPS) into biomolecular condensates or "membraneless organelles" (MOs). There are a number of distinct MOs within cells, each with unique composition and function. Although previous studies have identified electrostatic and cation-pi interactions as key contributors to phase separation of individual IDPs, far less is known about the mechanisms that maintain condensate identity to determine which substrates are recruited and prevent promiscuous interactions. To close this gap, we identified two orthogonal non-interacting model IDPs that can be co-expressed to form distinct compartments in cells and characterized the properties that impart selectivity to their condensates. We chose the low complexity (LC) domain of FUS and the arginine and glycine rich (RGG) repeat domain of P

granule protein LAF-1. We hypothesized that amino acid sequence features and polypeptide chain-level properties of FUS LC prevent it from mixing with RGG condensates. To test these hypotheses, we characterized modified FUS LC sequences and assessed their ability to enrich as clients within RGG condensates, using budding yeast as a living test tube. We observed that the addition and segregation of charged residues significantly enhanced mixing of FUS LC with RGG. Increasing the distance, or blockiness, of opposing charges was a crucial factor in promoting this coacervation. Local clustering or declustering of these charges additionally affected the levels of enrichment, indicating the importance of both sequence composition and ordering. Interestingly, we found that the presence of tyrosine residues is necessary but not sufficient to promote mixing. Lastly, increasing the valency of FUS LC mutant sequences lowered their apparent c_{sat} and in some cases contributed to further enrichment with the RGG scaffold. Taken together, these data uncover new rules toward a predictive framework to both understand IDP partitioning into distinct organelles and engineer orthogonal microcompartments.

B438/P1423

Manipulate and study biomolecular condensate dynamics and properties in real time to understand phase separation

S. Rahmanseresht[1], T. Simpson[1], B. Groen[2]; [1]LUMICKS, Waltham, MA, [2]LUMICKS, Amsterdam, Netherlands

Membrane-less organelles and other subcellular structures result from liquid- liquid phase separation of proteins and RNA. These include stress granules, nucleoli, RNA-transport granules, and possibly heterochromatin formation. Studies have progressively contested the conventional notion that the protein machinery is homogeneously distributed in the cytoplasm - like a soup of soluble molecules and membranous organelles. Instead, they suggest a formation of structures through multivalent interactions associated with specific protein regions. Understanding the formation of these structures, their physical properties, and mechano-chemical interactions have aided our understanding of several cellular processes. On top of that, the link between droplet formation and medical conditions, such as neurodegenerative amyotrophic lateral sclerosis (ALS) and cancer, has enhanced the need for appropriate assays that can assess related properties. In these cases, proteins can aggregate to promote a successive solidification of droplets, forming gel-like or irreversible solid structures known as amyloid fibrils (plaques). While we have come a long way in understanding such processes, these droplets are extremely dynamic, dissolving and forming in response to cues that we do not yet fully understand. As a result, the proponents of liquid-liquid phase separation have been unable to capture the dynamics and properties of these droplets with the current techniques. We will introduce you to a unique approach that correlates optical tweezers and the latest imaging techniques to study phase separation properties in real time. We show you how you can use the Optical Tweezers combined with Fluorescence Microscopy (C-Trap) to investigate the assembly and disassembly of droplets and the properties that can lead to the pathological solidification of these structures. The optical tweezers enable you to trap micron-sized particles, such as protein droplets or other condensates, with a highly focused laser beam and fuse them to study their fusion dynamics with a high temporal resolution. The correlated fluorescence microscopy lets you visualize the trapped biocondensates and study their dynamics, as the droplet structure is manipulated in real time. The C-Trap is a powerful tool that complements and expands the phase separation field allowing the users to study physiologically relevant conditions in real time.

Condensation of ER-Golgi interface component Trk-fused gene (TFG) into vesicle-like structures

W. R. Wegeng, S. M. Bogus, K. S. M. Noori, A. M. Ernst; University of California, San Diego, La Jolla, CA

The mechanisms that allow for specific contacts between organelles in human cells, which often coincide with a distinct membrane topology, remain largely unknown. One such contact is formed between the ER and Golgi, which together form the early secretory pathway that controls secretion of biosynthetic cargo. At this interface, both ER donor membranes as well as acceptor Golgi membranes are concave, forming a nearly 300-nm spherical interface. It is not known how this anatomy is achieved or what its purpose is. In search of candidate proteins that could structure the ER-Golgi interface, we quantified the local concentrations of multiple interface components by combining segmentation of immunolabeled HeLa cells with published proteomics data. COPII coat components achieve local concentrations in the mM range, which was rivaled only by a similarly high concentration of the protein Trk-fused gene (TFG). TFG localized between ER exit site (ERES) and cis-Golgi markers, and the number of TFG-positive foci in HeLa cells matched those observed for ERES components, suggesting that TFG serves as a cytoplasmic extension of ERES. We found that upon overexpression, TFG undergoes a liquid-liquid phase transition, forming micron-sized condensates that exhibit high protein mobility as well as hallmarks of liquidity. Surprisingly, the distribution of TFG within condensates is highly anisotropic, assuming a sponge-like appearance both in induced condensates *in vivo* and in supersaturated solutions of TFG *in vitro*. Notably, individual TFG condensates readily form under physiological conditions and at critical concentrations well below its average cellular concentration. Upon forming, individual TFG condensates assume the shape of vesicle-like hollow spheres that closely match the dimensions of the ER-Golgi interface. These condensates are permeable for dextrans that mimic the molecular weight of COPII components but are impermeable to those mimicking coatomer (COPI). We propose that a vesicle-like TFG sphere serves to connect ERES to the Golgi, thereby creating a diffusion-limited space between the two organelles. Vesicle-like TFG condensates may also aid in compartmentalizing anterograde carriers enclosed within from retrograde carriers outside the condensates, suggesting an explanation for how bidirectional membrane flux is spatially controlled at the ER-Golgi interface.

B440/P1425

Enzyme regulated biomolecular condensate structure and dynamics

S. Coupe, N. Fakhri; Massachusetts Institute of Technology, Cambridge, MA

Enzyme activity has been postulated to be central to regulating native ribonucleoprotein condensate properties within living cells. One class of enzymes believed to act as condensate regulators is the DEAD-box helicase. However, few mechanistic insights into this process exist beyond mutational studies, which show disruptions to DEAD-box helicase activity often result in disrupted host condensate localization, morphology, and dynamics. By altering RNA length, protein-RNA interactions, and RNA-RNA interactions we are able to assign two modes by which DEAD-box helicases can alter condensate dynamics: 1) ATPase-dependent RNA release and 2) ATP-dependent disruption of RNA-RNA interactions. To uncover the first mode, we alter the ability for a well-studied DEAD-box helicase to release from RNA, resulting in the effective crosslinking of RNA within the condensed phase. To study the second, we correlate RNA unwinding by the helicase to condensate dynamics and material properties. Together, these insights provide a biochemical and biophysical framework for understanding the function of DEAD-box helicases within biomolecular condensates. These results have implications for targeting condensates that contain

DEAD-box helicase for engineering and pharmaceutical purposes but also provide broader insight into the interactions that govern condensate structure and dynamics.

Peroxisomes and Chloroplasts

B441/P1426

Elucidation of Genes Regulating Peroxisome Homeostasis in Human Cells

J. T. Vu[1], K. Tavasoli[2], M. Morrissey[2], C. D. Richardson[2], B. M. Gardner[2]; [1]BMSE/MCDB, University of California, Santa Barbara, Santa Barbara, CA, [2]MCDB, University of California, Santa Barbara, Santa Barbara, CA.

The peroxisome is a conserved, membrane-bound organelle that compartmentalizes specialized metabolic reactions that enable the cell to adapt to its environment. Disruptions to peroxisome homeostasis impair development and contribute to disease in humans, yet the genetic factors that contribute to peroxisome homeostasis are understudied. To identify genes that regulate peroxisome homeostasis in human cells, we engineered a human colorectal cell line "Pex-ZeoR" to sequester the Zeocin resistance protein (ZeoR) in the peroxisome, thereby linking cell viability to peroxisomal import. We then performed a genome-wide CRISPRi screen with the goal of uncovering novel genes involved in peroxisomal biogenesis and maintenance. Our primary screen enriched both known PEX genes and new candidate genes, thereby validating our strategy and providing intriguing candidates. To further refine our results, we implemented a fluorescence microscopy secondary screen to characterize candidate genes knockdowns that influence peroxisomal morphology. We identified that CRISPRi induced suppression of the E3 ligase RNF146 dramatically reduces peroxisome import. The RNF146-mediated loss of peroxisome import depends on an increase in the poly-ADP polymerase tankyrase (TNKS), which has been previously reported to localize to the peroxisome. Intriguingly, we also found that the loss of peroxisomes alters RNF146 and TNKS activity, linking the stability of known TNKS/RNF146 substrates to peroxisome abundance. These observations not only suggest previously undescribed roles for RNF146 in peroxisomal regulation, but also implicates the peroxisome in an intricate and vital network in developmental cell biology and signal transduction.

B442/P1427

Characterization of the N-terminal domains of the Pex1/Pex6 AAA-ATPase

R. M. Judy[1], D. Castanzo[2], T. Glastetter[1], A. Martin[2], **B. M. Gardner**[1]; [1]Molecular, Cellular, and Developmental Biology, University of California, Santa Barbara, Santa Barbara, CA, [2]University of California, Berkeley, Berkeley, CA.

The heterohexameric AAA-ATPase Pex1/Pex6 is essential for the formation and maintenance of peroxisomes. Pex1/Pex6, similar to other AAA-ATPases, uses the energy from ATP hydrolysis to mechanically thread substrate proteins through the central pore of the motor, thereby unfolding them. In related AAA-ATPase motors, substrates and co-factors bind the motor's N-terminal domains, which positions the substrate in the central pore. Here we use structural and biochemical techniques to characterize the function of the Pex1 and Pex6 N1 domains in the budding yeast, *S. cerevisiae*. Truncation of the Pex1 N1 domain does not inhibit motor ATPase or unfoldase activity *in vitro*, but dramatically impairs peroxisome formation *in vivo*. The Pex1 N1 domain does not impair binding to the Pex1/Pex6 peroxisomal tether Pex15, suggesting that it must bind another essential substrate for

peroxisome formation, most likely the ubiquitinated PTS1 receptor Pex5. Additionally, we solved an X-ray crystal structure of the isolated Pex6 N1 domain. Integrating this structure with existing cryo-EM structures and Alphafold2 predictions, we found that the Pex6 N1 domain interacts with the D2 ATPase domain of Pex1/Pex6. This interaction may help coordinate binding of the Pex1/Pex6 substrates with Pex1/Pex6 ATPase activity.

B443/P1428

Investigating the role of peroxisomal membrane proteins and retromer proteins in peroxisomal inner membrane dynamics

A. Swearingen, Z. J. Wright, B. Bartel; BioSciences, Rice University, Houston, TX.

Peroxisomes are organelles that house metabolic reactions, including fatty acid beta oxidation and reactive oxygen species detoxification, and are essential in most multicellular eukaryotes. Despite the importance of peroxisomes for cellular health, peroxisome biogenesis and structure are incompletely understood. Indeed, instead of a simple lumen surrounded by a lipid bilayer, our lab visualized multiple inner membranes, or intralumenal vesicles (ILVs) within Arabidopsis peroxisomes. Many questions remain about the formation, protein composition, and function of peroxisomal ILVs. We are exploiting the unusually large size of Arabidopsis peroxisomes, which allows confocal imaging of peroxisome sub-structure, to characterize proteins associated with ILVs. We are investigating a subset of peroxin (PEX) proteins that are peroxisomal membrane proteins (PMPs) that function in peroxisome biogenesis and protein import. To determine whether PMPs differentially localize among peroxisomal membranes, we are imaging trifluorescent constructs with reporters for peroxisomal membranes, lumen, and individual PMPs in Arabidopsis. Using confocal microscopy, we observed a PEX3B-mTagBFP2 fusion localize to some ILVs and the outer peroxisomal membrane, suggesting that PEX3B may be involved in ILV biology. Additionally, we used CRISPR-Cas9 to generate a viable *pex3a pex3b* double mutant to determine whether ILV formation is altered when PEX3 function is reduced. To identify other proteins involved with ILV biology, we are investigating the retromer complex, which sorts and transports cargo among ILVs in the endocytic pathway. The retromer complex consists of VPS26, VPS29, and VPS35, and *vps29* and *vps35* seedlings display sucrose-dependent growth, which can reflect disruption of peroxisomal beta oxidation. We crossed *vps29*, *vps35a*, *vps35c*, and *vps35a vps35c* insertional mutants to lines expressing fluorescent reporters for peroxisomal membranes and lumen. By imaging the resulting progeny, we will determine if ILV formation or morphology is altered in retromer mutants. These experiments will reveal what proteins localize to ILVs, which may clarify ILV function(s) in peroxisome biology. (This research is supported by the NIH and the Welch Foundation.)

B444/P1429

Transport of specialized peroxisomes is not required for septal closure in filamentous fungi

L. D. Songster[1], J. R. Christensen[2], S. L. Reck-Peterson[2]; [1]Biological Sciences, University of California, San Diego, La Jolla, CA, [2]Cellular & Molecular Medicine, University of California, San Diego, La Jolla, CA.

The localization of many cellular components, such as organelles and protein complexes, must be precisely controlled. Proper distribution of components is largely achieved by motor proteins that selectively bind and transport cargos along cytoskeletal tracks. Peroxisomes are important metabolic organelles that exhibit different transport properties depending on the organism and cell type. In the filamentous fungus *Aspergillus nidulans*, peroxisomes move long distances along microtubules by

hitchhiking on motile early endosomes. Peroxisomes are the only organelle demonstrated to hitchhike on early endosomes in *A. nidulans*, but it is unclear why. Peroxisome hitchhiking requires the protein PxdA, which is conserved within the Pezizomycotina clade of filamentous fungi. This suggests that peroxisome hitchhiking may be important for a cellular process present within this fungal clade. Woronin bodies are specialized peroxisomes that are unique to the Pezizomycotina. Upon local damage to a hyphal segment, Woronin bodies "plug" septal pores to prevent widespread cytoplasmic leakage. Here, we investigated why peroxisomes hitchhike in filamentous fungi by testing if peroxisome hitchhiking is important for Woronin body motility, distribution, and function in *A. nidulans*. We found that Woronin bodies colocalized with peroxisomes during long-distance movements but moved less frequently when dissociated from peroxisomes. Loss of peroxisome motility by knocking out *pxdA* significantly affected Woronin body distribution in the cytoplasm and significantly decreased the frequency of Woronin body localization at septa. However, this altered distribution of Woronin bodies was not important for septal plugging after damage to hyphal tips. Our data suggest that Woronin bodies remain attached to peroxisomes during long-distance hitchhiking motility, then separate from peroxisomes once they reach a cortical or septal tether. Future work will address if other cellular processes require peroxisome hitchhiking.

Investigating the role of peroxisomes in innate immunity during microbial infection

M. Munawar[1,2], S. Leung[1], E. Miraglia[1,2], P. Kim[1,2]; [1]The Hospital for Sick Children, Toronto, ON, Canada, [2]The University of Toronto, Toronto, ON, Canada

Background: Peroxisomes are organelles involved in the metabolism of lipids and reactive anionic species. Defects in peroxisome number and function result in a class of metabolic disorders called peroxisome biogenesis disorders (PBD). Clinical data shows that patients with PBD's have early deaths linked to infection and sepsis. In the last decade, peroxisomes were found to be signalling hubs for antiviral activity; however, their antimicrobial properties lack sufficient characterization. This project identifies that peroxisome are required for adequate antimicrobial response during murine bacterial infection. Our current work aims to elucidate the cellular processes behind peroxisomes effects on antimicrobial immunity.

Hypothesis: We suspect that peroxisomes have a role in initiating inflammatory signalling in the intestine; In peroxisome-deficient mice, lack of this initiation results in defects in inflammatory pathways that dictate immune cell recruitment and immune cell diversity. Additionally, peroxisomes or peroxisome-derived metabolites have anti-inflammatory properties, whose fluctuations result in prolonged inflammation and infection.

Methods: We generated transgenic peroxisomal knockout mice ($PEX16^{IEKO}$), which are then infected with the bacterium, *Citrobacter rodentium*, and assessed at various infection timepoints for bacterial clearance, infection severity, inflammation, and gene expression. Novel single cell technologies, such as time-of-flight cytometry (CyTOF) and single-cell RNA-sequencing, will be used to assess changes in anti-inflammatory and pro-inflammatory signalling involved with epithelial cell-immune cell communication during bacterial infection.

Results: Throughout bacterial infection, $PEX16^{IEKO}$ mice have increased pathogen load, increased colitis severity, delayed hyperplasia, and prolonged infection. Additionally, $PEX16^{IEKO}$ mice demonstrate infection mortality, which is uncharacteristic for typical *C. rodentium* infection. $PEX16^{IEKO}$ females have mortality rates of 80%, whereas males have a mortality rate of 20%, which suggests a sex-specific role of

peroxisomes during infection. Using qPCR, common inflammatory pathways displayed no difference in gene expression between control and knockout mice. The novel role of peroxisomes in bacterial infection remains to be characterized in our upcoming single-cell experiments.

B446/P1431

Loss of intestinal peroxisomes increases susceptibility to *Citrobacter rodentium* infection in mice

E. Miraglia[1,2,3], M. Munawar[1,2], S. Leung[1], R. Bandsma[3,4], P. Kim[1,2]; [1]Cell Biology, Hospital for Sick Children, Toronto, ON, CANADA, [2]Department of Biochemistry, University of Toronto, Toronto, ON, CANADA, [3]Translational Medicine, Hospital for Sick Children, Toronto, ON, CANADA, [4]Department of Nutritional Sciences, University of Toronto, Toronto, ON, CANADA.

Peroxisomes have recently been identified as a regulator of immune function, expanding the organelle's repertoire of roles in the cell beyond their classically considered metabolic processes. The role of peroxisomes as signaling platforms in antiviral immunity has been characterized, but their involvement in responding to bacterial infections is not well understood. We developed an intestine-specific peroxisome knockout mouse model to study antibacterial peroxisome function by infecting animals with the gut pathogen *Citrobacter rodentium* and characterizing their response. We found that *PEX16* knockout mice developed more severe intestinal *C. rodentium* colonization associated with a 20% mortality rate in males and 80% mortality rate in females, whereas littermates who lack the peroxisome knockout have a 100% survival rate. Histological examination of infected knockout mouse tissue showed a delay in the colonic crypt hyperplasia response as well as increased damage in the colon epithelial layer compared to controls. This correlated to an increase in the bacteria load found in other tissues such as the liver, indicating exacerbated bacterial translocation from the gut. Together, these findings reveal that peroxisomes are a necessary component of the innate response of intestinal epithelial cells to bacterial pathogens. Ongoing studies are investigating multiple aspects of epithelial cell function in knockout vs control mice using various technical approaches including Airyscan superresolution microscopy of gut sections. Our goal is to ultimately elucidate the cause of enhanced susceptibility to intestinal bacterial infections in peroxisome deficient mice.

Association of single algal septin with evolutionarily related chloroplast translocons

S. Delic[1], S. Ramundo[2], M. Onishi[1]; [1]Duke University, Durham, NC, [2]Gregor Mendel Institute, Vienna, AUSTRIA.

Cell division is a fundamental process for every organism. In addition to DNA, the cell must effectively divide and distribute organelles to their daughter cells. Many organisms, including photosynthetic algae, possess single large organelles known as chloroplasts. These membrane-bound organellar compartments arose from endosymbiosis of cyanobacteria approximately 1 billion years ago. For cells with single organelles, it is imperative to coordinate both cell and plastid division. What are the cellular and molecular pathways behind this coordination? Septins are cytoskeletal GTPases that form filaments and rings at sites of membrane curvature. While initially thought to only exist in animals & fungi, our lab has identified septin sequences in a range of eukaryotes, including many algal species. *Chlamydomonas reinhardtii,* a unicellular green alga, possesses only a single septin protein (SEP1). We previously identified by coimmunoprecipitation mass spectrometry experiments that SEP1 interacts with components of the translocons at the outer chloroplast envelope (TOCs). Interestingly, septins are

evolutionarily related to TOCs and share homology among their GTPase domains, however their physical and functional interaction has never been explored. Our results suggest that the loss of septin leads to mislocalization of the plastid division protein, FtsZ2. This protein normally forms a ring with its homolog, FtsZ1, at the chloroplast division site. The loss of septin, however, impairs ring formation and leads to FtsZ2 fragments to be dispersed in the chloroplast. This data, combined with SEP1's interaction with translocons implicates its function in chloroplast translocation. Formally, this could be due to the failed translocation of FtsZ2 directly or other proteins responsible for assembling and positioning the FtsZ ring. To investigate this, we are using two orthogonal proteomic approaches. First, we are performing native coimmunoprecipitation experiments using FtsZ2 as bait in either wildtype or septin null mutants to compare the FtsZ2 interactome. Additionally, we seek to identify peptides with intact chloroplast-targeting sequences to characterize proteins that preferentially utilize SEP1-bound translocons. This project is the first functional characterization of septins in a photosynthetic organism and explores a novel interaction of septin proteins with a distantly related family of proteins.

B448/P1433

Lack of peroxisomal catalase affects heat shock response in *C. elegans*

M. Musa[1], **P. A. Dionísio**[2], R. Casqueiro[2], I. Milosevic[3], N. Raimundo[4], A. Krisko[5]; [1]Mediterranean Institute for Life Sciences, Split, Croatia, [2]MIA-Portugal, University of Coimbra, Coimbra, Portugal, [3]Wellcome Centre for Human Genetics, Nuffield Department of Medicine, NIHR Oxford Biomedical Research Centre, University of Oxford, Oxford, United Kingdom, [4]Penn State University College of Medicine, Pennsylvania, PA, [5]University Medical Center Göttingen, Göttingen, Germany

The exact mechanisms of heat shock-induced lifespan extension, while documented across species, are still not well understood. Here, we put forth evidence suggesting that fully functional peroxisomes, specifically peroxisomal catalase, are needed for the activation of canonical heat shock response and heat-induced hormesis in *C. elegans*. While during heat shock the HSP-70 chaperone is strongly upregulated in the wild-type (WT), as well as in the absence of peroxisomal catalase (*ctl-2(ua90)II*), the small heat shock proteins display modestly increased expression in the mutant. Nuclear foci formation of HSF-1 is reduced in the *ctl-2(ua90)II* mutant. In addition, heat-induced lifespan extension, observed in the WT, is absent in the *ctl-2(ua90)II* strain. Activation of the antioxidant response and pentose phosphate pathway are the most prominent changes observed during heat shock in the WT worm, but not in the *ctl-2(ua90)II* mutant. Preliminary work on a human cell line with silenced catalase exposed to transient heat shock did not recapitulate the blunted expression of small heat shock proteins, although different models may be needed to compare the heat shock response-dependent mechanisms between *C. elegans* and human cells. Overall, involvement of peroxisomes in the cell-wide cellular response to transient heat shock reported here gives new insight into the role of organelle communication in the organism's stress response.

Study of the role of chloroplast unusual positioning 1 (CHUP1) in regulation of chloroplast and stromule movement dynamics

A. Nedo[1], K. Seward[1], N. Meier[2], Y. Liu[1], H. Liang[1], C. Kambhamettu[1], S. Dinesh-Kumar[2], J. Caplan[1]; [1]University of Deleware, Newark, DE, [2]University of California, Davis, CA

Plant innate immunity is regulated by the generation and transmission of various signals. Key examples of this are hydrogen peroxide (H2O2), a type of reactive oxygen species (ROS), and salicylic acid (SA). Chloroplasts are a major source of these signals, and it's believed that chloroplast repositioning and tubular extensions called stromules play a major role in regulating the transmission of these signals in cellular signaling. The direct mechanics behind chloroplast movement remain unclear. It is known that chloroplast movement is dependent on the actin microfilament network, however the direct causes are not known. Chloroplast Unusual Positioning 1 (CHUP1) is believed to play a major role in regulating of the blue light movement (BLM) as part of an avoidance response, however, the exact role it plays other than being required for proper BLM based repositioning in the mesophyll is not been reported in the literature. Specifically, data has been collected to show that the avoidance response as part of BLM is a behavior that is still present in mesophyll cells. Additionally, this process is still primarily regulated by phototropin 2 (PHOT2), with a complete lack of the avoidance response when PHOT2 is silenced. As such, establishing the role of CHUP1 is likely a key component for fully understanding the mechanisms behind chloroplast movement, localization and cellular signaling in plants. This work was supported by a grant from NIH-NIGMS (R01 GM097587).

Giant peroxisomes: optogenetic enlargement of candidate organelle for future use as a synthetic organelle

N. Menjivar, M. Chan; San Francisco State University, San Francisco, CA

Emerging research on artificial cells and organelles shows great potential for refined production of biomolecules including pharmaceuticals. Synthetic organelles are at the forefront for deeper understanding and control of cellular reactions. In this poster, we focus on the peroxisome that has previously shown to be capable of compartmentalizing heterologous proteins, a necessary ability for usage as a synthetic organelle. Previous studies have shown that the amount of protein able to be imported into the peroxisome depends on the organelle's size, so we aim to engineer cells with larger peroxisomes to maximize capactiy. Furthermore, initial studies have shown that the size of organelle's typically scales closely with cell size. Therefore, we aim to produce larger peroxisomes in budding yeast by applying optogenetic perturbations to grow cells to artificially large sizes. Preliminary results showed that in these enlarged cells, peroxisomes do maintain a scaling relationship with cell size, and this occurs via proliferation rather than expasion in volume. Future experiments will use mutants targeting peroxisome biogenesis, fission, and fusion pathways to gain more mechanistic insight into how peroxisome size is regulated.

Signaling Scaffolds and Microdomains

Hedgehog pathway modulation by glypican 3 conjugated heparan sulfate

C. Liu[1], B. Wierbowski[2], A. Salic[3]; [1]Biology, Hood College, Frederick, MD, [2]Whitehead Institute, MIT, Boston, MA, [3]Cell Biology, Harvard Medical School, Boston, MA.

Glypicans are a family of cell surface heparan sulfate proteoglycans that play critical roles in multiple cell signaling pathways. Glypicans consist of a globular core, an unstructured stalk modified with sulfated glycosaminoglycan chains, and a glycosylphosphatidylinositol anchor. Though these structural features are conserved, their individual contribution to glypican function remains obscure. Here, we investigate how glypican 3 (GPC3), which is mutated in Simpson Golabi Behmel tissue overgrowth syndrome, regulates Hedgehog signaling. We find that GPC3 is necessary for the Hedgehog response, surprisingly controlling a downstream signal transduction step. Purified GPC3 ectodomain rescues signaling when artificially recruited to the surface of GPC3-deficient cells but has dominant-negative activity when unattached. Strikingly, the purified stalk, modified with heparan sulfate but not chondroitinsulfate, is necessary and sufficient for activity. Our results demonstrate a novel function for GPC3 associated heparan sulfate and provide a framework for the functional dissection of glycosaminoglycans by in vivo biochemical complementation.

B453/P1437

Mutual Regulation between Membrane Rafts and Protein Condensates in T Cell Activation

S. Chan[1], H. Wang[1], S. Dey[1], I. Castello-Serrano[1], J. A. Ditlev[2], M. K. Rosen[3], K. R. Levental[1], I. Levental[1]; [1]University of Virginia, Charlottesville, VA, [2]University of Toronto, Toronto, ON, CANADA, [3]University of Texas Southwestern Medical Center, Dallas, TX.

T cells are central effectors of adaptive immunity, mediating critical defenses against infections and cancer. T cell activation must be tightly regulated to integrate and transduce various signals detected at the plasma membrane and elicit proper immune responses. Inappropriate T cell activation results in anergy, auto-immune disease, and inflammatory disorders. Despite decades of research, the regulatory mechanisms of normal and aberrant T cell activation are not fully understood. Recently, we reported that biomolecular condensates form at the T cell immunological synapse (IS) via liquid-liquid phase separation (LLPS) driven by multivalent macromolecular interactions. Specifically, the transmembrane protein Linker for Activation of T cells (LAT) is phosphorylated upon antigenic stimulation to multivalently interact with proteins called Grb2 (growth factor receptor-bound) and Sos1 (son of sevenless) to form condensates with fluid properties *in vitro* and in living cells. Lying near phase coexistence boundaries, membrane lipids can also undergo LLPS and de-mix to form phase-separated lateral domains, which may serve as platforms for organizing and regulating condensates. Notably, LAT is recruited to the ordered, cholesterol-rich membrane domains known as lipid rafts, and such recruitment has been implicated in T cell activation. Thus, we hypothesized that LAT may mediate interplay between protein and membrane lipid phase separation in T-cell signaling. Here, we report physical, thermodynamic and functional coupling between membrane rafts and protein condensates via LAT using both *in vitro* reconstituted membrane systems and in live cells. We have observed that LAT condensates recruit and stabilize ordered membrane domains in reconstituted membrane systems. Using Jurkat cells under activating conditions, we observe that Grb2 condensates recruit markers of raft

proteins. Stabilizing raft domains potentiates LAT condensate formation, which in turn induces T cell signaling. To study how LAT condensates and membrane rafts cooperatively regulate T-cell signaling, we perturbed membrane raft domains and observed changes in condensate density and signaling. Moreover, using fluorescent probes that are sensitive to local membrane lipid packing in living cells, we quantitatively measure changes in membrane biophysical properties induced by condensate assembly. By evaluating the effects of lipid remodeling on LAT condensate properties, and effect of condensate formation on membrane properties, we provide evidence that membrane rafts and LAT condensates mutually regulate T cell activation for optimal immune signaling.

Dissecting the function of glycolytic condensates at the maternal-fetal interface

A. Skinkle, A. Gladfelter; University of North Carolina, Chapel Hill, NC.

The placenta is an organ that is indispensable in maintaining mammalian species. Aberrations of placental development have been linked to common pregnancy-related problems such as preeclampsia and miscarriage. Key to the placenta's development is formation of a large multinucleate cell, the syncytiotrophoblast (STB). The STB acts as the barrier between maternal and fetal circulation where it performs the vital task of transferring nutrients and oxygen between the mother and developing fetus. This meters-long cell is exposed to very different local nutrient microenvironments along its length. To meet its unique metabolic demands, the STB relies heavily on aerobic glycolysis. How a non-compartmentalized process such as glycolysis is differentially regulated in a continuous cytoplasm is unknown. Here, we demonstrate for the first time the organization of glycolytic enzymes into membraneless compartments termed biomolecular condensates within placental tissue. Immunostained tissue sections obtained from term placentas demonstrate glycolytic condensates are heterogeneously localized in the STB, suggesting condensates are sensitive to local environmental cues. In an STB model cell line starved of glucose, glycolytic condensates are reduced in number but grow larger. These results are consistent with studies conducted in other species where glycolytic condensates grow in size under energy stress and promote increased rates of glycolysis. We hypothesize that glycolytic condensates promote glycolysis in the STB and that their physical properties are important for their function. Future work will characterize how the physical properties of glycolytic condensates are affected by energy stress and how this relates to metabolite levels in the STB.

B455/P1439

The eisosome-associated proteins, Pil1 and tetraspan membrane proteins regulate TORC2 signaling during the stress response in budding yeast

K. Sakata[1], K. Hashii[1], K. Yoshizawa[1], Y. O. Tahara[2], N. Tanaka[1], T. Maeda[3], M. Miyata[2], M. Tabuchi[1]; [1]Faculty of Agriculture, Kagawa University, Kagawa, JAPAN, [2]Graduate School of Science, Osaka City University, Osaka, JAPAN, [3]Department of Biology, Hamamatsu University School of Medicine, Kagawa, JAPAN.

Saccharomyces cerevisiae has three distinct plasma membrane domains, MCC (Membrane Compartment occupied by Can1), MCT (Membrane Compartment occupied by TORC2), and MCP (Membrane Compartment occupied by Pma1). MCC corresponds to inner membrane furrows termed eisosome. Eisosome contains various membrane associated-proteins, transporters, and tetraspan membrane proteins, which are considered to contribute to normal eisosome structure and function. Pil1

is a core eisosome protein and is responsible for MCC-invaginated structures. In addition, six-tetraspan membrane proteins (6-Tsp) are localized in the MCCs and classified into two families, the Sur7 family, and the Nce102 family. To understand the coordinated function of these MCC proteins, single and multiple deletion mutants of Pil1 and 6-Tsp were generated. These deletion mutant cells analyzed the structure of the eisosome and assayed growth under various stress conditions. Genetic interaction analysis indicated that the Sur7 family and Nce102 function in stress tolerance and normal eisosome assembly, respectively, by cooperating with Pil1. To further understand the role of MCCs/eisosomes in stress tolerance, we screened for suppressor mutants using the SDS-sensitive phenotype of *pil1Δ 6-tspΔ* cells. The growth defect on the SDS-contained medium was suppressed by the loss of function of Tor2, which is the component of the Tor kinase complex 2 (TORC2). This data indicated that the SDS sensitivity in *pil1Δ 6-tspΔ* cells is caused by hyperactivation of TORC2-Ypk1 signaling. Interestingly, inhibition of sphingolipid metabolism, a well-known downstream pathway of TORC2-Ypk1 signaling, did not rescue the SDS-sensitivity of *pil1Δ 6-tspΔ* cells. In summary, the eisosome-located proteins, Pil1, and 6-Tsp cooperatively regulate TORC2 signaling during the stress response.

B456/P1440

ZO-2 is a scaffold for Hippo signaling that restores tight junction sealing in the steatotic liver

L. Gonzalez-Mariscal[1,2], L. González-González[3], H. Gallego-Gutiérrez[3], D. Martin-Tapia[3], J. E. Avelino-Cruz[4], C. Hernández-Guzmán[3], M. C. Gutiérrez-Ruiz[5], D. Hernández-Melchor[6], E. López-Bayghen[6]; [1]Physiology, Biophysics, and Neuroscience, Lorenza Gonzalez Mariscal y Muriel, CDMX, MEXICO, [2]Physiology, Biophysics, and Neuroscience, Cinvestav, Cdmx, MEXICO, [3]Physiology, Biophysics, and Neuroscience, Cinvestav, CDMX, MEXICO, [4]Laboratory of Molecular Cardiology, Institute of Physiology, Benemérita Universidad Autónoma de Puebla, Puebla, MEXICO, [5]Department of Health Sciences, Autonomous Metropolitan University-Iztapalapa (UAM-I), CDMX, MEXICO, [6]Department of Toxicology, Cinvestav, CDMX, MEXICO.

ZO-2 is a peripheral protein of tight junctions involved in the regulation of cell size. Previously we demonstrated the development of hypertrophy in MDCK ZO-2 KD cells and accordingly observed that in renal compensatory hypertrophy induced in rats by unilateral nephrectomy, ZO-2 is silenced. Now, we show that in another model of hypertrophy, the steatotic liver of obese Zucker (OZ) rats, ZO-2 expression is also silenced. Moreover, we demonstrate that the reduced expression of ZO-2 is accompanied by a decreased activity of the kinase LATS of the Hippo signaling route, and the nuclear concentration of YAP, the final effector of this pathway. LATS1 binds to the carboxyl segment of ZO-2 that contains the actin-binding and proline-rich regions of the protein, and the absence of ZO-2 reduces LATS activity and concentration at the cell border, thus indicating that ZO-2 acts as a platform for the Hippo signaling pathway. Silencing of ZO-2 in hypertrophic tissue is due to a reduction in ZO-2 mRNA due to a diminished expression of the Sp1 transcription factor, which is critical for *TJP2* gene expression in renal cells. Previously, we had shown that AMPK activation induces the appearance of ZO-2 at the cell borders, even in cells cultured in a low calcium condition. Now, in the steatotic liver of OZ rats, we demonstrate that the activation of AMPK with metformin augments the expression of ZO-2, activates LATS, and diminishes the nuclear concentration of YAP. This, in turn, restores claudin-1 expression and ameliorates the increased paracellular permeability of hepatocytes and the augmented content of bile acids in serum found in the steatotic liver, through a process mediated by a diminished JNK activation. These results indicate that ZO-2 silencing is a common characteristic of hypertrophic tissue, and reveal

that ZO-2 is a crucial scaffold of the Hippo pathway. This study identifies AMPK, JNK, and ZO-2 as therapeutic targets for treating pathologies with blood-bile barrier dysfunction.

B457/P1441

Tetraspanin CD82 regulates Hematopoietic Stem and Progenitor Cell Quiescence through the modulation of TGFb signaling

E. Pascetti, M. Floren, C. Saito-Reis, J. Gillette; University of New Mexico, Albuquerque, NM

The significant cellular demand of the hematopoietic system is maintained by a rare pool of tissue-specific, hematopoietic stem and progenitor cells (HSPCs) that are primarily found in a quiescent state. Upon hematopoietic stress, HSPCs undergo rapid cell cycle activation, but ultimately must return to quiescence to prevent hematopoietic exhaustion. Evidence from our laboratory demonstrates that the tetraspanin CD82 plays a critical role in the regulation of HSPC maintenance. Tetraspanins are membrane scaffold proteins with the ability to modulate signaling through the organization of membrane receptors and intracellular signaling molecules. Using a CD82 knockout (CD82KO) mouse model, we find a reduction in long term-HSPCs, resulting from increased HSPC activation and a reduction of quiescent G_0 cells, indicating a role for CD82 in the regulation of HSPC quiescence and activation. To further delineate how the CD82 scaffold modulates HSPC quiescence, we transplanted CD82 overexpressing (CD82OE) progenitor-like cells into mice. Despite the fact that CD82OE cells display similar proliferation rates to control cells in culture, once localized to the bone marrow, CD82OE cells demonstrate reduced proliferation and increased quiescence, as indicated by diminished BrdU incorporation and IVIS signal. Additional mechanistic insight is provided by analysis of cells expressing a mutant form of CD82, where three N-linked glycosylation sites are inhibited (Ngly-CD82). Ngly-CD82 cells do not exhibit the same level of quiescence as CD82OE cells when injected into NSG mice, demonstrating an important role for CD82 glycosylation in the regulation of HSPC quiescence. Mechanistically, the cytokine TGFβ plays an essential role in supporting HSPC quiescence and activation, as one of the most potent inhibitors of HSPC growth. To investigate a critical role for TGFβ signaling in the observed *in vivo* CD82-mediated quiescence phenotype, we injected a TGFβ neutralizing antibody. Interestingly, CD82OE cells are stimulated out of quiescence when TGFβ is inhibited, confirming viability of the CD82OE cells within the marrow and supporting a critical role for TGFβ signaling in CD82-mediated quiescence. Additionally, *in vitro* studies indicate that when progenitor cells or primary HSPCs with differential CD82 expression are TGFβ stimulated, cells with higher CD82 expression have increased SMAD2/3 activation when compared to lower expressing CD82 cells or Ngly-CD82 cells, but only when cells are engaged with fibronectin. Together, these data indicate that the CD82 scaffold has the capacity to modulate TGFβ signaling through niche-mediated interactions and implicate integrins in the modulation of signal transduction.

Scaffold Protein RACK1 mediates plant hormone Auxin and Salt stress Cross-talk pathway

A. Webber-Deonauth[1], S. Dakshanamurthy[2], H. Ullah[1]; [1]Howard University, Washington, DC, [2]Georgetown University, Washington, DC

Auxin is a primary plant hormone directly implicated in growth, development, and differentiation of plants cells during every stage of the plant life cycle. In addition to the growth and development, auxin is reported to regulate diverse environmental stresses including osmotic stress signaling pathways.

However, the precise cellular mechanism of this auxin mediated environmental stress signaling pathways is poorly defined. Using genetic knock-out and chemical inhibitors of scaffold protein RACK1, previously we have reported that the protein regulates auxin induced lateral root development signaling. Separately, we have also reported that RACK1 protein regulates salt stress resistance signaling pathways. Here we tested our hypothesis of RACK1 mediating the cross-talk between auxin and salt stress pathways. Using transgenic *Arabidopsis* with auxin reporter construct pIAA5::GUS, we investigated the cross-talk mediating function of the RACK1 protein. While pIAA-GUS plants showed salt-induced auxin reporter gene expression, use of RACK1 small compound inhibiting RACK1 failed to induce such response. The response was found to be present in both whole seedlings and in mature leaves. To provide molecular genetic evidence for RACK1 in this pathway, construction of the double 'mutant' of pIAA5::GUS and rack1 knock-out plant is underway. Additional auxin reporter containing transgenic plants (DR5::GFP, pIAA5::Luc, and BA3::GUS) are being used to elucidate the pathway. Molecular understanding of this cross-talk between auxin and stress signaling pathway will pave a pathway to bioengineer crop plants to combat climate change induced potential environmental stresses.

B459/P1443

Receptor for Activated C Kinase 1 (RACK1) Regulates Plant Nitrogen Stress Signaling Pathways

A. K. Mascarenhas[1], S. Dakshanamurthy[2], H. Ullah[1]; [1]Howard University, Washington, DC, [2]Georgetown University, Washington, DC

Plant stress hormone Abscisic acid (ABA) regulates diverse plant responses to environmental stresses such as drought, high heat, salinity, water stress, and Nitrogen (N) availability. Nitrogen is an essential nutrient for plant growth and development such as seed germination, root branching, shoot branching, and flowering time. ABA is known to regulate nitrate uptake, metabolism and signaling pathways that result in changes of primary and lateral root architecture. Scaffold protein RACK1 is known to negatively regulates ABA signaling pathway. By using our lab developed RACK1 inhibitor compounds, the role of RACK1 in the ABA mediated nitrogen stress signaling pathway is investigated. Depending on the nitrogen availability (25% to 100%), the inhibitor compounds improved nitrogen use efficiency significantly as evident by the superior growth and development under limited nitrogen availability. Particularly, the root architecture (both primary and lateral root) and the hypocotyl length are significantly impacted by the compounds. Availability of small compounds to make crop plants utilize nitrogen efficiently can potentially lower the usage of nitrogen-based fertilizers whose wide-spread usage is known to cause myriad of negative impacts in the overall quality of the environment.

The scaffold protein CNK2 drives cell migration and invasion in cancer cells

G. Serwe[1,2], D. Kachaner[2], J. Gagnon[1,2], C. Plutoni[2], D. Lajoie[2], E. Duramé[1,2], M. Sahmi[2], D. Garrido[2], M. Lefrançois[2], G. Arseneault[2], M. K. Saba-El-Leil[2], S. Meloche[3,2], G. Emery[4,2], M. Therrien[4,2]; [1]Molecular Biology Program, Faculty of Medicine, Université de Montréal, Montréal, QC, CANADA, [2]Institute for Research in Immunology and Cancer, Montréal, QC, CANADA, [3]Department of Pharmacology and Physiology, Faculty of Medicine, Université de Montréal, Montréal, QC, CANADA, [4]Department of Pathology and Cell Biology, Faculty of Medicine, Université de Montréal, Montréal, QC, CANADA.

Scaffold proteins of the Connector enhancer of KSR (CNK) family are evolutionarily conserved from invertebrates to mammals. In *Drosophila*, CNK is a positive regulator of the oncogenic Ras-MAPK

signaling pathway. In contrast, the role of its human orthologs (CNK1, CNK2, CNK3, and IPCEF1) in this pathway is unclear, and instead, they have been linked to small GTPases of the ARF and RHO subfamilies. These GTPases function in membrane trafficking and cytoskeletal remodeling and are crucial regulators of cell morphology and motility. Yet, the role of human CNKs in these processes is almost completely unknown. Interestingly, we observed that human CNKs, especially CNK2 and CNK3, are expressed in a variety of cancer cell lines of diverse tissue origin. Our objective was therefore to identify the biological functions of CNKs in cancer cells and to characterize their roles in signal transduction.
Using a proteomics approach (BioID), we identified the proximal interactomes of different CNKs in human cells to obtain a global view of their potential functions. This led us to the unexpected discovery that CNK2, which is normally expressed in neuronal tissues, is required for cell migration and invasion in multiple cancer cell lines of diverse tissue origin. Using osteosarcoma cells as a model, we found that CNK2 exerts a positive effect on motility by regulating the activity of ARF and RHO GTPases and by limiting downstream contractility and adhesion. Through immunofluorescence and biochemical assays, we then showed that CNK2 operates at the plasma membrane and forms functional interactions with several binding partners. Additionally, we found that the membrane localization of CNK2 is regulated by growth factors and membrane receptors. Finally, using a mouse xenograft model, we confirmed that the function of CNK2 in motility is conserved in vivo.
In summary, we identified the CNK2 scaffold as a novel regulator of motility in cancer cells and uncovered aspects of its mechanism of action in signal transduction. Since cell motility is a defining feature of cancer cell dissemination, the characterization of CNK2 and its associated partners could lead to the identification of novel biomarkers and therapeutic targets for metastasis.

Evolution of the β-catenin destruction complex: Insights from the anthozoan cnidarian *Nematostella vectensis*

H. Sun, **A. Wikramanayake**; University of Miami, Coral Gables, FL

Axin and APC are critical scaffolding proteins in the Wnt/β-catenin (cWnt) pathway that heterodimerize and recruit several proteins including β-catenin, CK1α and GSK3β that together form the β-catenin destruction complex (DC). Work done in bilaterians has indicated that β-catenin is recruited to the DC through binding a conserved β-catenin binding site on Axin. Axin also has a GSK3β binding site and current models propose that heterodimerization of Axin and APC mediates phosphorylation of β-catenin by CK1α and GSK3β that targets β-catenin for degradation via the proteasome. Bilaterian APC also has multiple β-catenin binding domains distinct from the Axin β-catenin binding domain indicating that these motifs had separate evolutionary origins. Intriguingly, Axin proteins in all non-bilaterian taxa (Ctenophora, Porifera, Placozoa, and Cnidaria) lack the β-catenin binding domain questioning a conserved role for Axin in regulating β-catenin stability in non-bilaterians. Using loss- and gain-of-function approaches in the cnidarian *Nematostella* we show that NvAxin has a clear role in regulating cWnt. We also show that NvAxin can regulate cWnt in the bilaterian sea urchin embryo. Using a rescue assay we show that only the GSK3β binding domain of NvAxin is essential for its function in the DC in sea urchin embryos. Finally, we show that Nvβ-catenin directly interacts with NvAPC but not NvAxin. Our results indicate that NvAxin forms an essential part of the DC in *Nematostella* even though it does not directly bind to β-catenin. We propose that whereas bilaterian β-catenin directly binds to both Axin and APC, in *Nematostella,* Axin binds to GSK3β and heterodimerization of Axin and APC allows GSK3β to

phosphorylate β-catenin bound to APC targeting it for degradation. Evolution of the β-catenin binding site in bilaterian Axin may have produced a more tightly regulated DC to downregulate β-catenin. Our work is providing insight into the evolution of the β-catenin DC in metazoans.

Extracellular Vesicle Signaling

B462/P1446

Hepatocyte extracellular vesicle (EV) mRNA content is linked to EV-regulated gene expression in activated hepatic stellate cells, the principal fibrosis-producing cell in the liver

X. Li, R. Chen, S. Kemper, Z. Xu, **D. Brigstock**; Nationwide Children's Hosp, Columbus, OH.

Background: Extracellular vesicles (EVs) are membrane-limited nanoparticles that are involved in intercellular signaling via shuttling of molecular payloads between cells. In the liver, EVs produced by non-injured hepatocytes may mediate therapeutic outcomes following injury. For example, hepatocyte EVs are therapeutic in experimental hepatic fibrosis through their binding to and regulation of hepatic stellate cells (HSC), a normally quiescent cell type that becomes activated during chronic injury and produces fibrotic scar. In this study, the miRNA content of hepatocyte EVs was determined and assessed for its potential relevance to the ability of these EVs to cause the transcriptome of activated HSC (aHSC) to trend towards that of quiescent HSC (qHSC). **Methods:** EVs purified by sequential centrifugation of serum-free cultures of mouse AML-12 hepatocytes were characterized by Nanosight tracking analysis and Western blot. Small RNA or mRNA sequencing (Illumina HiSeq 4000) was performed, respectively, on RNA from AML-12 EVs or on Swiss Webster mouse Day 1 qHSC or P1 aHSC that had been treated with or without 8 μg/ml AML-12 EVs for 48 hrs. Differentially expressed genes (DEGs) were categorized by an adjusted P-value (false discovery rate (FDR)) of <0.05 and fold-change of >2. KEGG pathway enrichment, protein-protein interactions or predicted miR targets were assessed using DAVID, STRING or MiRwalk software respectively. **Results:** In comparing aHSC to qHSC, 6505 protein-coding DEGs were identified of which 3325 were upregulated (genes enriched for metabolism, oxidative phosphorylation, lysosome pathways) and 3180 were downregulated (genes enriched for complement/coagulation, cancer, Hippo pathways). EV treatment of aHSC led to 638/6505 genes being differentially regulated, of which 207 were downregulated (genes enriched for hematopoietic cell lineage, phagosome, calcium signaling) and 431 were upregulated (genes enriched for cancer, PI3K-Akt signaling pathway, rheumatoid arthritis). AML-12 EVs contained 71 miRNAs, with miR-122-5p being the most abundant (34% of total miR counts). Of the EV-regulated DEG genes in aHSC, 172/638 DEGs were identified as miR-122-5p targets, including 56/207 downregulated genes and 116/431 upregulated genes. At least 7 major protein-protein interaction clusters including ECM genes, cell adhesion, and signaling transduction were identified in the 172 targets. **Conclusion:** Addition of hepatocyte EVs to aHSC results in the altered expression of 638 genes to levels more typical of qHSC. 71 miRNAs were identified in AML-12 EVs of which miR-122-5p was the most enriched and predicted to regulate 172/638 DEGs in aHSC. Modulation of gene expression in HSC by hepatocyte EV miRs likely contributes to EV-mediated anti-fibrotic actions.

Ceramide drives microglial recruitment by altering exosome cargo and secretion in retinal neurodegenerations

C. J. Germer[1], L. Tan[1], N. R. La Cunza[1], G. Rathnasamy[1], E. Iorio[2], F. Elahi[3], A. Lakkaraju[1]; [1]Ophthalmology, UNIVERSITY OF CALIFORNIA SAN FRANCISCO, San Francisco, CA, [2]Memory and Aging Center, UNIVERSITY OF CALIFORNIA SAN FRANCISCO, San Francisco, CA, [3]Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY.

Abnormal secretion of exosomes and activation of microglia have been implicated in the pathogenesis of intractable neurodegenerations such as Alzheimer's and Parkinson's diseases. Yet, the link between exosome secretion and microglial activation is not well understood. What triggers the biogenesis and secretion of pro-inflammatory exosomes from specific cell populations in disease? How is exosomal cargo modified to recruit microglia? We addressed these questions in cell-based and mouse models of macular degeneration, a complex neurodegenerative disease of the retina that causes irreversible vision loss. Using super-resolution microscopy, live-cell imaging, nanotracking analysis, and electron microscopy along with complementary molecular and cellular assays, our study identifies a novel mechanism that implicates the bioactive lipid ceramide in driving the secretion of proinflammatory exosomes from the retinal pigment epithelium (RPE), the tissue that sits beneath the photoreceptors and is the primary site of damage in macular degenerations. Excess ceramide in diseased RPE increases the biogenesis of intraluminal vesicles, induces missorting of the gap junction protein connexin43 to these ILVs, and causes expansion of Rab11-positive apical recycling endosomes. Collectively, these lead to the secretion of Cx43-containing exosomes at the apical surface of the RPE, which induce migration of microglia into the subretinal space. Small molecule therapeutics that decrease RPE ceramide prevent exosome biogenesis and secretion in mouse models of macular degeneration. By identifying how ceramide-driven exosome release leads to microglial activation, our studies establish a novel, druggable mechanism that could pave the way for exciting new therapeutics for neurodegenerations, which impact millions of people across the globe.

Identification of polycystin interactors within ciliary extracellular vesicles using proximity labeling in *Caenorhabditis elegans*.

I. Nikonorova, E. desRanleau, J. Saul, J. Walsh, J. Wang, M. Barr; Rutgers University, Piscataway, NJ.

Ciliary EV shedding is evolutionarily conserved. Disrupted ciliary EV signaling is an emerging driver of the pathophysiology of many ciliopathies. The ciliary EV field lacks a basic understanding of how EVs form, what cargo is packaged in different types of EVs originating from different cell types, and how different cargoes influence the range of ciliary EV bioactivities. We use *Caenorhabditis elegans* to tackle these major challenges. In *C. elegans* evolutionarily conserved ciliary EVs are released from male-specific ciliated neurons and transferred to vulva of mating partners, suggesting a role in interorganismal communication. We recently identified the proteome of enriched ciliary EVs released by the animal into the environment. Here we present a much-improved pipeline for dissection of the proteome of individual EV subtypes using proximity-labeling approach. We engineered targeting of a proximity-labeling enzyme TurboID to the evolutionarily conserved polycystin PKD-2::GFP EVs using an anti-GFP nanobody domain. Targeted EVs were enriched using buoyant density centrifugation, followed by pulldown of biotinylated proteins. Mass spectrometry analysis revealed 20 candidate interactors of PKD-

2, as opposed to 2,888 EV cargo of the whole EV proteome. For validation, we generated CRISPR knock-in fluorescent reporters for the top 8 hits and analyzed their trafficking to ciliary PKD-2 EVs. **Results**: We discovered that PKD-2 proximity-interactors comprise two categories: (i) a genus-specific set of transmembrane adhesion proteins and (ii) an evolutionarily conserved set of soluble proteins with signaling function. All analyzed proximity-interactors colocalize with PKD-2 in cilia and ciliary EVs. The adhesion proteins are expressed and shed in ciliary EVs in non-overlapping PKD-2 ciliated sensory neurons, suggesting a role in EV targeting, whereas evolutionarily conserved soluble cargo are expressed in all PKD-2 neurons, suggesting a role in EV signaling. We are currently testing these hypotheses. **Conclusion**: Coupling density equilibration with pulldown of biotinylated proteins resulted in at least 10,000-fold specific enrichment for interactors of the targeted EV cargo with virtually no false-positive hits. This methodology may be applied systematically to many EV cargo to break the code of ciliary EV cargo sorting and combinatorial composition.

The characterization and functional analysis of IRSp53-mediated secretion of the extracellular vesicles from tumor cells

H. T. Hu, T. Nishimura, S. Suetsugu; Nara Institute of Science and Technology, Ikoma, Nara, JAPAN.

The Inverse-Bin/Amphiphysin/Rvs (I-BAR) domain protein, insulin receptor substrate protein of 53kDa (IRSp53), is a membrane shaping protein that could bind to the phosphoinositide-rich membrane and generate membrane protrusions, called filopodia. Filopodia are often implicated in cancer cell metastasis, especially in cell adhesion and migration. We found that IRSp53 serves as an essential regulator for filopodia formation and positively correlated to the lifespan of head and neck carcinoma patients. The head and neck tumor cells could secrete IRSp53-containing particles, which were thought to be the vesicles, to the surrounding tissues. However, the role of these IRSp53-containing particles in the tumor has been unclear. In this study, we isolated the particles, and studied the large-EVs (l-EVs, or microvesicles) fraction to examine their physiological function on tumor growth. We found that the head and neck carcinoma cells secreted a larger amount of the l-EVs that carry integrin-α2 than the IRSp53-knockout cells. These l-EVs could promote the activation of ERK kinase and the proliferation of the recipient cells. The presence of the RGD (Arg-Gly-Asp) peptide, which binds to integrin on the l-EV, inhibited the promotion of proliferation of the recipient cells upon the l-EV treatment, suggesting that the promotion of the proliferation was dependent on the functional integrin on the l-EVs. Collectively, these results demonstrate that IRSp53 could promote the secretion of integrin-α2-containing l-EVs that trigger ERK activation and lead to tumor cell proliferation.

Plasma Membrane Damage-Induced Senescent Cells Accelerate Wound Healing via Extracellular Vesicles and Soluble Molecules

H. Barbee, Y. Moriyama, K. Kono; OIST, Onna, JAPAN.

Cellular senescence is an essentially irreversible cell cycle arrest that contributes to physiological and pathological processes in vivo, including organismal aging, development, cancer progression, and wound healing. The three best-studied triggers of cellular senescence are telomere shortening, oncogene activation, and DNA damage. We previously showed that transient plasma membrane damage induces a novel subtype of senescence (PMDS) in normal human fibroblasts. However, the pathophysiological

functions of PMDS cells remain unknown. Here, we investigated the paracrine functions of PMDS cells, via extracellular vesicles (EVs) and soluble molecules, and found that PMDS cells accelerate wound healing in vitro. We first measured the number of EVs and found that PMDS cells produce more EVs than DNA damage repair-dependent senescent (DDRS) cells. Then, we conducted scratch assays with PMDS cell co-culture and PMDS conditioned media transfer and saw acceleration of wound healing in young fibroblasts, which was more significant than with DDRS cells. We next separated the EV fraction and the soluble fraction to test their ability to accelerate wound healing. We found that these two fractions were less effective on their own but synergistically contribute to wound healing. Mass spectrometry analysis of PMDS cell-derived EVs revealed that wound-healing and Ca^{2+}-signaling regulators are enriched in the EVs. Altogether, these results revealed that the PMDS cells contribute to wound healing in vitro via EVs and soluble molecules. Our findings raise the possibility that PMDS cells may accelerate tissue repair in vivo.

Multivesicular Body Fusion and Exosome Secretion Links Repair of Single Cell Injuries to Tissue-Wide Health

D. C. Bittel, M. Hogarth, A. Defour, J. Jaiswal; Children's National Medical Center, Washington DC, DC

Cells of all tissues are routinely subjected to sublethal plasma membrane (PM) injury. The success and efficiency of repair of these cellular injuries influences long-term tissue health. As such, impaired or inefficient PM repair causes multiple tissue-degenerative diseases. Yet, how cellular PM injury activates tissue-wide adaptive responses remains poorly understood. Exosomes are implicated in long-range, tissue-wide intercellular signaling that regulates tissue health. While PM injury triggers vesicle fusion, MVB fusion and accompanying exosome secretion in response to PM injury - a potential link between cell repair and tissue homeostasis, has not been explored. Here we have studied the effect of PM injury on MVB fusion and exosome secretion in healthy and diseased (PM-repair deficient) muscle cells. Using live cell focal injury assays we monitored individual MVB fusion events and found that calcium stimulates robust MVB exocytosis within seconds post-injury. Moreover, MVB fusion is polarized to injury-proximal regions (5-fold higher vs. injury-distal regions). Calcium-dependent translocation of Annexin A2 on injury-proximal MVBs facilitated their fusion, and lack of Annexin A2 compromised exosome release. Using super-resolution and electron microscopy we have characterized these exosomes and found that injury-triggers a 5-fold increase in exosome release by injured cells, which was prevented by Annexin A2 deficit. In a wound closure assay exosomes secreted by injured cells, but not from uninjured cells, stimulated cell migration in a concentration-dependent manner. Using in vivo exercise-induced muscle injury, we observed that muscle fiber PM injury also triggers exosome accumulation in the injury-proximal endomysium, and causes a corresponding increase in inflammatory cell accrual. Additionally, injury-triggered MVB fusion was increased in muscle cells from PM-repair deficient Limb Girdle Muscular Dystrophy 2B (LGMD2B) patients and concomitantly, these LGMD2B mouse muscles showed greater muscle inflammation. This increased inflammation was ameliorated by the lack of Annexin A2 in the LGMD2B mouse. Thus, our results show that MVBs are previously unrecognized injury and calcium responsive secretory vesicles that undergo rapid, calcium-triggered, polarized exocytosis to secrete their exosome cargoes. This is facilitated by Annexin A2 and is enhanced in LGMD2B patient and mouse models. Reducing exosome secretion offers a target to mitigate chronic muscle inflammation and degeneration in LGMD2B and other disease where the cells show poor PM repair ability.

B468/P1452

Role of exosomal endoglin in filopodia formation and tumor cell metastasis

C. McAtee[1], D. Hoshino[2], N. Hong[3], B. Sung[1], E. Krystofiak[1], A. von Lersner[4], A. Zijlstra[5], A. Weaver[1,4]; [1]Vanderbilt University, Nashville, TN, [2]Kanagawa Cancer Center Research Institute, Yokohama, Japan, [3]Fred Hutchison Cancer Research Center, Seattle, WA, [4]Vanderbilt University Medical Center, Nashville, TN, [5]Genentech, San Francisco, CA

The objective of this study is to determine the role of extracellular vesicles and their protein cargoes on filopodia formation and metastasis in tumor cells. Exosomes are small extracellular vesicles (SEVs) that carry a variety of cargoes and have been shown to promote tumor cell motility and metastasis. Cell motility is influenced by dynamic formation and stability of filopodia: actin-rich protrusions that extend from the leading edge and perform directional sensing. Filopodia regulators such as fascin are upregulated in multiple epithelial cancers and can promote invasive phenotypes. However, how filopodia are induced and controlled by extracellular factors is poorly understood. Here, we describe a role for SEVs in regulating filopodia formation, tumor cell motility, and metastasis. We utilized B16F1 melanoma cells and HT1080 fibrosarcoma cells for fixed- and live-cell imaging to quantify filopodia numbers and dynamics in control and exosome-deplete conditions. iTRAQ proteomics was used to identify SEV protein cargoes that contribute to filopodia formation. *In vivo* experiments were performed using a chick embryo model for metastasis. Our results show that inhibition of exosome secretion in cancer cell lines, via Rab27a or Hrs knockdown, led to decreased filopodia numbers. Specificity to SEVs was demonstrated by rescue experiments in which purified SEVs but not large EVs rescued the filopodia phenotypes of exosome-inhibited cells. Live imaging of Hrs-KD cells revealed that exosome secretion regulates formation and stability of filopodia. Proteomics data and molecular validation experiments identified the TGF-beta coreceptor endoglin (Eng) as a key SEV cargo regulating filopodia formation, cancer cell motility, and metastasis. Additionally, we identified the RGD integrin binding motif present in endoglin as essential for it's effect on filopodia formation and tumor cell motility. In conclusion, our data identifies endoglin as a SEV cargo and regulator of filopodia, motility, and metastasis in tumor cells. These data are relevant to cancer as endoglin expression is altered in many cancer types. In addition, endoglin is the disease gene for hereditary hemorrhagic telangiectasia, and may influence angiogenesis. Overall, our data implicate SEV-carried endoglin as a key cargo regulating filopodia.

B469/P1453

Role of stimulus-elicited human neuronal extracellular vesicles in regulating inflammation and mitochondrial repair response

R. L. Nyunoya[1], J. G. Bauer[2], C. L. Howe[2], B. D. Clarkson[2]; [1]Soka University of America, Aliso Viejo, CA, [2]Mayo Clinic, Rochester, MN

Extracellular vesicles (EVs) are small lipid membrane particles involved in immunity. They are naturally released from cells and carry miRNA, mRNA, proteins, and cellular mitochondrial DNA. Mitochondrial components in EVs may play important roles in certain cellular contexts. For example, the packaging of mitochondrial components or mRNA may help repair dysfunctional mitochondria. Mitochondrial dysfunction increases with age and is associated with neurodegenerative diseases. This dysfunction is caused by the impairment of mitophagy, which is the degradation of mitochondria, especially damaged ones. Neuronal EVs may carry mitochondrial parts that repair dysfunctional mitochondria, acting as a therapeutic agent. To explore the therapeutic effect of human neuronal EVs, neural stem cells were

treated with a drug called CP2. This drug mildly inhibits mitochondrial complex I in human and mouse brain mitochondria. In response, mitochondrial genes are activated for mitochondrial repair. In this study, we focused on stimulus-elicited human neuronal EVs. Specifically, we investigated whether treating neurons with CP2 may cause these cells to increase their export of EVs containing mitochondrial repair parts by generating human neuronal aggregates and treating them under three conditions: DMSO (control), low dose CP2, and high dose CP2. From these cells, EVs were collected. Additionally, EVs from neurons that were electrically stimulated through a C-Pace EM machine were collected for analysis. We report changes in mitochondrial gene expression in 1) neurons treated with CP2, 2) neurons treated with EVs isolated from CP2 treated neurons, and 3) EVs isolated from CP2 treated neurons. Most notably, NDUFS2 was downregulated in high dose CP2 treated neurons after 24 hours, upregulated in EVs from high dose CP2 treated at 72 hours, and upregulated in neurons treated with 24 hr EVs. This may be due to neurons exporting EVs containing NDUFS2 mRNA. Additionally, both unstimulated and electrically stimulated EVs modulate cytokine secretion by human peripheral blood mononuclear cells and microglia in response to danger signals such as pan-bacterial or pan-viral Toll-like receptor ligands. EVs isolated at 72 hours from CP2 treated neurons may be more effective on mitochondrial repair response, and regardless of the stimulation, EVs seem to play a role in regulating inflammation.

B470/P1454

Optimization and characterization of the isolation of brain-derived exosomes from human plasma/serum: A pilot study for blood-based biomarker development for neurodegenerative diseases

J. Rack, E. Kosa, A. Agbas; Kansas City University, Kansas City, MO

Chemically modified aberrant Transactive Response DNA Binding Protein 43 (TDP-43) derivatives were found to represent a major accumulating protein in neuronal cytoplasmic inclusions and in exosomes in Frontotemporal Lobar Degeneration (FTLD), and in ALS patients. Exosomes are nano-size membranous vesicles that contain several macromolecules including aberrant pathological proteins. The size and membranous structure of exosomes allows them to pass through the blood brain barrier. These features make exosomes a potential platform in which targeted biomolecules can be analyzed. Our objective is to develop a method to isolate serum/plasma-derived brain-cell originated exosomes and their TDP-43 content as part of a surrogate biomarker development for limbic-predominant age-related TDP-43 encephalopathy (LATE). A heterogenous mixture of extracellular vesicles was obtained by running healthy human plasma through an Izon qEVoriginal size exclusion chromatography column with 70-1000nm matrix size. The exosome enriched fractions were pooled, and brain-derived exosomes were isolated by antibody cross-linked high-performance immunoprecipitation (HPIP) tips in conjunction with urea elution. For the isolation of astrocyte-derived exosomes, anti-GLAST antibody was cross-linked for the HPIP. Anti-TMEM119 and anti-MOG antibodies were cross-linked to HPIP tips to isolate microglia-derived and oligodendrocyte-derived exosomes, respectively. Western blot analysis and transmission electron microscopy (TEM) were used to confirm the presence of exosomes. Western blot results showed the presence of TSG101, GLAST, TMEM119 and TDP-43 in the HPIP eluates. TEM images confirm the presence of intact exosomes in the GLAST cross-linked HPIP eluates. These results suggest that intact astrocyte-derived exosomes and microglia-derived exosomes can be isolated from human plasma and that these exosomes contain TDP-43, a potential blood-based biomarker for neurodegenerative disease. The blood-based biomarker (a.k.a. liquid biopsy) would be a minimally invasive way to check for the progress of neurodegenerative diseases. Being able to isolate brain-derived exosomes from blood, our

prediction is that TDP-43 and pTDP-43 levels in these brain-derived exosomes will be a good analytical tool to monitor longitudinal changes of TDP-43 and its derivatives during neurodegenerative diseases.

Analysis of extracellular vesicles isolated from *Sorghum bicolor* utilizing an improved isolation method.

T. Chaya[1], A. Banerjee[1], D. Adekanye[1], B. Rutter[2], J. Ross[1], G. Hu[3], J. L. Caplan[1]; [1]University of Delaware, Newark, DE, [2]Indiana University, Bloomington, NY, [3]Brookhaven National Laboratory, Upton, NY

Extracellular vesicles (EVs) are implicated in a variety of biological functions across living systems. Extensive research on EVs has been conducted in animal systems, but the field of plant EVs is relatively new. EVs isolated from plants have yielded proteins, small RNAs, and other metabolites, however the isolation methods have greatly varied across plant species. Our group has developed a method that robustly isolates EVs from the monocot *Sorghum bicolor*, an important crop for grain and energy production. This method collects the apoplastic flow-through as well as vesicles that are released during the buffer infiltration process, which are then purified via density gradient ultracentrifugation. Incorporated into this isolation process is a staining method for light microscopy that utilizes the membrane permeable dye Calcein AM Green and the membrane binding dye Potomac Gold. Correlative light and electron microscopy has shown that the staining method precisely tags isolated vesicles. Transmission electron microscopy (TEM) and cryo electron tomography (cryo-ET) and nanoparticle tracking showed a diverse population of vesicles. Proteomics yielded 437 proteins across three replicates and 404 proteins were common to all three EV isolation replicates. Gene ontology analysis shows an enrichment of proteins involved in metabolism, transmembrane transport, vesicle docking and fusion, and protein secretion.

Kinases and Phosphatases 1

Regulation of the p38-MAPK Pathway by Hyperosmolarity and by WNK Kinases

Z. Liu[1,2], D. Rotin[1,2]; [1]Cell Biology, Hospital for Sick Children, Toronto, ON, CANADA, [2]Biochemistry, University of Toronto, Toronto, ON, CANADA.

p38-MAPK is a stress-response kinase activated by hyperosmolarity. Here we interrogated the pathways involved. We show that p38-MAPK signaling is activated by hyperosmotic stimulation in various solutions, cell types and colonic organoids. Hyperosmolarity sensing is detected at the level of the upstream activators of p38-MAPK: TRAF2/ASK1 (but not Rac1) and MKK3/6/4. While WNK kinases are known osmo-sensors, we found, unexpectedly, that short (2 hrs) inhibition of WNKs (with WNK463) led to elevated p38-MAPK activity under hyperosmolarity, which was mediated by WNK463-dependent stimulation of TAK1 or TRAF2/ASK1, the upstream activators of MKK3/6/4. However, this effect was temporary and was reversed by long-term (2 days) incubation with WNK463. Accordingly, 2 days (but not 2 hrs) inhibition of p38-MAPK or its upstream activators ASK1 or TAK1, or WNKs, diminished regulatory volume increase (RVI) following cell shrinkage under hyperosmolarity. Overall, our study reveals a tight connection between the p38 and the WNKs pathway and both pathways are important in regulating RVI.

The DUSP Domain of the Pseudophosphate MK-STYX Interacts with G3BP1 to Decrease Stress Granules

O. Mitchell, J. Smaileys, F. Jiang, L. Zavada, S. D. Hinton; College William & Mary, Williamsburg, VA.

Mitogen-activated protein kinase phosphoserine/threonine/tyrosine-binding protein (MK-STYX) is a dual specificity (DUSP) member of the protein tyrosine phosphatase (PTP) family. In particular, MK-STYX is a pseudophosphatase, which lacks the essential amino acids histidine and cysteine in the catalytic active signature motif (HCX_5R), of the MAPK phosphatases (MKPs). We previously reported that MK-STYX interacts with G3BP1 [Ras-GAP (GTPase-activating protein) SH3 (Src homology 3) domain-binding-1], and the DUSP domain to reduce stress granules, the protective response of cells to environmental stressors. Stress granules are stalled mRNA and proteins that form cytoplasmic aggregates. They serve as temporary sites of mRNA modification, sorting, and translation of essential proteins during cellular stress. To determine how MK-STYX reduces stress granules, simplified versions of MK-STYX's two domains, CH2 (cdc 25 homology) and DUSP, were used. HEK/293 cells were co-transfected with G3BP1-GFP (stress granule nucleator) and mCherry-MK-STYX, mCherry-MK-STYX-CH2, mCherry-MK-STYX-DUSP or mCherry and analyzed with fluorescent microscopy and coimmunoprecipitation. Cells co-expressing G3BP1-GFP and mCherry (control) formed stress granules. Whereas G3BP-GFP and mCherry-MK-STYX cells showed a decrease in stress granules, which was expected. In addition, cells expressing G3BP1-GFP and mCherry -MK-STYX-DUSP showed a decrease in stress granules compared to G3BP1-GFP and mCherry or mCherry -MK-STYX-CH2. To further analyze the interaction of G3BP1 and the domains of MK-STYX, coimmunoprecipitation experiments were performed. mCherry -MK-STYX-DUSP domain and G3BP1-GFP or G3BP1 (endogenous) were coimmunoprecipitated, suggesting that it is the DSUP domain of MK-STYX that interacts with G3BP1 to prevent stress granule assembly.

Hsp90 activity required for phosphorylation and nuclear accumulation of Akt1

A. Vogel, C. Corvalan, M. Doriti, O. Fida, E. Zolotareva, I. Yudushkin; University of Vienna, Vienna, AUSTRIA.

Akt localizes in the cytosol and in the nucleus in many cell types, yet whether nuclear Akt is catalytically active and how it is transported into the nucleus is not known. Previous reports suggested that Akt interacts with Hsp90. Here we propose that the nuclear accumulation of active, phosphorylated Akt is dependent on Hsp90 activity. To test this hypothesis, we compared the nuclear localization and phosphorylation of all three Akt isoforms upon inhibition of Hsp90 and upon allosteric inhibition of Akt in HeLa cells. We found that Akt2 shows higher nuclear localization in steady state conditions compared to Akt1 and Akt3. Hsp90 inhibition resulted in decreased nuclear localization of constitutively active (ca) $Akt1^{ca}$ and $Akt2^{ca}$, while the localization of the wildtype Akt1, 2 and 3 was unaffected. Hyperactive $Akt1^{ca}$ phosphorylation on T308 was decreased in a concentration dependent manner when Hsp90 was inhibited, suggesting that Akt1 in the nucleus is protected from dephosphorylation by Hsp90. Our data indicate that Akt1 but not Akt2 requires Hsp90 activity to sustain its phosphorylation and nuclear accumulation. Akt2 phosphorylation and nuclear accumulation appear to be independent of Hsp90 activity, but its nuclear localization is dependent on its conformation. Taken together these results suggest that Hsp90 can protect Akt from dephosphorylation and promote its nuclear accumulation in an isoform specific manner.

Identifying the Tao kinase as an upstream regulator of the Misshapen kinase in the *Drosophila* egg chamber

J. Paras; Butler University, Indianapolis, IN.

Intercellular bridges are an essential structural feature of developing eggs and sperm in many organisms, but the pathways that regulate their formation, stability, and growth are not fully understood. The developing *Drosophila* egg chamber provides an excellent model system to study intercellular bridges. Within the egg chamber, the developing oocyte is connected to the supporting nurse cells by large intercellular bridges, or ring canals. We have previously shown that the Ste20 kinase, Misshapen (Msn), localizes to these germline ring canals and regulates their size and stability; however, it is not known how Misshapen is targeted to the ring canals or how its activity is regulated during oogenesis. Here, we test the hypothesis that the Tao kinase phosphorylates and activates Msn in the germline to regulate the size and stability of the ring canals. Our preliminary data suggest that depletion of Tao in the germline alters ring canal size and the size of the mature eggs that are produced. In addition, Western blot analysis supports a role for Tao in phosphorylating Msn. In the future, we hope to further explore a role for Tao in regulating the localization and activity of Msn in the germline.

Interaction Between Pseudophosphatase MK-STYX and Vimentin

P. Singh, G. N. Wagner, L. Zavada, S. D. Hinton; Department of Biology, College of William & Mary, Williamsburg, VA.

The neuron has a unique structure required for efficient cellular communication. The specific mechanisms by which the neuron forms its unique shape still remains elusive. We previously reported that MK-STYX [mitogen-activated protein kinase (MAPK) phosphoserine/threonine/tyrosine binding-protein] induces neurite outgrowths in rat pheochromocytoma PC-12 cells and primary rat hippocampal neurons. Although MK-STYX is a catalytically inactive (pseudophosphatase) member of the MAPK phosphatase (MKP) family, it serves as a signaling molecule, which may interact with other proteins. A recent mass spectrometry interactome study revealed that MK-STYX interacts with cytoskeletal protein vimentin. Vimentin is an intermediate filament that supports growing neurites. We hypothesized that MK-STYX interacts with intermediate filament vimentin to regulate neuritogenesis. Our studies seek to validate the interaction of MK-STYX and vimentin. Here, we sought to characterize the dynamics between MK-STYX and vimentin through colocalization studies. We co-transfected HEK293 cells with MK-STYX-GFP and Vimentin-mCherry. Fluorescence microscopy showed partial colocalization of MK-STYX and vimentin. The partial colocalization was observed in the cytoplasm with a 45 percentage of cells with colocalization. Similar results were seen in cells overexpressing vimentin and the MK-STYX active mutant (MK-STYXactive) which suggests that the non-catalytic phosphatase function of MK-STYX is crucial for its function. The colocalization was observed within the cytoplasm of cells in both cases. Phosphorylated vimentin subunits are often found in the cell body of undifferentiated neurons. Thus, this cytoplasmic interaction may suggest that MK-STYX interacts with vimentin monomers to induce neuritogenesis. Taken together, these results support a previously reported protein-protein interaction, dynamics between MK-STYX and vimentin, and give new insights into the mechanisms underlying neuronal differentiation.

B477/P1461

Dsk1 and Kic1 kinases in heterochromatin dynamics

A. Sugarman[1], A. Vyas[2], Z. Ralston[2], B. Alhoch[2], P. Zhang[2], C. Ylagan[1], X. Yang[3], C. Tang[3], Z. Tang[2]; [1]Scripps College, Claremont, CA, [2]Claremont McKenna College, Claremont, CA, [3]Peking University, Beijing, CHINA.

Dsk1 is the ortholog of human serine-arginine (SR) protein-specific kinase1 (SRPK1 and Kic1/Lkh1 (LAMMER kinase homolog1) is a homolog of mammalian Clk/Sty kinases in the fission yeast, *Schizosaccharomyces pombe*. Dsk1 and Kic1 belong to the evolutionarily conserved LAMMER-related kinase family. While these kinases have been previously identified as important regulators of cellular function with roles in mitotic cycle, differentiation, and development, the molecular mechanisms through which they act remain unclear. Previous results spurred our interest in the potential involvement of Dsk1 and Kic1 in heterochromatin dynamics. Genome-scale epistasis analysis uncovered strong genetic interactions of Dsk1 with components of the DASH complex, an essential component of kinetochores. We thus tested the functional involvement of Dsk1 and Kic1 and found that Dsk1 or Kic1 kinase activity is required for complete gene silencing at centromeres, implicating their role in the dynamic state of the centromeric heterochromatin. Also, Kic1 predominantly localizes to the nucleus as 2-5 discrete dots, similar to the localization pattern of Swi6/HP1 (heterochromatin protein1), a key protein for centromeric heterochromatin and the ortholog of human HP1. We further investigated possible colocalization of Kic1 and Swi6/Hp1 at nuclear heterochromatin foci, as well as whether the Dsk1 and Kic1 kinases affect the cellular localization, modification, and overall production of Swi6/HP1 protein. Indirect immunofluorescence analysis provides evidence for the colocalization of GFP-Kic1 with Swi6 in wild-type cells, with the characteristic pattern of nuclear heterochromatic foci. Additionally, using GFP-tagged *swi6* strains, we detected some delocalization of the Swi6/HP1 signal to the cytoplasm in the *dsk1* or *kic1*-deletion strains compared with the wild-type nuclear punctate pattern. Notably, this cytoplasmic delocalization phenotype is significantly exacerbated in *Δkic1* mutants under the condition of temperature shift to 42^{o}C. Further, preliminary co-immunoprecipitation data are consistent with potential physical interactions between Kic1 and Swi6/HP1. Our results suggest that Dsk1 and Kic1 kinases may be involved in the recruitment of Swi6/HP1 to the nuclear heterochromatin foci, influencing the dynamic state of chromatin.

Effects of GSK3 Isoforms on Skeletal Muscle Differentiation and Autophagy

Y. Hsu, M. Chuang, Y. Liu; Institute of Molecular Medicine, National Taiwan University, Taipei, TAIWAN.

Glycogen synthase kinase 3 (GSK3) is a ubiquitously expressed protein kinase involved in various signaling pathways, including insulin, mTOR, Wnt signaling pathways. GSK3 is comprised of two isoforms, GSK3α and GSK3β, encoded by two homologous and highly conserved genes. In the past, scientists have mostly paid attention to GSK3β, in part because of the embryonic lethality of GSK3β-knockout mice, whereas GSK3α-knockout mice were viable and fertile, leaving GSK3α neglected. Over the past few decades, increasing studies have shown that GSK3α has isoform-specific functions in distinct tissues. For instance, GSK3α was demonstrated as a critical regulator of aging in mouse cardiomyocytes potentially through autophagy regulation. In our work, we aim to investigate the role of GSK3α in skeletal muscle. We observed that the depletion of GSK3α does not affect the differentiation or insulin response in C2C12 myoblasts. On the other hand, GSK3β depletion results in less myotube

number yet with higher insulin sensitivity. On the contrary, we discover that the formation of autophagosome is promoted in GSK3α-depleted C2C12 myoblasts but restrained in cells with GSK3β depletion. In summary, our data suggest that GSK3α and GSK3β indeed have distinct functions on skeletal muscle differentiation and autophagy.

A computational characterization of a novel predicted NEK10 - MAP3K1 interaction

A. Silva Dos Santos[1,2], S. Singh[1,2,3]; [1]Biology, Brooklyn College, CUNY, Brooklyn, NY, [2]The Biochemistry PhD Program, The Graduate Center of the City University of New York, New York, NY, [3]Biology, The Graduate Center of the City University of New York, New York, NY.

The NEK kinase family of proteins comprises of eleven serine/threonine kinases that participate in the disjunction of the centrosome, mitotic spindle assembly, and primary cilium formation. NEK10 is the most divergent member of the NEK family. It is unique in having a catalytic domain that is centrally positioned and flanked by two coiled-coil domains, in contrast to the N-terminal location of the catalytic domains of other NEKs. NEK10, instead has four armadillo repeats in its N-terminus. NEK10 is suggested to play a key role in carcinogenesis and has been linked to melanoma, breast cancer, and various ciliopathies. As part of our long-term goal to construct interactomes of all the NEK members, we have formerly reported data for known and predicted NEK10 interacting proteins, including novel protein-protein interactions such as HSPB1 and MAP3K1, which have not been previously reported in the literature. In this study, we focused on understanding the molecular mechanism underlying NEK10's interaction with MAP3K1 (MAPKKK1, MEKK, MEKK1) and its functional consequences. MAP3K1 is a serine/threonine kinase and ubiquitin ligase that possess a pivotal role in a network of enzymes integrating cellular receptor responses to several mitogenic and metabolic stimuli. Recent studies have shown that MAP3K1 mutations are seen in a significant number of different cancers, being most prominent in luminal breast cancer. MAP3K1 contains a protein kinase domain, PHD finger (which has a RING finger domain-like structure) that serves as an E3 ubiquitin ligase, and scaffold protein regions that mediate protein-protein interactions. Using a computational approach, we modeled and characterized the full-length NEK10 and MAP3K1 proteins. In addition, we probed the role of the NEK10 kinase domain in its interaction with MAP3K1. Our docking analysis shows that I693 of NEK10 located within its kinase domain interacts with well-known phosphosite S275 of MAP3K1. Our results, therefore, suggest a scenario in which, upon UV irradiation, NEK10 phosphorylates and activates MAP3K1, which in turn phosphorylates MAP2K1/2-ERK1/2 promoting cell survival. Overall, this study shows sheds light on NEK10's structure-function relationships, especially in the context of its interaction with MAP3K1. Furthermore, it establishes the framework for elucidating the detailed molecular mechanisms of NEK10 interactions with other proteins to further explore its potential as a therapeutic target.

B480/P1464

Probing the role of subcellular populations of Extracellular Signal-Regulated Kinase on cell fate decisions

K. Slye, C. Scott, O. Webster, J. Keyes; Pennsylvania State University Erie, Erie, PA.

Extracellular signal regulated kinase (ERK) is a MAP kinase that regulates the proliferation and differentiation of mammalian cells. Although ERK has been an area of intense research for decades, an exact understanding of how ERK is differentially regulated to perform a plethora of functions remain

elusive. Previous work from our group indicates that, in PC12 cells, ERK inhibition at the plasma membrane does not inhibit ERK activity elsewhere in the cell. Upon plasma-membrane specific ERK inhibition, we observe changes in cell morphology and EGF-induced protrusion dynamics that mimics NGF-induced protrusions. This suggests that plasma membrane pool of ERK, which has previously been overlooked, plays a critical role in cell fate decisions. Here, we report that ERK activity displays unique subcellular spatiotemporal dynamics in response to an individual signals, and we report new genetically encodable tools to probe the function of subcellular dynamics.

B481/P1465

The Target of Rapamycin TORC2 complex regulates the activity of conserved NDR kinase Orb6 to control cell morphogenesis and chronological lifespan.

D. D'Urso, L. Doyle, C. Romero, C. Chen, **F. Verde**; University of Miami, Miami, FL

Conserved NDR kinase controls cell morphogenesis from yeast to human cells and has a role in the onset of disease. In fission yeast, the NDR kinase Orb6 controls cell polarity by spatial regulation of the key morphology factor Cdc42 GTPase, by direct phosphorylation of the Cdc42 GEF Gef1. Furthermore, Orb6 kinase promotes polarized cell growth and modulates chronological cell aging, by altering the phase separation properties of RNA binding protein Sts5. We previously showed that Orb6 kinase activity responds to nutritional availability and is downregulated by nutritional stress, however the signaling mechanisms that mediate this response are still unclear. Therefore, we performed a genome-wide screen to define the functional interaction network that controls Orb6 kinase activity. We found that Orb6 kinase genetically interacts with multiple key stress-sensitive kinase pathways involved in glucose starvation, nitrogen starvation, and salt stress. In particular, we found that *orb6* mutants display genetic interactions with mutants in components of the TOR (Target of Rapamycin) complex 2 (TORC2) complex, or in components that are shared with both the TORC1 and TORC2 complexes. Consistent with these observations, we found that *orb6* mutants display strong synthetic lethality with the TORC1 inhibitor Rapamycin. However, we found that Rapamycin does not promote Cdc42 delocalization, Gef1 dephosphorylation or Sts5 aggregation, hallmarks of Orb6 kinase inhibition. Conversely, we found that exposure of fission yeast cells to Torin1, an inhibitor of both TORC1 and TORC2, leads readily to Cdc42 delocalization, Gef1 dephosphorylation and Sts5 aggregation. To further analyze the role of TOR kinases in the control of Orb6 kinase activity, we tested the effect of Rapamycin and Torin1 on the phosphorylation state of Orb6 Serine 456, a crucial site for kinase activation in AGC kinases, using custom-made phosphospecific antibodies. We found that Torin1 strongly reduces the levels of Orb6 kinase phosphorylation on Serine 456, while Rapamycin has little or no effect. Finally, consistent with TORC2 functioning in the Orb6 pathway, we found that mutants of the TORC2 complex alter the response of Orb6 substrates Sts5 and Gef1 following exposure to Torin1 or nutrient stress. In summary, our observations indicate that conserved NDR kinase Orb6 functions downstream of TORC2, highlighting a novel functional connection for TORC2 in the control of cell morphogenesis and chronological lifespan in eukaryotes.

B482/P1466

Dissecting dynamics of glycans signaling by real-time microscopy

N. Baranova, H. Vrban, C. Rademacher; University of Vienna, Vienna, AUSTRIA.

We have detailed biophysical models on how immune cells manage to find an antigenic peptide in the sea of other peptides. However, we do not have the same level of understanding on how immune cells recognise pathogen-associated glycan motifs. Why is it important to consider the dynamics of interactions when we think about the immune response to glycans? The recognition of glycan motifs by innate immune cells is mediated through a dedicated family of receptors, such as C-type lectins. The affinities of most C-type lectins to glycans are very low, and this sort of recognition is a dynamic on- and off- process. Being intrinsically transient, some of the recognition events are sufficient to activate intracellular signaling pathways. How this activation is achieved on molecular level remains largely unclear. Here we developed an assay to investigate at nm-precision recognition of pathogenic glycans by engineered immune cells. The well-controlled reconstitution on silica beads enabled us to correlate the length and density of beta-glucans with the activation of NFkB or MAPK signaling pathways. Using this assay we found that soluble small molecular weight fragments of beta-glucans are capable to activate cell signaling *via* Dectin-1 receptor without a need to form an immune synapse. Using similar reconstitution, but on a planar surface, we aim to investigate the dynamics of Dectin-1 receptor oligomerization at a single-molecule level and correlate it with the activation of cell signaling. The gained here mechanistic knowledge can instruct further development of glycomimetic drug delivery systems for controlled engineering of immune response.

Characterizing the interaction between mTORC2-component SIN1 and the small GTPase Rap1

A. Orlinski[1], P. Charest[2]; [1]Chemistry and Biochemistry, University of Arizona, Tucson, AZ, [2]Molecular and Cell Biology, University of Arizona, Tucson, AZ.

The mechanistic Target of Rapamycin Complex 2 (mTORC2) is one of two evolutionarily conserved signaling complexes formed by the kinase mTOR. Whereas mTORC1 is a master regulator of cell growth, mTORC2 regulates cell survival and cell migration, as well as some aspects of metabolism. mTORC1 has been extensively studied and much is known about its biochemistry and regulation, but less is understood about how mTORC2 is regulated. Previously, we discovered that *Dictyostelium* mTORC2 is regulated by the small GTPase Rap1 through its interaction with the mTORC2 component RIP3/SIN1, an interaction that we found to be conserved with the human proteins. Here, using pull-down assays with recombinant proteins and in-cell Bioluminescence Resonance Energy Transfer (BRET) assays, we investigated the molecular determinants of the Rap1-SIN1 interaction *in vitro* and in live cells. Our results suggest that SIN1 preferentially interacts with active Rap1, and that this involves SIN1's Ras Binding Domain (RBD). Moreover, using BRET, we detected the interaction of SIN1 with both Rap1a and Rap1b isoforms in live HEK293T cells, and our analyses suggest a preference of SIN1 for the active forms of the GTPases. Ongoing work focuses on investigating the contribution of SIN1's PH domain in mediating the interaction with Rap1, and the dynamics of the interaction. mTORC2 is a key signaling hub in many pathways and has been implicated in oncogenesis. Therefore, a better knowledge of the molecular mechanisms involved in mTORC2 regulation and signaling is important to our understanding of tumorigenesis and identifying new therapeutic strategies.

B484/P1468

Design principles of Cdr2 node patterns in fission yeast cells

H. Opalko[1], S. Geng[2], A. R. Hall[2], D. Vavylonis[2], J. B. Moseley[1]; [1]Dartmouth Medical School, Lebanon, NH, [2]Physics, Lehigh University, Bethlehem, PA.

Pattern forming networks have diverse roles in cell biology from eukaryotic development to bacterial cell division. Rod-shaped fission yeast cells use pattern formation to control the localization of mitotic signaling proteins and the cytokinetic ring. During interphase, the mitotic kinase Cdr2 forms membrane-bound multiprotein complexes termed nodes, which are positioned in the cell middle due in part to the node inhibitor Pom1 enriched at cell tips. Node positioning is important for timely cell cycle progression and positioning of the cytokinetic ring. Here, we combined experimental and modeling approaches to investigate pattern formation by the Pom1-Cdr2 system. We found that Cdr2 nodes accumulate at cortical regions nearest to the nucleus, and Cdr2 undergoes nucleocytoplasmic shuttling when cortical anchoring is reduced. To explore how node patterns arise, we generated particle-based simulations based on tip inhibition, nuclear positioning, and cortical anchoring. We tested predictions from these models by investigating Pom1-Cdr2 localization patterns after perturbing each positioning mechanism, including in both anucleate and multinucleated cells. Experiments show that tip inhibition and cortical anchoring alone are sufficient for the assembly and positioning of nodes in the absence of the nucleus, but that the nucleus and Pom1 facilitate the formation of unexpected node patterns in multinucleated cells. Our results suggest that local node concentration is determined by competition between a positive (nucleus) and negative (Pom1) regulator buffered by cortical anchoring. This model has implications for spatial control of cytokinesis by nodes and for spatial patterning in other cell signaling networks.

B485/P1469

Functional Interaction between PKA and 4.1B During PDGF-signaling

P. B. Deming; University of Vermont, Burlington, VT

cAMP-dependent protein kinase A (PKA) is a serine/threonine kinase that regulates cellular processes including proliferation, survival, differentiation, and migration in response to a variety of extracellular cues. Our lab has previously identified the platelet-derived growth factor receptor (PDGFR), as a regulator of PKA activity through tyrosine phosphorylation of the catalytic subunit. However, the PKA-mediated downstream signaling events and functional impacts remain largely unknown. As tyrosine phosphorylation of proteins often generates a docking site for the recruitment of signaling proteins, we hypothesized that tyrosine phosphorylation of the PKA catalytic subunit may induce protein-protein interactions important for the cellular response to growth factors. Here we report that activation of the PDGFR in NIH 3T3 mouse fibroblasts induces a novel interaction between PKA and EPB41L3 (4.1B), a 4.1 family member known to serve an important role in cytoskeletal organization. Stable isotope labelling of amino acids in culture (SILAC) coupled with mass spectrometry identified induced binding of 4.1B to PKA in NIH3T3 cells stimulated with platelet derived growth factor (PDGF). Moreover, 4.1B was phosphorylated in PDGF-stimulated cells and this phosphorylation was blocked when cells were pretreated with the PKA inhibitor, H89. In vitro kinase assays revealed that PKA can directly phosphorylate 4.1B, and mass spectrometry identified the phosphorylation site as serine 428. Importantly, mutation of serine 428 to non-phosphorylatable alanine (S428A) ablated PDGF-induced phosphorylation of 4.1B, suggesting that this is the primary site of phosphorylation during PDGF-signaling. Taken together these results reveal a novel interaction between PKA and 4.1B during PDGF

signaling. Current studies are focused on elucidating the impact of PDGF-induced phosphorylation of 4.1B on cytoskeletal organization, cell adhesion and migration, which could shed light into the mechanism/s whereby PKA regulates these cellular processes.

Research Focal Areas Associated with Understudied Kinases, GPCRs, and Ion Channels: A Portfolio Analysis

B. Hair, K. Sharma, D. Sheeley; NIH, Rockville, MD

Introduction: In 2014 the National Institutes of Health's Common Fund launched the Illuminating the Druggable Genome (IDG) program to generate information on proteins that are currently understudied within three commonly drug-targeted protein families (kinases, G protein coupled receptors (GPCRs), and ion channels). The program funded Data and Resource Generation Centers (DRGCs) to generate innovative data and tools for the understudied proteins and pilot projects to study the proteins beyond the scope of the DRGCs.
Objective: The goal of this study is to assess the major focal areas of research associated with the understudied proteins by analyzing a portfolio of grants funded by IDG.
Methods: Publications associated with the DRGCs and abstracts for the pilot project awarded grants (R03 awards) were assessed. Each publication and R03 award was assigned a research focus area. Publications and awarded grants with more than one category were double-counted. Review publications were excluded.
Results: 57 grants and 46 publications were included in the analysis. Overall, approximately 60% of publications associated with the DRGCs focused on probe discovery, assay development, or probe development. Of the publications that focused primarily on a specific disease, cancer was the most frequent research focal area, followed by neurological and sleep cycle research. When assessing research areas by the protein families individually, cancer was the most frequent focus for kinases, followed by probe discovery and resource development. For GPCRs, probe discovery and assay development were the most focused on research areas. For both kinases and GPCRs, the majority of the publications were resource focused (probe development, probe discovery, assay development, or resource development) rather than disease focused.
For the R03 awards, the research areas were primarily disease focused. About a quarter of the grants focused on cancer and neurological diseases each. Diseases or disorders of the metabolic system were the focus of 11% of the awards, followed by the lymphatic system (10%), mental health/substance use (5%), and developmental disorders (5%).
Conclusion: IDG's portfolio includes a diverse mix of resource-focused and disease-focused research, which has enabled the program to generate information of broad scientific interest.

Pathogenic mutations in *TTBK2* localize at the peroxisome and modify primary cilia membrane composition

J. MUNOZ ESTRADA, S. GOETZ; Duke University, Durham, NC

Tau Tubulin Kinase 2 (TTBK2) is a kinase that localizes to the mother centriole and is required for primary cilia formation. *TTBK2* mutations cause neurodegenerative disorder Spinocerebellar ataxia 11 (SCA11), which affects the cerebellum. Our previous work showed that these pathogenic variants of *TTBK2*

dominantly interfere with primary cilium formation and Shh signaling in mice. Nevertheless, the molecular mechanisms underlying the dominant interference of mutations remain unknown. We found that the SCA11-associated mutations generate a reliable peroxisomal target sequence, and their expression in RPE cells alters the morphology of peroxisomes, reduces their numbers and alter the molecular machinery of peroxisomal division. Consistent with previous reports that peroxisomes supply ciliary membrane with cholesterol essential for Shh signaling, we find that cells expressing pathogenic *TTBK2* variants have reduced numbers of peroxisomes near the base of cilia, and defective trafficking of ciliary Smoothened. These results highlight and strengthen a novel communication between peroxisome and primary cilia and indicate that peroxisomes are necessary for maintaining ciliary membrane composition. Our findings uncover a dominant, neomorphic function of SCA11-associated mutations and shed light on the molecular mechanisms underlying SCA11.

B488/P1472

The dual roles of Pib2 in reactivating and inhibiting vacuolar TORC1 in *S. cerevisiae*

K. K. Troutman, N. V. Varlakhanova, M. G. J. Ford; University of Pittsburgh, Pittsburgh, PA

The target of rapamycin complex 1 (TORC1) is a kinase complex that is highly conserved through eukaryotes. TORC1 is essential for the control of cell growth and autophagy and dysregulation of the complex has been implicated in a variety of diseases. The TORC1 complex incorporates nutritional cues via several upstream regulators to appropriately modulate cell growth. TORC1 can be inhibited by nutrient starvation or treatment with the specific inhibitor rapamycin, which arrests cell growth and triggers an increase in autophagy. Reactivation of TORC1 can be achieved by amino acid stimulation. In *Saccharomyces cerevisiae*, this reactivation is dependent on phosphatidylinositol 3-phosphate-binding protein 2 (Pib2), which has been shown to interact with and activate TORC1 in a glutamine dependent manner. Pib2, has also been shown to have a TORC1 inhibitory function, however, the exact molecular mechanisms of Pib2 regulation remain poorly understood. Multiple sequence alignments of Pib2 from ascomycete fungi highlight several conserved regions and domains. Here we use rapamycin exposure assays and live-cell confocal imaging to functionally dissect these conserved Pib2 regions. Using these assays, we have identified regions and key residues that are essential for TORC1 reactivation and Pib2 localization. We demonstrate that the TORC1 inhibitory function of Pib2 can be pinpointed to residues in the N-terminal A and B regions, while the TORC1 activation function of Pib2 is dependent on its C-terminal helical E region, FYVE domain, and tail motif. TORC1 and Pib2 localize primarily to the vacuolar membrane as well as signaling endosomes. To determine the effects of subcellular localization of Pib2 on its ability to regulate TORC1 activity, we generated fusion proteins that target Pib2 to the vacuole or endosome. Using rapamycin exposure assays we demonstrate that vacuolar localization of Pib2 is essential for the reactivation of TORC1. We also show that while the Pib2 PI3P-binding FYVE domain is critical for vacuolar localization, it is interestingly not needed for rapamycin recovery. Here we have demonstrated that Pib2 plays a role as a dual modulator of vacuolar TORC1 activity in *S. cerevisiae* which may have implications for the regulation of TORC1 activity in higher eukaryotes.

B489/P1473

Peptide Lv promotes trafficking and membrane insertion of K_{Ca}3.1 through the PI3K-Akt signaling pathway

D. L. Pham, A. Niemi, R. Blank, J. Tham, M. L. Ko, **G. Y. P. Ko**; Veterinary Integrative Biosciences, Texas A&M University, College Station, TX.

Activation of endothelial cells (ECs) for angiogenesis requires EC membrane hyperpolarization, which is mediated by activating potassium channels. Peptide Lv is an endogenous angiogenic peptide that can elicit EC hyperpolarization by increasing the current density of intermediate-conductance calcium-dependent potassium (K_{Ca}3.1) channels. One way to enhance the current density of an ion channel is to promote its trafficking and insertion into the plasma membrane. The phosphoinositide-3-kinase (PI3K)-protein kinase B (Akt) pathway is known to mediate the trafficking and membrane insertion of various ion channels in neurons. However, it is unclear whether K_{Ca}3.1 current density increased by peptide Lv is in a similar manner in ECs. Our hypothesis was that PI3K-Akt mediates peptide Lv-elicited K_{Ca}3.1 channel trafficking and membrane insertion, leading to increased K_{Ca}3.1 current density. To test this hypothesis, we employed patch-clamp electrophysiological recordings and cell-surface biotinylation assays with cultured human umbilical vein ECs in the presence and absence of peptide Lv and pharmaceutical inhibitors of PI3K and Akt. Inhibition of PI3K or Akt diminished peptide Lv-elicited EC hyperpolarization and augmentation of K_{Ca}3.1 current density. Blocking PI3K or Akt decreased the level of plasma membrane-bound but not cytosolic K_{Ca}3.1 protein indicating that inhibition of PI3K-Akt did not affect the protein expression of K_{Ca}3.1 but dampened its trafficking and insertion to the plasma membrane. Therefore, the peptide Lv-elicited EC hyperpolarization and K_{Ca}3.1 augmentation are in part through channel trafficking and insertion mediated by PI3K-Akt signaling. These results elucidate the molecular mechanisms by which peptide Lv promotes EC-mediated angiogenesis.

Inhibition of collagen production in keloid fibroblasts through GSK-3β activation

M. Carulla, A. Asker, **D. Telgenhoff**; Oakland University, Rochester, MI

Keloid scars are abnormal wound healing processes characterized by excessive collagen deposition that exceed the borders of the original wound. These scars have a higher tendency to develop in individuals with a family history of keloid scarring, are under the age of 30, or are of African or Latin American descent. Keloid scarring may inhibit movement and have significant physical and psychological effects on the individual. Inactivated glycogen synthase kinase 3-β (GSK-3β), a molecule that breaks down β-catenin which is used by the Wnt/β-catenin pathway in hypertrophic scarring, has been found to be abundant in keloid fibroblasts. The Wnt/β-catenin pathway is known to influence hypertrophic scarring, and the activation of GSK-3β has been found to inhibit other hypertrophic scarring diseases. The objective of this study was to examine the effects of an activator or inhibitor of GSK-3β on keloid cell collagen production. Human keloid fibroblasts were cultured *in vitro* and treated with sodium nitroprusside (known to activate GSK-3β), lithium chloride (an inhibitor of GSK-3β), or a vehicle control. Cultured cells were permeabilized and incubated with antibodies for collagen I or collagen III followed by incubation in fluorescent labelled secondary antibodies and imaging. In duplicate cultures proteins were isolated in buffer, quantified, separated on 8% SDS-PAGE, and assessed through Western Blot analysis for changes in collagens I and III, elastin, fibronectin, and beta-catenin (normal and phosphorylated). All experiments were repeated in triplicate. The results of this study suggest that GSK-

3β is partially inactive in keloid fibroblasts and that activation of the protein activates the Wnt signaling pathway and decreases collagen and elastin production. Fibronectin levels were found to increase with treatment, possibly due to its role in cell adhesion and contraction in wound healing. These results indicate a role for GSK-3β in the Wnt/β-catenin pathway in the formation of keloid scars, and a potential target for inhibition of keloid formation.

Cytoskeletal-Membrane Interactions

The Ste-20 kinase Slik deforms membranes to regulate cytoneme biogenesis independently of its kinase activity

B. Rambaud[1], M. Joseph[2], C. De Jamblinne[1], R. Sabelli[1], E. Del Guidice[1], D. Hipfner[2], S. Carreno[1];
[1]Institute for Research in Immunology and Cancer, University of Montréal, Montréal, QC, CANADA,
[2]Institut de recherches cliniques de Montréal, University of Montréal, Montréal, QC, CANADA.

Cytonemes are specialized actin-rich filopodia in charge of long distance cell-cell communication. They have attracted much interest in the recent years, but the mechanisms regulating their biogenesis are still poorly understood. Here, we show that Slik, a drosophila Ste-20 kinase, deforms membrane to induce budding and elongation of cytonemes.
We used drosophila S2 cells, a cell line that form cytonemes in culture, to show that overexpression of Slik increases cytoneme length and number. We also found that the role of Slik on cytoneme biogenesis is independent of its kinase activity and relies on its C-terminal domain. By Correlative Light Electron Microscopy (CLEM), we also observed that Slik-Cterm induces strong membrane deformation of the cell cortex. Interestingly, Slik-Cterm contains three coiled-coil domains that are organized to form I-BAR like domain. We are currently testing the possibility that Slik-Cterm acts as a non-canonical I-BAR domain that generate negative membrane curvature.Our study opens new avenue for investigating the kinase-independent function of Slik for cytoneme biogenesis.

Three-dimensionally extending filopodia of neuronal growth cones, are associated with the localization of an axon guidance receptor

M. Nozumi, M. Igarashi; Dept of Neurochem & Mol Cell Biol, Niigata University Grad Sch Medical Dent Sci, Niigata, JAPAN.

Neuronal growth cones are the highly motile structures at the tip of extending axons in the developing or regenerating neurons. The highly dynamic actin structure in the peripheral domain is crucial to the growth cone motility and its guidance. Using SIM super-resolution microscopy, we have previously revealed that local endocytosis is associated with the F-actin-bundling at the leading edge of growth cones. The F-actin-dependent endocytosis most likely contributes to the membrane retrieval, containing the lipid rafts from the nonadherent, upper surface of the growth cone [Cell Rep 2017]. Using 3D-SIM, we also found that F-actin bundles were distributed along the upper surface, and part of them were protruding, not only towards the leading edge, but also in the z-axis direction. An axon guidance receptor neuropilin-1 was transiently concentrated in this type of filopodia. The localization of neuropilin-1 was extinguished by cholesterol depletion with methyl-beta cyclodextrin. Interestingly, synaptophysin and two endocytic components, endophilin A3 and dynamin 1, also were accumulated in

such a type of filopodia. These results suggest that the formation of this type of 3D-extending filopodia effectively promotes the neuropilin-1-associated local endocytosis, and our observation indicates that the growth cone has a cooperating, sensing mechanism by actin polymerization, as well as its advancing activity.

Deciphering an unconventional role fo BIN1 in filopodia-like structure formation

C. Gauthier-Rouviere[1], L. Picas[2], F. Comunale[1], C. André[2], H. Bousquet[3], F. Tsai[3], F. Rico[4], P. Maiuri[5], J. Pernier[6], S. Bodin[1], A. Nicot[7], J. Laporte[8], P. Bassereau[3], B. Goud[3], S. Miserey[3]; [1]CNRS-CRBM, Montpellier, FRANCE, [2]IRIM-CRBM, Montpellier, FRANCE, [3]Curie institute, Paris, FRANCE, [4]INSERM, Marseille, FRANCE, [5]Napoli university, Napoli, ITALY, [6]CNRS, Paris Saclay, FRANCE, [7]INSERM, Grenoble, FRANCE, [8]CNRS, Illkirch, FRANCE.

BIN1/M-Amphiphysin2 is a splice variant of Amphiphysin2 expressed in muscle that has been implicated in T-tubule biogenesis. BIN1 belongs to the BAR (Bin1-Amphiphysin-Rvs) domain family, which are known to induce membrane curvature and participate in endocytosis in certain cell types. Several BIN1 mutations are reported on centronuclear myopathies (CNMs), a heterogeneous group of inherited muscular disorders that are characterized by a compromised normal muscle function and nuclei positioning, ultimately leading to fiber atrophy and muscle weakness. The suppression of BIN1 on muscular cells has shown to impair the fusion of myoblast during muscle differentiation[1], although the exact mechanism remains elusive. Here, we report that BIN1 participates in forming filopodia-like structures at myoblasts' intercellular junctions, structures that promote adhesion and fusion of muscle cells. Furthermore, our results show that BIN1 assembles actin bundles *in vitro* and regulates plasma membrane tension. We identified ezrin as a new BIN1 partner and showed that ezrin association with $PI(4,5)P_2$-containing model membranes and the plasma membrane is favored by BIN1. Our results establish BIN1 and ezrin as central players to form long-lived filopodia-like structures, known to promote adhesion and fusion of muscle cells.

B495/P1478

Dissecting the Recruitment Kinetics of Mechanosensitive Proteins to Stress Fiber Strain Sites

S. Sala, P. W. Oakes; Loyola University Chicago, Maywood, IL

Cells respond to a variety of mechanical cues by converting them into biochemical signals, a process called mechanotransduction. This ubiquitous process underlies many fundamental functions in cell biology, including differentiation and division. The actin cytoskeleton and its associated adhesion and motor proteins play a key role in mechanotransduction. This network produces many dynamic architectures, including stress fibers (SF) and focal adhesions (FA), which enable cells to generate and transmit forces to the extracellular environment. How forces are actually sensed in the actin cytoskeleton, however, remains poorly understood. LIM domain proteins (LDPs) have emerged as cytoskeletal mechanosensors that recognize SF strain sites (SFSS) through a conserved mechanisms requiring their LIM domains. In the case of zyxin, its binding partners VASP and α-actinin are also recruited to these SFSS. These proteins are thought to stimulate SF repair through polymerization and crosslinking of actin, respectively. The role of myosin in SF strain repair, and how it contributes to the maintenance of cellular force generation during repair remains unclear. To answer these major questions, we combined laser photoablations with traction fore microscopy to locally induce SFSS and

quantify protein recruitment to these sites while simultaneously measuring cellular forces at FAs during and after SF repair. Within seconds post strain induction, we observed a massive recruitment of the LDPs testin and zyxin to SFSS which coincided with a loss of actin and myosin in the region of strain and hence a reduction in local traction forces. LDP relocation to SFSS was followed by the recruitment of the Ena/VASP family of proteins which are known to promote actin polymerization. Interestingly, only when the SFSS was fully repaired, as indicated by a complete recovery of the actin signal and concomitant loss of the LDP and Ena/VASP signals, myosin association with actin was restored, resulting in a recovery of the local traction stresses. Together, our data provide novel insights into how SF damage is detected and repaired to maintain tensional homeostasis in cells. We propose a model showing that SF damage impairs actomyosin contractility reducing local force transmission in the adjacent FAs, which is recovered by a repair mechanism mediated by LIM domain and Ena/VASP proteins.

Multistability and general relations of cell motion on Fibronectin lanes

B. Amiri[1], J. Heyn[2], J. Rädler[2], **M. Falcke**[1]; [1]Max Delbruck Ct Molec Med, Berlin, GERMANY, [2]Dept. of Physics, Ludwig-Maximilians-Universität, Munich, GERMANY.

Cell motility on flat substrates exhibits coexisting steady and oscillatory morphodynamics, the biphasic adhesion-velocity relation, and the universal correlation between velocity and persistence (UCSP) as phenomena common to many cell types and observed simultaneously. Their universality and concurrency suggest a unifying mechanism to exist causing all three of them. We search for such a mechanism by investigating a large ensemble of trajectories of MDA-MB-231 cells on Fibronectin lanes. We find cells with steady or oscillatory morphodynamics and either spread or moving. We observe apparently spontaneous transitions between the dynamic regimes, spread and moving motion states and direction reversals. We formulate a biophysical theory on the basis of the force balance at the leading edge, the noisy clutch of retrograde flow and a response function of friction and membrane drag to integrin signaling. The theory reproduces the experimental results with good quantitative agreement in a large Fibronectin density range. Analysis of the experiments with the biophysical model establishes a stick-slip oscillation mechanism, explains multistability of cell states and state transitions, and shows protrusion competition to cause direction reversal events, the statistics of which explains the UCSP. The model also explains cell behavior at Fibronectin steps and the adhesion-velocity relation. We suggest a mechanism, where signaling sets the cellular parameters for a multistable dynamic regime with steady or oscillatory morphodynamics, spread or moving motion states. These dynamics are driven by F-actin polymerization and shaped by the clutch mechanism of retrograde flow friction, protrusion competition via membrane tension and drag forces.

B497/P1480

Mechano- and phospho-regulation of End4p coordinates the temporal and spatial transmission of force during clathrin-mediated endocytosis

Y. Ren[1,2], J. Yang[1], B. Fujita[1,2], Y. Zhang[1,1], J. Berro[1,2,1]; [1]Yale University, New Haven, CT, [2]Yale University, West haven, CT

During clathrin-mediated endocytosis (CME), a patch of plasma membrane is reshaped into a cargo-filled vesicle by the choreographed action of more than 50 proteins conserved from yeasts to humans. Mechanical force from the actin cytoskeleton is crucial to overcome the energy barrier to deform the

membrane during CME, especially for mammalian cells with elevated membrane tension and cells with high turgor pressure such as the fission yeast *Schizosaccharomyces pombe*. Forces are transmitted to the membrane by adaptor proteins that physically connect the membrane's lipids to actin filaments. The onset and the termination of force transmission is tightly regulated temporally during different stages of CME, and spatially over the surface of the invaginated membrane. How force transmission is regulated and coordinated at the molecular scale is unclear.
Here we show that the THATCH actin-binding domain of the endocytic adaptor protein End4p (homologous to HIP1R in mammalian cells and to Sla2p in the budding yeast) is mechanosensitive, partially unfolds under 13 pN of force, and only gains affinity for actin filaments after partial unfolding. We also identified a previously uncharacterized domain upstream of THATCH, the R_{end} domain (**R** domain of **End**4p), a five-helix bundle which is homologous of Talin's R domains, yet cannot be functionally substituted by R_3. R_{end} unfolds under 15 pN in an all-or-none manner. R_{end} promotes the localization of End4p to endocytic sites and mediates End4p protein condensation with prolonged binding to either F-actin or the membrane. Membrane anchored R_{end} dimers form condensates, which are inhibited by the phosphorylation of R_{end} at T841. By using the new coiled-coil force sensors we developed, we measured forces during CME in wild type fission yeast cells on End4p are around 19 pN before THATCH and around 15 pN before R_{end}. We propose that the unfolding of THATCH initiates force transmission through End4p, that transient condensation of R_{end} spatially coordinates the transmission of force, and that phosphorylation and mechanical unfolding of R_{end} promotes the disassembly of End4p at the end of CME.

B498/P1481

Mechanosensitive cell volume regulation via actomyosin and ion transport

Q. Ni[1], Z. Ge[1], Y. Li[2], J. Fu[1], K. Bera[1], Y. Yang[1], A. Sen[1], Y. Wang[1], K. Konstantopoulos[1], S. X. Sun[1]; [1]Johns Hopkins University, Baltimore, MD, [2]The State University of New York at Binghamton, Binghamton, NY.

The mammalian cell volume plays an important role in regulating the mechanical and physiological functions of cells. During mitosis or exposure to extracellular mechanical and physiological challenges, cells are able to dramatically change their volume within minutes. Within this timescale, cell volume change comes from cell surface water flux, which is actively regulated by cell ionic fluxes and the hydrostatic pressure difference across the cell surface. The role of ion transporters in volume regulation has been well-established. However, the role of the actomyosin cytoskeleton mediated cell mechanics is still unclear. There is likely substantial interplay between ion channels/transports and cytoskeletal activity. In this paper, we applied osmotic shocks to several cell lines and studies their sequential cell volume response. We uncover that, in addition to the ion transport dominant cell volume regulation found in HT1080 and MDA-MB-231, there exists a mechanosensitive cell volume regulation system that combines both ion transport and actomyosin activity in NIH-3T3 and MCF-10A. In the latter cases, hypotonic stress triggers a 20% delayed volume increase over the timescale of 30 minutes following the initial volume regulatory recovery. We found that the delayed volume increase is initialized by Calcium influx through stretch-activated channel Piezo1, which induces actomyosin remodeling through Calmodulin. Rather than generating forces that directly contract cells, actomyosin regulates cell volume by activating Sodium-Hydrogen exchanger 1 (NHE1) through actin binding partner ezrin. Overall, our findings reveal the central role of Calcium and actomyosin mediated mechanosensation in regulating ion transportation and cell volume.

Trogocytosis in macrophages is governed by target membrane tension

C. E. Cornell, A. Chorlay, D. A. Fletcher; Bioengineering, University of California, Berkeley, Berkeley, CA.

Macrophages are immune cells responsible for detecting and eliminating pathogenic bacteria and viruses, as well as cancerous and apoptotic host cells. While macrophages will often completely engulf their target through phagocytosis, in a growing number of examples they are observed to 'nibble' fragments off their target instead. Do the physical properties of the target membrane play a role in determining whether a target is phagocytosed or 'nibbled', a process known as trogocytosis? To address this question, we developed an assay using cell-sized giant unilamellar vesicles (GUVs) with fluid membranes containing biotinylated lipids bound by anti-biotin IgG, which are recognized by macrophage Fcγ receptors and trigger the phagocytic machinery. For GUVs under high membrane tension, macrophage-like RAW 264.7 cells bind and can fully engulf them within a matter of minutes. However, when we reduce membrane tension via micropipette aspiration or osmotic shock, we find that these highly deformable GUVs are only partially engulfed, leading to the internalization of target fragments that resembles trogocytosis. High-resolution fluorescence microscopy shows that broad extension of the phagocytic cup around GUVs under high membrane tension is replaced by short phagocytic cup extensions and target membrane deformation in the case of low membrane tension GUVs. We propose a model in which mechanical feedback during extension of the phagocytic cup leads to premature constriction and scission of membrane fragments under low target membrane tension. In the case of high membrane tension, the phagocytic cup continues to grow and eventually seal around the target.

Focusing the Effort: Polarized cell adhesive recognition by Junctional Adhesion Molecule C orients granule neuron migration selectivity in a mouse model for cerebellar development

L. Hallada[1], D. Solecki[2]; [1]Developmental Neurobiology, St Jude Graduate School of Biomedical Sciences, MEMPHIS, TN, [2]Developmental Neurobiology, St. Jude Children's Research Hospital, Memphis, TN.

The laminar organization of the cerebellum is a result of intersecting mechanisms that regulate normal neural development and suppress disease. Cerebellar granule neuron (CGNs) coordinate differentiation, orientation, and migration to exit from their germinal zone in the external granule layer (EGL) via glial-guided migration. How CGNs encode the adhesive selectivity for the Bergmann glia substrate for migration has not been answered because it requires 1) identifying surface interactions that initiates this transition and 2) developing the techniques to study these cell-cell adhesions at sufficient resolution in the developing cerebellum. Previous work from the Solecki Lab showed that the intracellular partitioning defective (PAR) protein complex is responsible for the coordination of when and where the CGNs migrate by modulating morphological asymmetry, also known as cell polarity. In this research, the polarity-dependent junctional adhesion molecule (JAM)-C enabled us to develop a modular system of experimental models to live image cell-cell adhesions, manipulate the interfaces, and parse the composition of distinct surfaces in complex environments. We used single point mutants of JAM-C to show how the *cis* and *trans* interactions of JAM-C in CGNs cue glial-guided migration. Live-imaging neurons in *ex vivo* cerebellar slice cultures showed that JAM-C specificity in *cis* influences the proportion of cells transitioning to radial migration without fully inhibiting motility. While Fluorescent Recovery after Photobleaching of JAM-C adhesions showed that *cis* interactions distinguish JAM-C adhesions from

freely diffusing membrane, both *cis* and *trans* mutants reduced JAM-C to JAM adhesive recognition. Further live imaging studies showed that this JAM recognition regulates the actin during leading process extension and stabilization. Altogether these results suggest that JAM-C interactions constrict the architecture of the leading process in migrating CGNs to govern the timing of glial-guided migration based on the probabilistic efficiency of delimiting cytoskeletal dynamics.

B502/P1485

An investigation of how the physicochemical properties of membranes impacts septin association and assembly

B. Curtis[1], C. Edelmaier[2], A. Gladfelter[3]; [1]Department of Biochemistry and Biophysics, University North Carolina-Chapel Hill, Chapel Hill, NC, [2]Department of Applied Physical Science, University North Carolina-Chapel Hill, Chapel Hill, NC, [3]Department of Biology, University North Carolina-Chapel Hill, Chapel Hill, NC.

Throughout the lifecycle of most cells, they must be able to sense, generate, and react to changes in their shape. One such shape-defining structure is the cell membrane, which can be described in terms of its curvature over a range of nanometer to micrometer length scales. While nanometer-scale curvature sensors are well-documented in processes such as in endocytosis and cell trafficking, there are few known sensors of micrometer-scale curvature. Septins are filament-forming proteins necessary for cell processes involving major changes to cell shape, such as cytokinesis and polarized growth, and are intrinsically sensitive to micrometer-scale membrane curvature. Interestingly, they possess an amphipathic helix (AH) that is necessary and sufficient for septin curvature sensitivity but is structurally similar to AH domains specific to nanometer-scale curvature. How do these small helical domains give rise to micrometer curvature sensitivity? Previous work has shown that changes to lipid composition that alter lipid packing may mimic membrane curvature, and this may be especially relevant for septins which are capable of localizing to many different membrane geometries, both in vitro and in vivo. This work focuses on revealing the impact of lipid composition on septin association and assembly by changing the physicochemical properties of the membrane that may help septins “sense” curvature, such as the identity of the head group and the degree of lipid packing. Using a combination of molecular dynamics simulations and the membrane tension dye, FLIPT-R, we have assembled lipid compositions that span from loosely packed to tightly packed. We measure septin adsorption and observe septin assembly over time on these different compositions using in vitro reconstitution assays on supported lipid bilayers to assess how modulating membrane properties may alter septin assembly independently of curvature. As lipid packing becomes tighter, septin adsorption and assembly rates decrease, signifying both membrane geometry and lipid packing may be regulating spatio-specific localization of septins.

B503/P1486

Biophysical properties governing septin assembly

E. Vogt[1], I. Seim[1], B. Woods[1], J. Liu[2], G. McLaughlin[1], K. Cannon[1], A. Gladfelter[1]; [1]University of North Carolina At Chapel Hill, Chapel Hill, NC, [2]North Carolina School of Science and Mathematics, Durham, NC.

Across the biosphere, cells utilize nanometer-scaled proteins to form micron-scaled structures. Septins are a highly-conserved class of GTP-binding proteins that dynamically assemble into higher-order structures. These higher-order structures such as rings, lattices, and gauzes provide a scaffold for signaling molecules and other cytoskeletal elements and organizing cell membranes. How the geometry

of these septin assemblies is controlled by the cell remains open for intensive study. Marrying a filament polymerization reconstitution system with cell extracts utilizing yeast genetics, we begin to investigate how regulators tune biophysical processes necessary to build higher-order septin assemblies. Filaments polymerized from extracts were paired and their flexibility could be tuned by regulators. Septin assembly is a multi-step process involving septin interactions with the membrane and between septin proteins during filament polymerization. Whereas septin adsorption onto membranes is a cooperative process, multiple aspects of filament assembly on membranes are consistent with isodesmic filament polymerization. We parameterized a physical model of septin filament assembly on membranes, laying the groundwork for future investigations into how regulators control the assembly of higher-order septin structures.

B504/P1487

Dissection of a potentially ancient septin in the emerging model black fungus *Knufia petricola*

G. E. Hamilton, A. S. Gladfelter; Biology, University of North Carolina, Chapel Hill, NC.

Septins are filament-forming, GTP-binding cytoskeletal proteins. They self-assemble into diverse higher-order structures and sense micron-scale membrane curvature, two abilities that allows septins to function in processes including cytokinesis, membrane remodeling, scaffolding of signaling pathways, and cell polarity. Though conserved across eukaryotes (excepting land plants), septins are still relatively mysterious compared to other cytoskeletal polymers such as actin and microtubules. The best-characterized septins are the mitotic septins of budding yeast, founding members of four septin "Groups" of orthologous proteins that self-assemble into orthologous, palindromic hetero-oligomers Though the number of septin genes varies between organisms, likely due to gene duplication events, phylogenetic analysis indicates that nearly all septins studied to date fall into one of those four Groups. Another septin Group, however, is missing in unicellular yeasts, but present in the genomes of specific ciliates, diatoms, chlorophyte algae, brown algae, and filamentous fungi, suggesting that this "Group 5" septin-type is likely ancestral. To our knowledge, no Group 5 septin has ever been purified, nor characterized on the biophysical level.I identified a Group 5 septin in the genome of the emerging model black fungus *Knufia petricola*. I recombinantly expressed and purified this septin, dubbed KpAspE in recognition of its Aspergillus homolog. Remarkably, *in vitro*, KpAspE alone recapitulates many of the abilities of canonical septin heteromers. Gel filtration and mass photometry indicate that KpAspE forms homopolymers in a salt-dependent manner, much like canonical septins. Similarly, in a membrane curvature-sensing assay, KpAspE appears able to both bind supported lipid bilayers and discriminate between different degrees of positive membrane curvature- just as heteropolymeric septins do . Taken together, these results suggest that KpAspE homo-oligomers may replicate some of the most vital functions of core septin hetero-oligomers: forming micron-scale higher-order structures and sensing micron-scale membrane curvature. Current and future experiments are focused on potential KpAspE interactions with septins from Groups 1-4. If physical interactions exist, I will compare the functional consequences of KpAspE incorporation into homopolymers versus heteropolymers.Because septin genes are thought to have arisen from repeated gene duplication events, septin homo-oligomers may represent an ancestral state from which now-canonical septin hetero-oligomers evolved. Thus, Group 5 septins from non-model organisms- such as KpAspE- may offer us a window into the evolutionary history of septins.

B505/P1488

Deciphering the Role of RhoA and Cell Geometry in Septin Recruitment to the Actin Cortex

S. Chandrasekar, H. Wu, J. R. Beach, P. W. Oakes; Loyola University, Chicago, IL.

The cytoskeleton provides an architectural framework which cells use to generate and respond to physical forces. Historically, actin, microtubules and intermediate filaments have been the most well studied components of the cytoskeleton. More recently, septins have been recognized as a fourth important component of the cytoskeleton. These GTP-binding proteins not only localize to a subset of actin stress fibers, but also to regions that are thought to need mechanical reinforcement (e.g., base of cilia and blebs). In many of these regions there is also a concomitant enrichment of active RhoA (e.g. the cleavage furrow). This suggests septins could be playing a role in either altering or sensing local mechanical properties of the cytoskeleton. While the preferential localization of septins to micron-scale membrane curvatures has been previously shown, the mechanism by which septins are recruited to these structures and their specific contributions to the mechanosensitive properties of the cytoskeleton are yet to be explored. Here we test whether septins are recruited in response to RhoA activation, changes in cell geometry and mechanics, or a combination of these inputs. We find that global activation of RhoA is insufficient to spur additional septin polymerization in the cytoskeleton, but that RhoA inhibition leads to relocation of septins from stress fibers to the actin cortex/membrane. Interestingly, when cells migrate through microchannels featuring constrictions, septins accumulate along the cortex at the site of constriction. This suggests that septins relocate to sites of compression along the cortex. To test this further, future experiments will utilize an optogenetic RhoA probe to test how septins respond to locally induced contraction in both adherent and non-adherent cells. Together, these experiments will help reveal the mechanism(s) that govern septin localization and function in the cytoskeleton.

B506/P1489

ERM proteins respond to extracellular matrix mechanosensing

Z. Baster[1], A. Massey[2], A. X. Cartagena-Rivera[2], C. M. Waterman[1]; [1]National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, [2]National Institute of Biomedical Imaging and Bioengineering, NIH, Bethesda, MD

Cells sense the stiffness of their extracellular matrix (ECM) and respond by modulating their mechanical properties, behavior, or identity. Such mechanosensing behavior can be mediated by signaling pathways that alter cytoskeletal protein activity to change cell mechanics and behavior, or that effect transcriptional regulators to change gene expression. For example, when cells sense a stiff ECM, they stiffen their own surface and the transcriptional co-activator Yes-Associated Protein (YAP) translocates from the cytosol to the nucleus to affect gene expression. We sought to determine if these two responses were linked, and if so, how. Cell surface mechanics are well known to be regulated by proteins of the Ezrin, Radixin and Moesin (ERM) family, which bind to phosphatidylinositol 4,5-bisphosphate (PIP2) in the plasma membrane and to the cortical actin cytoskeleton. ERM proteins are activated by phosphorylation and recent evidence suggests that their expression can be regulated by YAP. We thus sought to explore whether ERM proteins were required for changes in cell surface mechanics in response to ECM mechanosensing, and if this was mediated by ERM phosphorylation or YAP-dependent changes in ERM expression.

To investigate this hypothesis, we plated U-2 OS cells on polyacrylamide substrates with elastic modulus of 4 kPa or 50 kPa, and on plastic or glass coated with fibronectin. We assessed ERM protein expression,

phosphorylation and distribution using molecular biology- and light microscopy-based techniques. We found that Ezrin protein abundance decreased with decreasing substrate stiffness. Interestingly, Moesin did not show this same dependence. Furthermore, with atomic force microscopy, we analyzed how these changes impacted biophysical parameters such as cell surface stiffness.
In our next step, using YAP knock-down and overexpression, and Ezrin knock-down systems, we plan to investigate the role of YAP signaling pathway in the observed changes. Moreover, we want to examine whether the lower abundance of ERM on in cells plated on soft substrates influence plasma membrane - actin cortex organization.
Our results show that the function of ERM proteins is regulated by the surrounding mechanical environment. Furthermore, the observed changes in Ezrin levels may be involved in regulation of cell surface biophysical properties in response to different matrix stiffness.

B507/P1490

Defining the structure and function of the multivalent protein network at cell-cell adherens junctions during *Drosophila* morphogenesis

A. Schmidt[1], D. Kong[2], T. Finegan[3], M. Peifer[1]; [1]University of North Carolina At Chapel Hill, Chapel Hill, NC, [2]Philipps-University Marburg, Marburg, Germany, [3]University of Rochester, Rochester, NY

Adherens junctions (AJs) mediate cell-cell adhesion, and through their linkage to the cytoskeleton, permit shape changes and rearrangements during *Drosophila* embryonic morphogenesis. AJs need to be strong yet also dynamic, allowing cell rearrangement without tissue rupture. We want to understand how proteins like the multi-domain scaffold Polychaetoid (Pyd; fly homolog of ZO-1), work together to allow AJs to react dynamically to cell shape change and force generation. We hypothesize that the junctional complex and its linkage to the cytoskeleton involves multivalent connections among multiple proteins, assembled into a structured molecular complex that mediates binding to the cytoskeleton. My goal is to explore Pyd's functional role as one player in this network. While Pyd is not absolutely essential for embryonic viability, mutants display defects in cell shape and AJ integrity during germband extension, suggesting defects in responding to elevated force on AJs. However, these occur without major tissue rupture, suggesting other proteins act in parallel. Tension-dependent enrichment of some AJ proteins is affected in *pyd* mutants. Both observations led to the hypothesis that AJs in *pyd* mutant embryos are under less tension- we confirmed this by laser cutting. We also hypothesize that AJs assemble as a structured and layered molecular complex, comparable to the structured focal adhesions connecting cells to the extracellular matrix. I used structured illumination microscopy (SIM) to explore localization of AJ proteins in high resolution. My data reveal that the core junction-associated proteins Canoe (Cno; fly homolog of Afadin) and Armadillo (Arm; fly homolog of β-Catenin) are differentially enriched in different AJ puncta along the zonula adherens. Furthermore, Pyd surrounds these core junctional proteins in a cloud-like pattern of strands and puncta. I will apply live imaging to understand if these clouds are formed by phase-separation, as ZO-1 is known to phase-separate. Strikingly, localization of Arm and Cno is not perturbed in *pyd* mutants. Together our data suggest that Pyd balances tension on AJs by acting in parallel with Cno to directly strengthen AJ-cytoskeleton connections to resist force perpendicular to the junction, and potentially by or by scaffolding and stabilizing AJ- and cytoskeleton associated proteins parallel to the junction.

B508/P1491

Planar Cell Polarity Dependent Organization of the Actin Cortex during Convergent Extension

V. Bejar-Padilla, C. Devitt, S. Weng, J. Alvarado, J. Wallingford, J. Stachowiak; University of Texas At Austin, Austin, TX.

Planar cell polarity (PCP) complexes are highly conserved macromolecular assemblies associated with the plasma membrane that confer directional polarity to cells along a specific axis. During vertebrate development, PCP coordinates proper elongation of tissues along the anteroposterior axis. It achieves this by enabling changes in cell shape and motility required for the collective cell behavior termed convergent extension. Accordingly, understanding how PCP regulates cytoskeletal mechanics is critical for understanding vertebrate tissue morphogenesis. To probe the role of PCP in regulation of the actin cytoskeleton, we disrupted PCP in the dorsal marginal zone tissue of *Xenopus laevis* embryos by knocking down expression of Vangl2 and Sept7. Using mRNA microinjection of a fluorescent actin probe in conjunction with TIRF microscopy, we visualized actin filaments in the anterior and posterior compartments of cells undergoing convergent extension. Actin filament dynamics were quantified using TSOAX, an automated image analysis program. Results showed that the persistence length of actin filaments, which reflects their bending stiffness, was enhanced in the anterior of the cell compared to the posterior. This subcellular mechanical polarization was not observed in Vangl2-KD and Sept7-KD cells, suggesting PCP is required to establish a subcellular stiffness gradient. To explore the relationship of PCP complexes and cortical actomyosin, we labeled PCP proteins using mRNA microinjection of fluorescent fusion proteins and dissociated the plasma membrane from the cell cortex using chemical vesiculation. Results showed that Vangl2 is retained in the plasma membrane following vesiculation. Interestingly, the cytoplasmic PCP protein Prickle2, which is recruited to the plasma membrane by Vangl2, does not colocalize with Vangl2 during vesiculation, suggesting that association of Vangl2 with the cell cortex is necessary for its interaction with Prickle2. These finding help clarify the poorly understood relationship between PCP and the actin cytoskeleton and highlight novel methods to probe this relationship.

Collective Chemotaxis and Directed Migration

B509/P1492

Migration of zebrafish epidermal T-cells in response to electrical signals after wounding

M. Sathe, C. K. Prinz, N. M. Belliveau, M. J. Footer, J. A. Theriot; Department of Biology, University of Washington/Howard Hughes Medical Institute, Seattle, WA.

Skin wound healing is a complex process that requires precise spatio-temporal coordination between multiple cell types (e.g. epithelial cells and leukocytes). Motivated by a desire to investigate leukocyte behaviour in a physiologically relevant environment, we developed an adult zebrafish scale explant system as a model skin tissue (‘skin-on-glass’). It retains several key features of animal skin, including the co-existence of multiple cell types (epithelial cells, mechanosensory cells, T-cells, neutrophils and macrophages) in a near-native organisation. The presence of T-cells in the ‘skin-on-glass’ explant system is particularly exciting since T-cells have not yet developed in the more easily studied embryonic and early larval stages of zebrafish development. After laser wounding, ‘skin-on-glass’ exhibits complex wound recovery features including extrusion of damaged cells from the wound and cell division in the nearby epidermis. Skin, in vivo, maintains a trans-epithelial potential (TEP) due to asymmetric ion flow.

Wounding disrupts the TEP and induces a lateral electric field (EF). EFs are such a strong migratory cue that an externally applied EF oriented in the opposite direction can even compel epithelial tissue to migrate away from an endogenous wound. In 'skin-on-glass' exposed to EFs, we observed the epithelial cells and neutrophils rapidly migrating towards the cathode (i.e. toward the wound), as expected based on previous reports. However, surprisingly, T-cells migrated towards the anode (i.e. away from the wound). Isolated primary T-cells also displayed directed migration toward the anode, indicating that this unusual directional response is a cell-intrinsic behaviour. This hypothesis is supported by preliminary data from the late larval stage, which demonstrates that T-cells in vivo migrate away from an epidermal wound, unlike neutrophils.

Physical limits on galvanotaxis

A. Kim, I. Nwogbaga, **B. Camley**; Johns Hopkins University, Baltimore, MD.

Eukaryotic cells of many types can polarize and migrate in response to electric fields via "galvanotaxis"; this ability helps skin cells heal wounds. Recent experimental evidence suggests galvanotaxis occurs because membrane proteins redistribute via electrophoresis, though the sensing species has not yet been conclusively identified. We want to understand how precisely eukaryotic cells can sense the direction of an electrical field. We use a physical model to show that randomness from the finite number of sensing proteins limits the accuracy of galvanotaxis via electrophoresis. Using maximum likelihood estimation, we show how cells can best interpret this noisy signal, and how their accuracy should depend on the cell size and electric field strength. Our model can be fit well to data measuring galvanotaxis of keratocytes, neural crest cells, and granulocytes. Our results show that eukaryotic cells can likely achieve experimentally observed directionalities with either a relatively small number (around 100) of proteins that are highly asymmetric in the electric field, or a large number (around 10,000) proteins with a relatively small change in concentration across the cell (~4% change from cathode to anode). This may explain why identifying the sensor species has been difficult, as candidates need not be strongly polarized even in large electric fields. A second prediction of the model is that the accuracy of cells should only weakly depend on their size.

Welcome to the Zellenstaat: learning the rules of collective cell behavior from microscopy data

J. LaChance[1], K. Suh[2], M. Heinrich[1], **D. J. Cohen**[3]; [1]Mechanical Engineering, Princeton University, Princeton, NJ, [2]Chemical and Biological Engineering, Princeton University, Princeton, NJ, [3]Princeton Bioengineering Institute; Mechanical Engineering, Princeton University, Princeton, NJ.

Groups of cells constitute communities whose complex behaviors, such as healing and development, emerge from myriad interactions amongst individual cells. Similarities between tissues and other communal structures were first recognized by Vichow (19th c.) who coined 'Zellenstaat' ('cell state'), writing that 'the body is a state and every cell a citizen.' This comparison was prescient, as data today increasingly emphasizes how complex collective cell dynamics are critical to multicellular life. Many of these behaviors are dynamic, and even a 'simple' transmitted light microscopy movie contains deep information about cellular behavior, health, and more. Extracting and interpreting collective data from large-scale timelapse movies is an exciting challenge and we have been combining tools from swarm dynamics, machine learning, and tissue engineering to explore these questions, with two examples

discussed here. At the cellular scale, we have built neural networks to convert transmitted light microscopy data into predicted fluorescence microscopy images for key biomarkers such as nuclei, cadherins, and cytoskeletal structures. Such augmented microscopy allows us to conduct massive timelapses with little-to-no phototoxicity needed to segment and track tens of thousands of cells in growing and healing epithelia. We then built 'Attention Networks' to predict for any given focal cell in a tissue which of its neighbors strongly influence how that cell will migrate. These attention heatmaps provide snapshots of the underlying rules of collective cell migration and can detect how these rules change over space and time within a tissue, across different cell types (e.g. healthy vs. metastatic), and in response to different drugs. At the tissue scale, we engineer and film the growth dynamics of arrays of large-scale epithelia as they grow and collide with each other. In addition to cellular-scale analyses, we also rely heavily on large-scale approaches from swarm theory where we use particle-image-velocimetry of transmitted light data to extract tissue flow dynamics and large-scale correlations well above the cellular scale. These methods are computationally efficient and broadly accessible, and we have coupled their outputs to biophysical continuum models to describe key collective rules governing how tissues grow, collide, and heal. Overall, our approaches are part of a growing body of tools developed by the broader collective behavior community to extract increasingly complex and, hopefully, interpretable data from collective behavior datasets

Physical and post-translational regulation of vinculin controls cellular coupling during collective cell migration

T. C. Shoyer, Jr., E. M. Gates, B. D. Hoffman; Biomedical Engineering, Duke University, Durham, NC.

The coordinated movement of groups of cells, termed collective cell migration (CCM), plays an important role in morphogenesis, tissue repair, and cancer metastasis. CCM is driven by mechanical forces between cells and with the substrate, which are mediated by specialized structures known as Adherens Junctions (AJs) and Focal Adhesions (FAs), respectively. Recent work indicates that frictional forces at these interfaces are major determinants of CCM, however, the molecular mechanisms regulating friction at these structures remain poorly understood. Here, we used a combination of tension- and conformation-sensitive biosensors, site-directed mutagenesis, CCM assays, and mechanochemical models to probe the relationship between mechanosensitive protein dynamics, friction, and cellular coupling. We focused on vinculin as it can participate in mechanical linkages at both FAs and AJs, is known to stabilize these adhesions under loads, and forms a strong catch bond with actin. We found that vinculin transmitted molecular forces at both the FAs and AJs of collectively migrating MDCK cells and that vinculin's conformation and loading were regulatable thru the S1033 phosphorylation site in this context. Vinculin expression and mechanical loading controlled the speed and coordination of CCM, which were also regulatable by the S1033 site. To understand this effect, we developed mathematical models of frictional forces at the FAs and AJs based on force-sensitive binding kinetics from the literature and interpreted them in the context of existing macroscopic models of CCM. Our models demonstrated increases in frictional forces at both FAs and AJs due to vinculin mechanical loading, which was consistent with the experimentally observed effects of vinculin on CCM. This work suggests a new control paradigm for CCM, where physical and biochemical regulation of vinculin connectivity within FAs and AJs regulates frictional forces to tune the speed and coordination of multicellular migration. Broadly, this work provides a framework to bridge molecular scale dynamics to

macroscopic physical parameters, connecting biological and mechanical descriptions of CCM across scales.

Cell junctional proteins are involved in straightforward directional movement and enhance cell migration in malignant gastric cancer cells

S. Kee, S. Kim, S. Park, H. Jang, Y. Park; Korea University, Seoul, KOREA, REPUBLIC OF.

Efficiency of cell migration is influenced by speed and directionality of cell movement. Here, we analyzed quantitatively cell movements by tracing individual cells in micropatterned free edge migration model using several malignant gastric cancer cells. MKN28 cells expressing high level E-cadherin with strong cell-cell adhesion showed lower migration speed than that of MKN1 cells which express low level of E-cadherin, but both cells showed similar cell migration accessed as colony expansion in our model system, suggesting that straightforward movement of MKN28 cells may be associated with efficient cell migration. Overexpression of E-cadherin in AGS (EC96) and MKN1 cells led to increase of ZO-1 expression and straightforward movement of cells, suggesting that establishment of cell junctions is important for directional cell movement. Subsequent knock-out experiments of ZO-1 reduced straightforward movement of both EC96 and MKN28 cells. Immunofluorescence analysis showed that tight junctions (TJs) of EC96 cells might play important roles in intracellular communication among boundary cells. ZO-1 is localized to the base of protruding lamellipodia and cell contact sites at the rear of cells, indicating that ZO-1 might be important for the interaction between traction and tensile forces. Overall, dynamic regulation of E-cadherin expression and localization by interaction with ZO-1 protein play a role directional movement of cells especially in a mode of collective cell migration.

Optimal collective durotaxis through E-cadherin adhesions

R. Sunyer[1,2], M.-E. Pallarés[3], I. Pi-Jaumà[1], I. Corina Fortunato[3], V. Grazú[4], M. Gómez-González[3], P. Roca-Cusachs[3], J. M de la Furente[4], R. Alert[5], J. Casademunt[1], X. Trepat[3]; [1]University of Barcelona, Barcelona, Spain, [2]Institute for Bioengineering of Catalonia, Sant Just Desvern, Spain, [3]Institute for Bioengineering of Catalonia, Barcelona, Spain, [4]Instituto de Nanociencia y Materiales de Aragón, Zaragoza, Spain, [5]Max Planck Institute for the Physics of Complex Systems, Dresden, Spain

The directed migration of cellular clusters enables morphogenesis, wound healing, and collective cancer invasion. Gradients of substrate stiffness are known to direct the migration of cellular clusters in a process called collective durotaxis, but underlying mechanisms remain unclear. Durotaxis has been mainly studied when mediated by focal adhesions at the extracellular matrix (ECM) interface. However, in ECM-depleted environments cells migrate through the cell-cell adhesion protein E-cadherin. Here we show that when cell adhesion is mediated by E-Cadherin, clusters of cancer cells dewet on soft substrates and wet on stiff ones. At intermediate stiffness, clusters on uniform-stiffness substrates become maximally motile, and clusters on stiffness gradients exhibit optimal durotaxis. Durotactic velocity increases with cluster size, stiffness gradient, and actomyosin activity. We first demonstrate this new migratory mode on substrates coated with E-cadherin and then establish its generality on substrates coated with extracellular matrix. We develop a physical model of three-dimensional active wetting that explains this mode of collective durotaxis in terms of a balance between in-plane active traction and tissue contractility, and out-of-plane surface tension. Finally, we show that the distribution

of cluster displacements has a heavy tail, with infrequent but large cellular hops that contribute to durotactic migration. Our study demonstrates a new physical mechanism of collective durotaxis, through both cell-cell and cell-substrate adhesion ligands, based on the wetting properties of active droplets.

Luteinizing hormone induces inward migration of granulosa cells in mouse preovulatory follicles

C. M. Owen, L. A. Jaffe; UConn Health Center, Farmington, CT

Mammalian preovulatory follicles respond to luteinizing hormone (LH) by initiating a cyclic AMP-dependent signaling cascade in the granulosa cells that surround the oocyte, resulting in ovulation. Among the complex of responses, LH is known to increase motility in isolated granulosa cells, but it is unknown whether LH causes cells to migrate within intact follicles. Here, we used mice with a hemagglutinin tag on the LH receptor (LHR) to investigate LH-induced changes in the localization of HA-LHR-expressing cells within intact follicles. Mice were injected with kisspeptin, which induces a surge-like release of LH that reaches a peak amplitude 90 minutes after injection. Ovaries were collected at 0, 2, 4, 6, 8, and 10 hours after injection, then fixed in 4% paraformaldehyde and frozen before cutting 10 µm cryosections. Immunofluorescence using an HA antibody was performed on the cryosections to observe the localization of HA-LHR-expressing cells. Before the LH surge, the LHR-expressing mural granulosa cells are localized almost entirely in the outer half of the mural granulosa region, in cells contacting the basal lamina. Within 30 minutes after the peak of the LH surge (or 2 hours after kisspeptin injection), the LHR-expressing cells begin to elongate into the inner mural granulosa layers and move farther away from the basal lamina. The proportion of LHR-expressing cell bodies in the inner half of the mural region continues to increase until ovulation. Accompanying the movement of the granulosa cells into the follicle interior, LH receptors are endocytosed from the plasma membrane into the cytoplasm, and the cells begin to detach from the basal lamina. At about 6 hours after the LH peak, the follicle undergoes a transient contraction, and at sites associated with patches of LHR-expressing cells, the basal lamina is pulled inwards. These findings suggest that the LH-induced inward migration of granulosa cells could contribute to the contraction of the follicle and breakdown of the basal lamina, which could in turn contribute to causing ovulation.

COPD Alters Bronchial Epithelial Wound Closure Dynamics*In vitro*

K. T. Wilmsen, C. Swaby, E. Parajon, A. Wally, V. K. Sidhaye[1]; Johns Hopkins University, Baltimore, MD

Chronic Obstructive Pulmonary Disease (COPD), a progressive and irreversible chronic disease of the lungs, can be characterized *in vitro* through structural and functional changes in cultured bronchial epithelial cells. Patient derived COPD cells exhibit reduced barrier function, partial EMT (p-EMT), reduced ciliation and ciliary function, and the induction of collective cellular motion within the epithelial sheet. Interestingly, the collective motion of COPD cells *in vitro* occurs under normal culture conditions in intact and undisturbed epithelial cells. To better understand the functional consequences of increased collective motion in COPD we are striving to understand the cellular processes that are driving the observed motion and if these changes impact migration dependent processes like wound closure. Scratch wound closure assays of Normal and COPD patient derived cells cultured at air-liquid interface (ALI) uncovered interesting differences in the cellular dynamics of wound closure. 15-hour timelapse

imaging of wound closure showed that COPD cells exhibit increased wound closure compared to Normal cells, however, measurements of cell movement speed were unchanged between the two groups. Additionally, normal cells had an approximately 2-hour delay prior to collective migration to close the scratch, compared to COPD cells, where a slight retraction of the wound edge could be observed. Along with these findings we have observed altered localization of the focal adhesion protein vinculin coupled with increased stress fiber formation in intact COPD cells, compared to normal cells, suggesting that the collective motion observed in COPD cells may be due to cellular reprogramming that primes COPD cells for migratory processes even in the absence of a wound edge. Further research is required to understand the gene and/or protein level changes leading to the observed COPD phenotype, and to better understand if COPD cells can resolve a wound and return to their previous steady state condition.

***Drosophila*NPAS4 negatively regulates JAK/STAT signaling to constraint the invasive cell population**

J. W. Wu[1], C. W. Wang[1], R. Y. Chen[1], L. Y. Hung[1], Y. C. Tasi[2], Y. T. Chan[1], Y. C. Chang[3], A. C. C. Jang[1]; [1]National Cheng Kung University, Tainan, Taiwan, [2]Tunghai University, Taichung, Taiwan, [3]National Sun Yat-sen University, Kaohsiung, Taiwan

Cell migration is a critical process for embryonic development and cancer metastasis, but the epithelial cells are selected and adapt to migratory cell fate remains elusive. To understand the underlying mechanism, we apply border cells (BCs), a small group of cells disseminating from the epithelium and migrating through germ cells in *Drosophila* oogenesis, as a model to study collective cell movement. In a forward genetic screen, we find that overexpression of *dysfusion* (*dysf*) severely impedes BC recruitment which is governed by Jak/Stat signaling. Conversely, loss of *dysf* led to extra migratory BCs. It is noteworthy that Dysf gain of function dramatically impairs the phosphorylation, transcriptional activity, and nuclear import of Stat protein. The ectopic BC phenotype caused by Jak or Upd overexpression can be suppressed by overexpression of UAS-*dysf*, indicating that *dysf* negatively regulates Jak/Stat signaling. Furthermore, Dysf protein is located at the nuclear membrane of all germline and follicle cells but specifically reduced in BCs upon migration. Moreover, when BCs reach their destination, oocyte their Dysf becomes undetectable. Further research showed that Notch is upstream of Dysf to regulate its downregulation. To elucidate how Dysf regulates Stat nuclear transport, we carried out a biochemical screen to seek proteins interacting with endogenous knock-in tagged Dysf. We found that Dysf gates Stat nuclear imports by interacting with Pendulin, a member of the Importin-alpha protein family, and that mammalian homologue of Dysfusion (Npas4) negatively regulates the Stat3 and cancer cell migration. Therefore, *dysf* may determine the size of border cell clusters by regulating Jak/Stat signaling.

Intermediate Filaments

B518/P1501

Gigaxonin is required for intermediate filament transport on microtubules

B. Renganathan, J. P. Zewe, Y. Cheng, M. Kittisopikul, P. Opal, K. M. Ridge, V. I. Gelfand; Northwestern University, Chicago, IL.

Giant axonal neuropathy, a neurodegenerative condition, causes disorganization of intermediate filaments (IFs) in multiple cell types, including neurons. Giant axonal neuropathy is caused by mutations in the *GAN* gene that encodes Gigaxonin, an E3 ligase substrate adaptor protein. Gigaxonin is required

for ubiquitination and subsequent degradation of IF proteins. Although IF disorganization is a hallmark of giant axonal neuropathy, the molecular mechanism behind IF aggregation remains unknown. We used IF proteins tagged with photoconvertible protein mEOS3.2 to study the role of Gigaxonin in the dynamics of IFs. We observed that the loss of gigaxonin halts transport of IFs along microtubules by kinesin-1. This transport inhibition was specific for IFs, as other types of kinesin-1 cargo moved normally after Gigaxonin loss. Thus, IF disorganization observed in *GAN* knock-out cells is caused by inhibition of kinesin-dependent IF transport. Interestingly, we observed a significant increase in the soluble form of vimentin with the loss of Gigaxonin protein. We hypothesize that soluble oligomers of IF protein sequester a yet unidentified adaptor that mediates IF-motor interactions, inhibiting IF transport along microtubules.

Alterations to the Keratin Composition of Progenitor Keratinocytes Drive Stem Cell Exhaustion and Premature Aging

C. Redmond[1,2], R. Q. Alvarado[1], B. Albedry[1], P. A. Coulombe[1,3]; [1]Cell and Developmental Biology, University of Michigan Medical School, Ann Arbor, Ann Arbor, MI, [2]Doctoral Program in Cancer Biology, University of Michigan Medical School, Ann Arbor, Ann Arbor, MI, [3]Dermatology, University of Michigan Medical School, Ann Arbor, Ann Arbor, MI.

Complex epithelia function as physical and chemical barriers in numerous organs and tissues across the body, including skin, eye (cornea), oral mucosa, and reproductive tract. Barrier function is maintained by carefully balancing the proliferation and differentiation of keratinocytes, the predominant cell type in complex epithelia, through the incompletely defined process of epithelial homeostasis. Common to all complex epithelia is the type I intermediate filament forming protein keratin 14 (K14). K14 and its type II co-assembly partner keratin 5 (K5) are highly expressed by progenitor keratinocytes, in which they provide essential mechanical integrity. Recent work in our laboratory has expanded on this mechanical function of K14 with the identification of a novel role for K14 in the regulation of epidermal homeostasis via the Hippo signaling pathway. Using the novel transgenic mouse model *Krt14*$^{C373A/C37A}$, a novel and differentiation-dependent signaling role was uncovered for a disulfide-bonded form of K14 through the cooperation of the scaffolding protein 14-3-3σ and the Hippo pathway effector YAP1. Here we build on this new finding through the characterization of *Krt14*$^{C373A/null}$ compound heterozygous mice. *Krt14*$^{C373A/null}$ mice possess 50% less K14 than WT or homozygous *Krt14*$^{C373A/C373A}$ animals, while maintaining expression of an additional progenitor type I keratin, keratin 15 (K15). *Krt14*$^{C373A/null}$ mice develop a unique aging phenotype in addition to exhibiting the intriguing molecular phenotype of *Krt14*$^{C373A/C37A}$ mice. We hypothesized that the increased contribution of K15 within the progenitor keratin network alters the sensitivity threshold for K14 disulfide-bonding in response to differentiation cues, including reactive oxygen species (ROS), which abnormally keeps progenitor keratinocytes in a pro-proliferative state. This pro-proliferative state results in both precocious development and premature exhaustion of these stem-like cells and aging of K14-expressing epithelia. Using morphological and molecular analyses, both in vivo and ex vivo, we are characterizing the aging phenotype of *Krt14*$^{C373A/null}$ mice and further defining the molecular mechanism enabling keratin intermediate filaments, ROS-catalyzed disulfide bonding, and the Hippo pathway to regulate homeostasis in complex surface epithelia.

B520/P1503

K14 and K15 Influence Airway Basal Cell Proliferative Capacity and Fate

V. Ievlev[1], T. J. Lynch[1], F. W. Kyle[2], C. B. Gries[2], A. Shah[1], A. C. Pai[2], B. A. Ahlers[3], S. Park[1], J. F. Engelhardt[1], K. R. Parekh[2]; [1]Anatomy and Cell Biology, University of Iowa, Iowa City, IA, [2]Surgery, University of Iowa, Iowa City, IA, [3]University of Iowa, Iowa City, IA.

Background: Airway basal cells (ABCs) are marked by expression of Keratin5 (K5) - an abundant cytoskeletal protein which can heterodimerize with Keratin14 (K14) or Keratin15 (K15) to make intermediate filaments. K15 is expressed in ABCs at homeostasis *in vivo,* while K14 turns on in the surface airway epithelium (SAE) during injury regeneration and in the disease setting. This altered basal cell state has been associated with a decline in stem cell function, but the causality of this trend as well as the functional differences between K14 and K15 have not been evaluated. **Methods:** In this study we used genetic knockout approaches in vitro and in vivo to study the functions of K14 and K15 in ABCs. We additionally present there a novel ex vivo ferret tracheal injury model that provides new insights into the mechanics of airway epithelial wound healing. **Results:** After evaluating the changes in basal keratin profile of cultured ABCs we conclude that it resembles that of regenerating ABCs in vivo, with enhanced K14 expression and reduced K15 expression after several passages. Knockout of K14 and K15 in primary ABCs leads to contrasting phenotypes: loss of K15 impairs colony formation efficiency, while the loss of K14 enhances it. Knockout of K14 also leads to re-activation of K15 expression in advanced-passage ABCs. We generated in vivo and in vitro knockout models of K14 and K15 and observed that loss of K14 (but not of K15) results in decreased abundance of club cells in mouse trachea and in vitro. Additionally, the nuclei of K14-KO ABCs appear enlarged and elongated during differentiation in vitro and produce fewer club cells. K14-KO cultures have reduced levels of tumor suppressor Sfn and increased oncogene p63 early in differentiation which can explain the observed phenotypes. K15-KO mice have fewer label retaining basal cells 21 days after injury potentially suggesting an importance of this keratin for stem cell maintenance. **Conclusions:** Airway repair and regeneration by basal progenitors happens in most lung and airway diseases that lead to injury to the airway epithelium, including Cystic Fibrosis. The mechanisms driving commitment of basal stem cells to regeneration are not completely understood. In this work we demonstrate that one such mechanism involves switching K15 for K14 which can affect structure, function and fate of basal progenitors. Overall, this work suggests that keratins may be actively involved in regulation of ABC behavior and fate decisions.

Expression of vimentin alters cell mechanics, cell-cell adhesion, and gene expression profiles suggesting the induction of a hybrid Epithelial to Mesenchymal Transition in human mammary epithelial cells

S. Sivagurunathan[1], A. Vahabikashi[1], H. Yang[2], J. Zhang[3], K. Vazquez[4], D. Rajasundaram[5], Y. Politanska[6], H. Abdala-Valencia[6], J. Notbohm[7], M. Guo[2], S. Adam[1], R. Goldman[1]; [1]Department of Cell and Developmental Biology, Feinberg School of Medicine, Northwestern University, Chicago, IL, [2]Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, [3]Biophysics program, Department of Engineering Physics, University of Wisconsin-Madison, Madison, WI, [4]Department of Engineering Physics, Department of Mechanical Engineering, University of Wisconsin-Madison, Madison, WI, [5]Department of Pediatrics, University of Pittsburgh School of Medicine, Pittsburgh, PA, [6]Department of Medicine, Feinberg School of Medicine, Northwestern University,

Chicago, IL, [7]Biophysics program, Department of Engineering Physics, Department of Mechanical Engineering, University of Wisconsin-Madison, Madison, WI.

Vimentin is a Type III intermediate filament (VIF) cytoskeletal protein that regulates the mechanical and migratory behavior of cells. Its expression is considered to be a marker for the epithelial to mesenchymal transition (EMT) that takes place in tumor metastasis. However, the molecular mechanisms regulated by the expression of vimentin in the EMT remain largely unexplored. We created MCF7 epithelial cell lines expressing vimentin from a cumate-inducible promoter to address this question. When vimentin expression was induced in these cells, extensive cytoplasmic VIF networks were assembled accompanied by changes in the organization of the endogenous keratin intermediate filament (KIF) networks and disruption of desmosomes. Significant reductions in intercellular forces by the cells expressing VIFs were measured by quantitative monolayer traction force and stress microscopy. In contrast, laser trapping micro-rheology revealed that the cytoplasm of MCF7 cells expressing VIFs was stiffer than the uninduced cells. Vimentin expression activated transcription of genes involved in pathways responsible for cell migration and locomotion. Importantly, the EMT related transcription factor *TWIST1* was upregulated only in WT vimentin expressing cells and not in cells expressing a mutant non-polymerized form of vimentin, which only formed unit length filaments (ULF). Taken together, our results suggest that vimentin expression induces a hybrid EMT correlated with the upregulation of genes involved in cell migration. **Keywords** - Vimentin, TWIST1, Desmoplakin, Hybrid/partial EMT, Intracellular mechanics, Intercellular forces, cell-cell adhesion.

Using Proximity Biotinylation to Investigate the Vimentin Interactome

K. Brock[1], K. Alpha[1], E. De Jong[2], G. Brennan[1], C. Turner[1]; [1]Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY, [2]Biochemistry and Molecular Biology, SUNY Upstate Medical University, Syracuse, NY.

The type III intermediate filament protein, vimentin, has been shown to be involved in a variety of cell processes including cell migration, focal adhesion dynamics, and maintenance of the mechanical integrity of a cell. Despite vimentin's role in these processes, there may potentially be novel interactors of vimentin that have yet to be identified. In an attempt to uncover more about vimentin's proximity interactome and identify possible candidates for further investigation, we utilized the BioID2 biotin ligase to label proteins in close proximity to vimentin. We developed stable lines of cells which express BioID2-tagged vimentin and confirmed that the construct localized to the vimentin filament network and was able to biotinylate proteins. We performed a pulldown of biotinylated proteins, followed by liquid chromatography - mass spectrometry to identify potential proximity interactors of vimentin. We further evaluated the potential proximity interactors identified in our mass spectrometry data using the CRAPome analysis pipeline, STRING analysis, and Gene Ontology. We found that the potential proximity interactors of vimentin were enriched for proteins that localize to exosomes, the extracellular space, focal adhesions, intracellular vesicles, and the cytoskeleton. Gene Ontology analysis of molecular function showed an enrichment for "cell adhesion molecule binding" and "cytoskeletal protein binding". This approach is a viable method for dissecting the vimentin interactome and yielded candidate proximity interactors for further investigation. Supported by NIH grant R35 GM131709 to CT. The mass spectrometry data was collected on an instrument purchased with NIH shared instrumentation grant 1S10OD023617-01A1.

Integrins and Cell-ECM Interactions

B524/P1506

Regulation of Cell Dynamics by Rapid Transport of Integrins Through the Biosynthetic Pathway

M. Lerche[1,2], M. Mathieu[1,2], L. Malerød[3,4], N. Pedersen[3,4], H. Hamidi[1,2], M. Chastney[1,2], B. Bruininks[5], S. Kaptan[5], G. Jacquemet[1,6,7], I. Vattulainen[5], P. Roca-Cusachs[8,9], A. Cells sense and respond to the extracellular matrix (ECM) milieu through integrin proteins. Integrin availability on the plasma membrane, regulated by endosomal receptor uptake and recycling, has been extensively studied and regulates cell dynamics in various normal and pathological contexts. In contrast, the role of integrin transport through the biosynthetic pathway has been considered primarily as a mechanism to replenish the receptor pool and too slow to influence cell dynamics. Here, we adopted the RUSH (Retention Using Selective Hooks) assay to synchronize integrin anterograde transport from the endoplasmic reticulum (ER), allowing spatial and temporal analysis of newly synthesized receptor traffic. We observe that the delivery of new integrins to the plasma membrane is polarized in response to specific ECM ligands, facilitates integrin recruitment specifically to the membrane-proximal tip of focal adhesions (FA) and contributes to cell protrusion and FA growth. We explain the augmented adhesion growth using a computational molecular clutch model, where increased integrin availability drives recruitment of additional integrins. Notably, a subset of newly synthesized integrins undergo rapid traffic from the ER to the cell surface to facilitate localized cell spreading, seemingly bypassing the Golgi. This unconventional secretion is dependent on cell adhesion and mediated by Golgi reassembling stacking proteins (GRASPs) association with the PDZ-binding motif in the integrin α5 cytoplasmic tail. This spatially targeted delivery of integrins through the biosynthetic pathway may propel cell dynamics by rapidly altering adhesion receptor availability, providing cells with an additional degree of plasticity to respond to their environment.

Fibronectin Fibrillogenesis Is Mediated by Autocrine TGF-β1-dependent Secretion of Soluble Fibronectin

M. Sofroniou, 1st, C. Lemmon; Biomedical Engineering, Virginia Commonwealth University, Richmond, VA.

Epithelial-Mesenchymal Transition (EMT) is a cellular transdifferentiation program in which epithelial cells transform into a mesenchymal-like phenotype. Transforming growth factor - beta 1 (TGF-β1) is a potent inducer of EMT, secreted from two distinct sources: 1) Exogenous TGF-β1 originating from neighboring cells, which is upregulated during wound healing, fibrosis and cancer and 2) Autocrine TGF-

β1 which is constitutively expressed at low levels but is upregulated in response to exogenous TGF-β1. A key process of EMT is the assembly of fibronectin (FN) into insoluble fibrils, which are the primary component of the provisional extracellular matrix (ECM). While it is well characterized that exogenous TGF-β1 is required for FN fibrillogenesis, we sought to investigate whether autocrine TGF-β1 plays a role in this process. The objective of this study is to determine the effects of autocrine TGF-β1 signaling on the deposition and assembly of FN fibrils in the context of EMT. To accomplish this, the *TGFB1* gene was deleted in both benign and malignant human breast cells using CRISPR-Cas9. We compared the ability of wild-type (WT) and *TGFB1* knockout (KO) cells to secrete and assemble FN in response to exogenous TGF-β1 and explored possible mechanisms behind alterations in FN deposition. FN expression, secretion, and assembly were assayed using RT-qPCR, ELISAs and immunofluorescence (IF) imaging. EMT markers and relevant signaling pathway components were also assayed.
In both benign and malignant cells, the deletion of the *TGFB1* gene led to a decrease in both the secretion of soluble FN and the assembly of FN fibrils. Interestingly impaired FN assembly occurs at the level of gene expression benign cells, but not in malignant cells. Instead, malignant KO cells upregulate FN comparably to the WT, but still appear to have a deficiency in FN secretion. Deletion of the *TGFB1* gene led to a general downregulation of mesenchymal markers and upregulation of epithelial markers. Data also revealed that *TGFB1*-KO cells express less of the *CDC42* gene and the active form of the Cdc42 enzyme. Cdc42 activity has been previously shown to regulate the secretion and deposition of ECM components, pointing to a potential explanation for the observed deficiency in FN secretion. These results demonstrate that autocrine TGF-β1 maintains a key role in regulating both the secretion and assembly of FN.

Epithelial adherens junctions regulate ECM remodeling via miRNAs

A. Daulagala[1], C. Bridges[1], J. Nair-Menon[1], D. Jiminez[1], A. Bradshaw[2], J. Jones[3], A. Kourtidis[1];
[1]Department of Regenerative Medicine and Cell Biology, Medical University South Carolina, Charleston, SC, [2]Division of Cardiology, Collage of Medicine, Medical University South Carolina, Charleston, SC, [3]Deparment of Surgery, Collage of Medicine, Medical University South Carolina, Charleston, SC.

Colon cancer is the third most common and second deadliest type of cancer. Colon cancer ischaracterized by compromised epithelial integrity and by aberrant extracellular matrix (ECM)remodeling. However, a possible connection between epithelial integrity and ECM remodelingthat contributes to the disease progression, has not been explored. The Adherens Junctions (AJs)is a cell-cell adhesion complex composed of cadherin and catenin family proteins and is essentialfor maintaining epithelial tissue integrity. We have found that the p120 catenin partner PLEKHA7is critical for epithelial integrity, and is responsible for recruiting core components of the RNAimachinery at mature apical AJs to regulate miRNA levels and activity. Loss of PLEKHA7 results indisruption of junctional localization of the RNAi machinery, miRNA dysregulation, oncogeneupregulation, and pro-tumorigenic colon cell behavior, in vitro and in vivo. Interestingly, MEP1A,MMP1, MMP9, LOX and CDX2, all of which are ECM remodeling markers, were among the topupregulated mRNAs in PLEKHA7 depleted colon epithelial Caco2 cells according to whole cell RNAsequencing results. We confirmed increased protein expression of these markers upon PLEKHA7depletion by western blot analysis. Bioinformatic analysis identified several PLEKHA7-regulatedmiRNAs as potentially targeting the above ECM-related mRNAs; among them, miR-24 and miR-30c indeed rescued the increased protein expression of aforementioned markers as confirmedby western blot results. Further, MMP1 and LOX enzyme activities as well as migration

andinvasion rates of cells increasedupon PLEKHA7 depletion and were rescued upon MMP inhibition.Moreover, preliminary examination of colon tissues from a PLEKHA7 knockout mouse modelshows increased collagen deposition which corroborates roles of MMPs and LOX in ECMremodeling upon PLEKHA7 loss. In summary, our data reveal anovel mechanism, through whichepithelial adherens junctions regulate ECM remodeling through miRNA activity, to suppress pro-tumorigenic cell behavior.

B527/P1509

Regulation of aVb6 integrin to facilitate TGFb1 activation

M. Bachmann, J. Kessler, B. Wehrle-Haller; Cell Physiology and Metabolism, Centre Medical Universitaire, Geneva, SWITZERLAND.

Integrin aVb6 activates the transforming growth factor beta 1 (TGFb1) cytokine by binding to, and mechanically pulling on, the prodomain of TGFb1 (called latency-associated peptide 1, LAP1). The signaling of TGFb1 is important for cell proliferation and differentiation, but also for protection of cancer cells from chemotherapy and for supporting invasiveness. The affinity of aVb6 integrin for LAP1 is unusually high supporting sustained, strong mechanical pull needed for activation of TGFb1. Here we asked whether this extracellular adaptation is accompanied by cytoplasmic adaptations of aVb6 integrin that allow force transmission via the actin-integrin-LAP1 axis. We developed new tools to study cell-LAP1 interaction with a variety of cell biological techniques. This allowed us to test the relevance of the intact actin cytoskeleton as well as different integrin adapters, in particular activators talin and kindlin and signaling scaffold paxillin, for LAP1 binding and TGFb1 activation. We show that dynamic cytoplasmic adapter recruitment to b6 integrin allows regulation of LAP1 binding and eventually TGFb1 activation. Given the excess amount of latent TGFb1 stored in the extracellular environment, it is crucial for cells to tightly regulate TGFb1 activation by cells. Our data highlights how regulation of aVb6 integrin activation, its stability in adhesions, and its connection to actin is involved in this important aspect of TGFb1 biology.

Heterogeneous Expression of Alternatively Spliced lncRNA mediates Vascular Smooth Cell Plasticity

J. Mayner[1], E. Masutani[2], E. Demeester[3], A. Kumar[1], P. Beri[1], V. Lo Sardo[4], G. Macapugay[5], A. J. Engler[1]; [1]Bioengineering, UCSD, La Jolla, CA, [2]Bioengineering, UCSD, San Diego, CA, [3]UCSD, La Jolla, CA, [4]University of Wisconsin Madison, Madison, WI, [5]University of Wisconsin Madison, Madison, CA.

9p21 locus polymorphisms have the strongest correlation with coronary artery disease, but as a non-coding locus, disease connection is enigmatic. Vascular smooth muscle cell (VSMC) phenotype may be regulated by lncRNA ANRIL found in 9p21. We observed significant variability in induced pluripotent stem cell-derived VSMCs from patients homozygous for risk (RR) versus isogenic knockout (RR KO) or non-risk (NN) haplotypes. Sub-populations of risk haplotype cells exhibited variable morphology, proliferation, contraction, and adhesion. When sorted by adhesion using a microfluidic device, VSMCs parsed into synthetic and contractile sub-populations, i.e., weakly adherent (WA) and strongly adherent (SA), respectively. RNA-seq revealed >2000 differentially expressed genes, and of those also sorted by haplotype, >90% were co-regulated and associated with Rho GTPases, i.e., contractility. WA sub-populations expressed more of ANRIL's short isoforms, and when overexpressed in knockout cells,

ANRIL suppressed adhesion, contractility, and αSMA expression. These data are the first to suggest that variable lncRNA penetrance may drive mixed functional outcomes that confounds pathology.

The *cis* association of CD47 with integrin Mac-1 regulates macrophage responses by stabilizing the extended integrin conformation

N. Podolnikova, S. Key, X. Wang, T. P. Ugarova; ASU, Tempe, AZ.

CD47 is a ubiquitously expressed cell surface integrin-associated protein. Recently, we have demonstrated that integrin Mac-1 ($\alpha_M\beta_2$, CD11b/CD18, CR3), the major adhesion receptor on the surface of myeloid cells, can be coprecipitated with CD47. However, the molecular basis for the CD47-Mac-1 interaction and its functional consequences remain unclear. Here, we demonstrated that CD47 regulates macrophage functions by directly interacting with Mac-1. In particular, adhesion of macrophages isolated from $CD47^{-/-}$ mice to fibrinogen and ICAM-1, the established physiological ligands of Mac-1, was significantly decreased compared to wild-type counterparts. Also, spreading of CD47-deficient macrophages was reduced by four- and two-fold on fibrinogen and ICAM-1, respectively. Compared to wild-type macrophages, migration of CD47-deficient macrophages was significantly decreased. The lack of CD47 on the surface of macrophages impaired their ability to fuse in the presence of IL-4. Finally, the deficiency of CD47 also reduced phagocytosis of opsonized beads, a process entirely dependent on Mac-1. The functional link between CD47 and Mac-1 was validated by co-immunoprecipitation analysis using various cultured and natural Mac-1-expressing cells. In HEK293 cells expressing individual α_M and β_2 integrin subunits, CD47 has been found to bind both subunits. Interestingly, the amount of CD47 recovered with the free β_2 subunit, which on the surface of these cells exists in the extended conformation, was higher than in complex with the whole integrin. Furthermore, activating Mac-1-expressing HEK293 cells with PMA, Mn^{2+}, and mAb MEM48 increased CD47 in complex with Mac-1, suggesting that CD47 has a greater affinity for integrin in the extended conformation. Notably, on the surface of cells lacking CD47, fewer Mac-1 molecules could convert into an extended conformation in response to Mn^{2+} treatment. The binding site in CD47 for Mac-1 was identified in its constituent IgV domain. The complementary binding sites for CD47 in Mac-1 were localized in the integrin epidermal growth factor-like domains 3 and 4 of the β_2 subunit and calf-1 and calf-2 domains of the α subunit. These results indicate that Mac-1 forms a lateral complex with CD47, which regulates essential macrophage functions by stabilizing the extended integrin conformation.

B530/P1512

Myosin 10 at the tips of filopodia-derived retraction fibers supports adhesion during mitosis when conventional focal adhesions disassemble

J. Hammer[1], A. T. Pedrosa[1], Y. Yim[1], X. Wu[1], L. Boley[1], R. Cheney[2]; [1]Cell and Developmental Biology Center, National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, [2]Cell Biology, University of North Carolina Chapel Hill, Chapel Hill, NC.

Historically, adhesion during mitosis for cells grown in 2D has been attributed to retraction fibers (RFs), which are thought to arise from a combination of the cell rounding that occurs upon mitotic entry and the persistence of interphase focal adhesions (FAs). A recent study showed, however, that Talin, the main clutch component connecting actin to integrin, largely disappears from sites of adhesion in mitotic cells (Dix et al Dev Cell 2018). What then connects actin to integrin during mitosis? Here we show that

endogenously tagged Myo10, an integrin-binding MyTH4/FERM domain myosin commonly referred to as the “filopodial myosin”, localizes together with active integrin and IRM signals along the shaft and at the tips of metaphase RFs. Consistent with the results of Dix et al, and with the idea that RFs are in fact filopodia, time lapse imaging shows that Talin-rich FAs at the cell perimeter vanish upon mitotic entry while pre-existing, Myo10-positive, interphase filopodia persist, such that ~95% of them become RFs. In support of this, metaphase RFs stain for the filopodial crosslinker fascin and the filopodial tip marker VASP, and endogenous Myo10 moves out RFs at 0.7 um/s, consistent with the bundled, barbed end-out organization of actin found within filopodia. These results, together with the fact that fluorescence intensity measurements within the TIRF field as proxies for adhesion support show that Myo10 increases and Talin decreases between mitotic entry and metaphase, suggest that Myo10 at the tips of filopodia-derived RFs is replacing Talin as the main clutch component connecting actin to integrins during mitosis. Consistent with this idea, measurements of RF failure frequency and the content of active integrin within RFs indicate that adhesion is attenuated in dividing cells lacking Myo10. Moreover, these defects are rescued by WT Myo10 but not by a version that cannot bind integrin. Together, these data reveal a self-organizing property of mitotic RFs: their ability to support adhesion during mitosis is hardwired by the fact that they pre-exist as Myo10-dependent adhesive filopodia, and their barbed end-out organization licenses Myo10-dependent adhesion reinforcement during mitosis.

B531/P1513

Early phases of αV-class integrin adhesion to vitronectin under mechanical load are β-subunit-dependent

U. Sharma[1], J. Reber[2], N. Strohmeyer[1], R. Faessler[2], D. J. Mueller[1]; [1]Department of Biosystems Science and Engineering, ETH Zuerich, Basel, SWITZERLAND, [2]Department of Molecular Medicine, Max Planck Institute for Biochemistry, Martinsried, GERMANY.

αV-class integrins have been implicated in several cellular paradigms ranging from fat and bone biogenesis, angiogenesis to tumor metastasis and poor prognosis of several cancers. Given the recent efforts to develop αV-class targeting pharmacophores, delivery strategies and biomarker research, most studies do not focus on the aspect that integrins encounter varying magnitudes of extra- and intra-cellular forces during early steps of adhesion. We employ single cell force spectroscopy (SCFS) to quantify early stages (~120s) of adhesion strengthening and observe a non-monotonic behavior for αV-class integrins on vitronectin (VN) but not on fibronectin (FN), under varying mechanical load. A similar response has earlier been reported for α5β1 integrins where the catch bond behavior of α5β1 integrins is consolidated due to a crosstalk with αV-class integrins upon FN binding. Interestingly, in case of vitronectin bound αV-class integrins, we find a non-monotonic response to increasing loading rate that is β-subunit-dependent. This subunit dependence is correlated to a differential contributions from signaling molecules, like - Arp2/3 complex, Src kinase and Phosphatidylinositol 3-kinase. Our work further enquires whether the integrin heterodimers synergize or antagonize during early phases of VN binding under mechanical load and explores if this depends on their commitment to different intracellular signaling pathways.

Control of Fibrotic Gene Expression in Cardiac Fibroblasts via the Rap1 GTPase

M. R. McLeod[1], J. G. Heywood[2], W. J. Richardson[2], A. D. Dubash[1]; [1]Biology, Furman University, Greenville, SC, [2]Bioengineering, Clemson University, Clemson, SC.

Fibrosis describes the excessive deposition of extracellular matrix components by cardiac myofibroblasts (CFs), a process which frequently promotes the adverse effects of pathological conditions damaging cardiac muscle, such as myocardial infarction and arrhythmogenic cardiomyopathy. Roughly 1 million Americans suffer a myocardial infarction each year, after which necrotic cardiac myocytes (CMs) are replaced by CF-derived extracellular matrix (ECM), in response to (a) biochemical signaling cues from necrotic CMs and (b) mechanical cues from the contracting myocardium and ventricle cavity pressure. Accumulation of ECM proteins (such as collagen) within the infarct scar is initially critical to prevent further tissue damage, but chronic and excessive collagen deposition is detrimental to regeneration of CMs and healing of the myocardium. While the physiological outcomes of cardiac fibrosis are well studied, the biochemical and mechano-responsive signaling mechanisms which regulate fibrotic gene expression remain poorly investigated. The GTPase Rap1 is very well-known to mediate both inside-out and outside-in signaling via attachment of integrins to ECM proteins, but less is known about its role in fibrotic gene expression. In our study, we show that expression of constitutively active (63E) Rap1A in cardiac fibroblasts results in a dramatic decrease in myofibroblast activation, measured via mRNA levels of smooth muscle alpha-actin (ACTA2). Further, Rap1A(63E) also inhibits expression of many different ECM proteins (COL1A1, COL3A1, COL4A1 and FN1), as well as other markers of fibrotic gene expression (CTGF and EGR1). In contrast, Rap1A(63E) increases the expression of matrix remodeling enzymes (such as MMP3 and MMP9) which have been shown to play a role in increasing collagen turnover, reducing ECM rigidity/stiffness and repair of damaged myocardial tissue. Moreover, we provide evidence that Rap1A(63E)-driven MMP expression is a consequence of elevated TNF-alpha/NF-kB signaling. Altogether, these data point to a significant role for Rap1A GTPase in reducing fibrotic gene expression and myofibroblast activation and suggest possible new therapeutic strategies to combat the damaging effects of cardiac fibrosis.

Invasively distinct subpopulations cooperate via a laminin-332/Rac1 axis in triple-negative breast cancer

S. Yoon[1], J. K. Mouw[1], L. Chen[2], H. Wu[2], A. I. Marcus[1]; [1]Hematology and Medical Oncology, Emory University, Atlanta, GA, [2]Department of Biostatistics and Bioinformatics, Emory University, Atlanta, GA.

Intratumoral heterogeneity poses a significant hurdle for cancer treatment, yet is under-characterized in the context of tumor invasion. Cancer cells from solid tumors can invade through two predominant modes: collective invasion, whereby cancer cells invade in multi-cellular packs or streams marked by intact cell-cell junctions; and single-cell invasion, whereby cells invade independently without intercellular adhesion. We have observed that collective and single-cell invasion co-occur within the same tumor microenvironment in triple-negative breast cancer, suggesting that invasive heterogeneity supports cooperative behavior between tumor subpopulations. To test this, we used a novel, published technique developed by the lab (SaGA) to isolate pure subpopulations of 4T1 cells that collectively invade (collectives) or single cells that invade alone (singles). 3-D spheroids of SaGA-purified collectives and singles exhibited almost exclusively collective and single-cell invasion, respectively, and these

invasive phenotypes were retained over multiple passages. Integration of RNA sequencing and methylation array data obtained from RNA and DNA isolates, respectively, of collectives and singles revealed that collectives exhibit drastic overexpression and promoter hypomethylation of two laminin genes that form the laminin-332 complex, *Lama3* and *Lamc2*. Additionally, an unbiased proteomic analysis of secreted proteins also revealed an overabundance of these laminins in collectives media. We found that singles have increased expression of integrin α6 and β4, which together have been found to specifically bind to laminin-332 to activate the Rac1 GTPase. Interestingly, our RNA sequencing data revealed a binary overexpression of a Rac1 GTPase, *Prex1* in singles, suggesting that singles have enhanced Rac1 activation when compared to collectives with the potential for hyperactivation upon laminin-332 binding. Indeed, laminin-332 resulted in higher GTP-bound Rac1 in singles and subsequently increased invasion of singles in 3-D models. Additionally, laminin-332 induced cell elongation at the leading edge of singles spheroids, which was reversable by treatment with a Rac1 inhibitor. Together, our data suggests that distinct subpopulations amidst a heterogeneous tumor cooperate via laminin-332 and Rac1 to facilitate tumor invasion in metastatic triple-negative breast cancer.

B534/P1516

CRP3 ABSENCE IMPAIRS FOCAL ADHESION SIGNALING AND AORTIC SMOOTH MUSCLE CELL CONTRACTION

J. Ribeiro-Silva[1,2], M. H. Fonseca-Alaniz[2], J. E. Krieger[2], A. A. Miyakawa[2]; [1]SUNY Upstate Medical University, Syracuse, NY, [2]University of Sao Paulo (USP) Medical School, Sao Paulo, Brazil

We have previously demonstrated that Cysteine and glycine-rich protein 3 (CRP3) is a mechanosensor regulating focal adhesion kinase (FAK) activation in stretched vascular smooth muscle cells (SMCs). Here, we tested the hypothesis that CRP3 is critical for aortic SMCs mechanotransduction by modulating focal adhesion (FA) signaling. Under basal conditions, $Crp3^{-/-}$ SMCs display greater FA size, increased spreading and type I collagen secretion when compared to wild type (WT) SMCs. Upon stimulation with angiotensin II (Ang II), WT SMCs increase Y397-FAK, Y118-Paxillin and Y165-p130CAS phosphorylation, an event associated with FA growth, increased cell stiffness and collagen gel contraction. In contrast, $Crp3^{-/-}$ SMCs display neither changes in FAK-Paxillin-p130CAS phosphorylation, nor FA growth and collagen contraction, despite the greater increase in cell stiffness upon Ang II stimulation compared to WT SMCs. Analysis of MLC phosphorylation, F/G-actin ratio, cofilin phosphorylation, YAP levels and MRTF-dependent SMC gene expression showed no difference between WT and $CRP3^{-/-}$ SMCs, suggesting that CRP3 absence affects FA signaling but not the actomyosin apparatus. In agreement with this theory, PDGF-BB-dependent chemotaxis was blunted in $CRP3^{-/-}$SMCs, consistent with a deficiency in FAK signaling. FAK inhibition partially recapitulates the $CRP3^{-/-}$contraction in WT SMCs, but not cell stiffness, demonstrating that FAK signaling deficiency is responsible for the reduced contraction but not for the increased stiffness of $CRP3^{-/-}$ SMCs. CRP3 protein structure analysis evidenced the presence of two phosphorylatable tyrosines (Y57 and Y167), responsive to Ang II in cardiac cells, which may explain the dependence of CRP3 for FAK activation and contraction. In summary, we demonstrated that CRP3 is required to FAK-paxillin-p130CAS activation, a necessary and sufficient signaling for migration and contractility. In the absence of CRP3, downstream mechanosignaling is compromised, leading to deficient vascular mechanotransduction. Collectively, these evidences demonstrate that CRP3 influences FA signaling mechanisms, thus impacting SMC mechanotransduction.

B535/P1517

Integrin inactivation as a mitotic check-point

M. Lerche[1], C. M. Waterman[1], H. R. Thiam[2]; [1]NIH/NHLBI, Bethesda, MD, [2]Stanford, Stanford, CA

Focal adhesions (FAs) link the intracellular actin cytoskeleton to the extracellular matrix (ECM) via transmembrane integrin receptors and a complex network of cytoplasmic proteins. In addition to providing cells with attachment to their environment, FAs regulate cell behaviors including migration and proliferation, and are therefore assembled and disassembled in a highly regulated manner. One important process during which FAs are coordinately disassembled is cell division that occurs during M phase of the cell cycle. During mitosis, cell de-adhesion allows flat spread or columnar cells to round up, creating a radially symmetric space for mitotic spindle assembly and the equal capture and segregation of chromosomes to prevent aneuploidy. As cell division mediates growth and homeostasis of organisms, progression through each phase of the cell cycle is monitored by checkpoints that ensure completion of one phase before entry into the next. This is driven and regulated by phosphorylation of so-called checkpoint proteins by cyclin dependent kinases (CDKs) or their downstream effectors. We have found previously (Thiam et al, unpublished) that cells disassemble FAs during early prophase, and this process is dependent on phosphorylation by CDK1 in the intrinsically disordered region of the FA protein tensin 1. In addition, we found that locking integrins in their active conformation blocks FA disassembly and prevents cells from undergoing mitosis. Although high integrin activity prevents FA disassembly and mitosis, the mechanism of integrin inactivation is unknown. Here we propose that integrin inactivation, mediated by dissociation of an integrin activator or association of an activity preventer, is a novel and previously unappreciated mitotic cell cycle check-point. Our preliminary results shows that the integrin inactivators SHANK 3 and SHARPIN, undergo an electrophoretic mobility shift and an increase in expression level respectively, after exit from G2 phase of the cell cycle and entry into M phase. These results provide important initial support of the notion that integrin inactivators are regulated by mitotic kinases as cells enter mitosis, and suggests that this regulation may mediate FA disassembly, cell rounding, and progression through the cell cycle.

B536/P1518

Integrin activation and deposition of extracellular matrix are stimulated and spatially guided by adherens junctions

R. Hadjisavva[1], O. Anastasiou[1], P. Ioannou[2], M. Zheltkova[1], P. Skourides[1]; [1]University of Cyprus, Nicosia, Cyprus, [2]Department of Biochemistry, University of Cambridge, Cambridge, United Kingdom

Integrins and cadherins have a major role in the mechanical integrity and organization of the tissues. Adherens junctions (AJs) and focal adhesions (FAs) are intrinsically linked through the actin cytoskeleton and they mechanically interact, while the crosstalk between the two adhesion systems is crucial during embryonic development and in the adult organism. With the use of artificial cadherin glass substrates, we show that cadherin clustering can stimulate and spatially guide integrin activation, which takes place in the absence of extracellular matrix ligands. The locally generated tension at adherens junctions creates a pool of primed integrin clusters, in the extended with closed headpiece conformation, which consequently determine where FAs will be formed if ligands are present, and where ligands will be deposited when available in soluble form. Integrin activation at AJs promotes the targeting of the microtubules, which facilitate their disassembly via caveolin-based endocytosis, impacting the stability of the cadherin complex. Thus, we show that the interplay between integrins and cadherins is more

intimate than described, rooting in the capacity of integrins to become activated and stabilized by AJ-generated tension. Altogether, our data suggest a cross-regulation mechanism between cadherins and integrins.

B537/P1519

Mitotic cell responses to substrate topological cues are independent of the molecular nature of adhesion

O. Anastasiou, R. Hadjisavva, **A. Christodoulou**, P. A. Skourides; University of Cyprus, Nicosia, Cyprus

Mitotic spindle orientation is essential for a broad spectrum of processes in multicellular organisms, including cell fate decisions, tissue morphogenesis and homeostasis. Integrins and cadherins, which mediate interactions with the extracellular matrix (ECM) and between cells respectively, are implicated in the determination of spindle orientation. Here, we showed that both cadherin- and integrin-based adhesion resulted in cell divisions parallel to the attachment plane and elicited identical spindle responses to spatial adhesive cues. In addition, the use of micro patterned FN and N-cadherin Fc substrates showed that spindle orientation regulation within the plane of attachment is independent of the molecular nature of adhesion. This suggests that mechanical cues provided by adhesion topology can guide spindle orientation, independently of the molecular link or signaling from the adhesive complexes. We also demonstrated that cortical integrin activation was essential for correct spindle orientation on both cadherin and fibronectin substrates. These data suggest that spindle orientation responses to adhesion topology are primarily a result of force anisotropy on the cell cortex and show that integrins play a central role in this process that is distinct from their role in cell-ECM interactions.

Contractility and adhesion to the matrix is impaired in vascular smooth muscle from Acta2 R149C mice

K. R. Ojha[1], H. Kim[2], S. Padgham[1], L. Hopkins[3], A. Chattopadhyay[4], G. Han[3], D. M. Milewicz[4], M. P. Massett[2], **A. Trache**[1]; [1]Texas A&M University Health, Bryan, TX, [2]Texas Tech University, Lubbock, TX, [3]Texas A&M University Health, College Station, TX, [4]University of Texas Health, Houston, TX.

Mutations in ACTA2, encoding smooth muscle alpha-actin, are associated with impaired vascular smooth muscle function. Vascular smooth muscle cells sense mechanical stresses from the extracellular microenvironment through cell-matrix adhesions. These adhesion structures contain clusters of integrins which connect to the actin cytoskeleton via specialized adhesion proteins. This study investigates the functional characteristics of vascular smooth muscle in aortic rings as well as isolated aortic vascular smooth muscle cells from mice presenting Acta2 R149C mutation. Functional experiments performed in aortic rings isolated from Acta2 R149C mice showed that stress relaxation was reduced at lower tensions, presumably due to reduced cytoskeletal-dependent contractility. Quantification of protein fluorescence measurements in vascular smooth muscle cells showed that smooth muscle alpha-actin mutation decreases stress fiber formation and induces a compensatory increase in smooth muscle gamma-actin. In addition, cell stiffness at the point of contact measured by atomic force microscopy showed a significant increase in Acta2 R149C cells by comparison with wild-type cells. These data suggest that upregulated smooth muscle gamma-actin may contribute to increased cell stiffness. Moreover, specific alpha5beta1 integrin recruitment at cell-matrix adhesions was reduced in Acta2 R149C cells. Taken together, the increased stiffness and reduced integrin recruitment in Acta2 R149C vascular smooth muscle cells lead to a reduced contractile phenotype.

B539/P1521

Extracellular matrix driven changes in cardiomyocyte organization and adhesion

S. Balasubramanian, A. Vallopra, J. Yang, L. Davidson, A. Kwiatkowski; University of Pittsburgh, Pittsburgh, PA

Extracellular matrix (ECM) transitions in the heart are critical for proper development, and deleterious changes in ECM composition are associated with heart disease and injury. The ECM of the embryonic and perinatal heart is dominated by fibronectin, whereas the ECM in the mature heart is primarily comprised of collagen type I. The fibronectin to collagen I ECM transition is associated with an increase in matrix stiffness and the activation of programs that coordinate cardiomyocyte maturation. However, it is not clear how the ECM regulates cardiomyocyte organization to promote heart tissue maturation and function. Integrins, adhesion proteins that bind ECM, also undergo spatiotemporal changes during heart development. Integrin-fibronectin adhesions decrease after birth and are replaced by integrin-collagen I adhesions, concurrent with junctional remodeling and cardiomyocyte maturation. Using advanced cell biology, microscopy, and bioengineering techniques, here we show that ECM composition regulates neonatal cardiomyocyte organization. On collagen I, cardiomyocytes adopt a mature, rod-shaped phenotype with myofibrils coupled to cell-cell adhesions at the longitudinal ends. In contrast, cardiomyocytes plated on fibronectin are not well organized, with basal myofibrils that largely fail to integrate at long, lateral cell-cell contacts. Our findings support a model in which the transition from fibronectin to collagen I promote junctional maturation and cardiomyocyte polarization. We speculate that cardiomyocytes recognize distinct ECM proteins to activate specific integrin-mediated signaling pathways that promote myofibril organization and cell-cell adhesion. Defining the relationship between cardiomyocytes and the surrounding ECM is critical to understanding heart biology and developing effective therapies to treat heart disease.

B540/P1522

A stiff matrix favors the mechanical cell competition that leads to extrusion of bacterially-infected epithelial cells

R. Aparicio-Yuste[1], M. Muenkel[2], A. Clark[3], M. Gomez-Benito[1], **E. Bastounis**[2]; [1]University of Zaragoza, Zaragoza, Spain, [2]University of Tübingen, Tuebingen, Germany, [3]University of Stuttgart, Stuttgart, Germany

Cell competition refers to the mechanism whereby less fit cells (“losers”) are sensed and eliminated by more fit neighboring cells (“winners”) and arises during many processes including intracellular bacterial infection. Extracellular matrix (ECM) stiffness can regulate important cellular functions, such as motility, by modulating the physical forces that cells transduce and could thus modulate the output of cellular competitions. Herein, we employ a computational model to investigate the previously overlooked role of ECM stiffness in modulating the forceful extrusion of infected “loser” cells by uninfected “winner” cells. We find that increasing ECM stiffness promotes the collective squeezing and subsequent extrusion of infected cells due to differential cell displacements and cellular force generation. Moreover, we discover that an increase in the ratio of uninfected to infected cell stiffness as well as a smaller infection focus size, independently promote squeezing of infected cells, and this phenomenon is more prominent on stiffer compared to softer matrices. Our experimental findings validate the computational predictions by demonstrating increased collective cell extrusion on stiff matrices and glass as opposed to softer matrices, which is associated with decreased bacterial spread in the basal cell monolayer *in vitro*.

Collectively, our results suggest that ECM stiffness plays a major role in modulating the competition between infected and uninfected cells, with stiffer matrices promoting this battle through differential modulation of cell mechanics between the two cell populations.

The kinesin-2 Kif3AC functions as an integrin recycling motor that interacts with talin and β1 integrin

J. A. Z. Rockenbach[1], G. P. F. Nader[1,2], S. Antoku[1], G. G. Gundersen[1]; [1]Columbia University, New York, NY, [2]University of Pennsylvania Perelman School of Medicine, Philadelphia, PA

Integrins released from disassembling focal adhesions remain in an active conformation and are endocytically recycled by a Rab11-dependent process that polarizes formation of new adhesions (Nader et al., Nature Cell Biol, 2016). The molecular motor(s) responsible for recycling the active integrin are unknown. We tested whether heterodimeric kinesin-2s (Kif3AB or Kif3AC), which interact with Rab11-FIP5, contribute to the recycling of active integrins. Knockdown of kinesin-2 subunit revealed that Kif3A caused a reduction in the size of focal adhesions. We tested whether this effect was due to impaired integrin recycling using the nocodazole washout assay to synchronize focal adhesion disassembly, integrin recycling and focal adhesion reformation. Knockdown and dominant negative approaches with Kif3 tails, revealed that Kif3A and Kif3C, but not Kif3B prevented formation of new focal adhesions after adhesion disassembly. In Kif3AC disrupted cells, cell surface levels of integrins did not return after adhesion disassembly, and integrins were instead detected in the Rab11 endocytic recycling compartment where they colocalized with Kif3AC. GST-pull down from cells expressing GST-Kif3C and myc-β1 integrin showed that Kif3C interacted with β1 integrin and endogenous talin but only during endocytic recycling. Depletion of Kif3AC decreased cell migration in a wound healing assay. These results indicate that Kif3AC is a motor for recycling integrins and suggest that talin may be necessary both to keep recycling integrin in an active state and contribute to its association with Kif3AC. This work was supported by NIH grant R35 GM12858593.

Structure and Function of the Extracellular Matrix

B542/P1524

Secreted footprints organize complex cell migration patterns

E. Perez Ipina, B. A. Camley; Johns Hopkins University, Baltimore, MD.

Eukaryotic cell migration is essential to biological processes like embryonic development, immune response, wound healing, or cancer metastasis. Successful cell migration usually requires adhesion to an extracellular matrix (ECM), a network of multiple components, such as collagen and glycoproteins. Cells can also modify the matrix by depositing new matrix proteins such as fibronectin. Recent experiments with MDCK epithelial cells on 1D fibronectin micropatterned stripes observed that cells move almost persistently in regions they have previously crawled over, but barely advance into unexplored regions, resulting in oscillatory motion of increasing amplitude. These observations suggest that cells leave behind a footprint which facilitates their own or other cells' passage. Here, we explore through mathematical modeling how footprint secretion affects cell motility patterns. We simulate cell crawling on micropatterns of different geometries with a phase field model. We hypothesize that local contact with the secreted footprint activates Rac1, a polarity protein at the front of the cell, and find that this minimal assumption can recapitulate many of the experimental observations. Depending on the

footprint secretion rate and the response to the footprint, cells can display a variety of motility patterns, including self-confined, oscillatory, and persistent motion. Our model provides insight into when cells' interactions with their own footprint can lead to oscillations, and what properties of the footprint and the cell regulate this behavior.

B543/P1525

A dominant modifier scree for genetic interactor of Jagunal in Drosophila

J. Abuel, B. Riggs; Biology, San Francisco State University, San Francisco, CA.

The Endoplasmic Reticulum (ER) is a multifunctional organelle involved in protein and lipid synthesis, secretory proteins, and post-translational modification of proteins. However, the organization and inheritance of the ER during cell division is poorly understood. A recent study highlighted the highly conserved tetraspanin ER protein Jagunal (Jagn) plays a role in the organization and asymmetric partitioning of the ER in pro-neural cells during mitosis in early embryonic development of drosophila just before cell fate determination. We hypothesized that Jagn interacts with other genes that drive the generation of neural cell diversity and cell fate determinants. To identify the specific genes that interact with Jagn, we examined a collection of deficiencies covering the entire 3rd chromosome and performed a dominant modifier screen to observe changes in the compound eye phenotype. Expression of JagnRNAi construct in the Drosophila compound eye resulted in an 80% rough eye phenotype. Using these results as a baseline, we examined whether the deficiency lines on the 3rd chromosome was an enhancement or suppression of the rough eye phenotype. We have identified eight suppressors and ten enhancers of Jagn-induced rough eye phenotype. Through our screening efforts, we identified 19 gene targets based on their involvement in many predicted functions of Jagn such as organelle assembly, microtubule attachment, and organelle movements. Here, we discovered a genetic interaction with the g-secretase subunit Presenilin (Psn), a transmembrane protein involved in proteolysis and activation of Notch signaling. These findings highlight a connection between Jagn-dependent mitotic ER partitioning and the Notch signaling pathway.

Eggshell membrane promotes homeostasis of skin and lung tissue associated with type III collagen and decorin expression and ameliorates pulmonary fibrosis in a bleomycin mouse model

E. Ohto-Fujita[1,2], M. Shimizu[1], A. Atomi[1], S. Horinouchi[1], N. Shibayama[1], R. Hosoda[1], H. Hiruta[1], T. Murakami[3], S. Miyazaki[3], M. Kurimoto[1], Y. Asano[4], T. Watanabe[5], Y. Hasebe[6], Y. Atomi[1]; [1]Material Health Science, Tokyo University of Agriculture and Technology, Tokyo, JAPAN, [2]Tokyo Woman's Christian University, Tokyo, JAPAN, [3]Cooperative Dep. Veterinary Medicine, Tokyo University of Agriculture and Technology, Tokyo, JAPAN, [4]Department of Dermatology, Tohoku University Graduate School of Medicine, Sendai, JAPAN, [5]Division of Applied Chemistry, Graduate School of Engineering, Tokyo University of Agriculture and Technology, Tokyo, JAPAN, [6]Almado, Inc., Tokyo, JAPAN.

The integrity of the extracellular matrix (ECM) of the dermal papilla in the skin and the interstitium in the lungs is critical for tissue homeostasis. We have previously reported that moderate amounts of eggshell membrane (ESM) provide a young and elastic ECM environment via type III collagen (COL3), decorin (DCN), and MMP2 expression by skin fibroblasts. In this study, we investigated the ESM response of lung fibroblasts and whether oral intake of ESM improves skin and lung homeostasis in mice, including the bleomycin lung fibrosis model (BLM model). The response of human lung fibroblast

cell line IMR-90 to ESM was investigated in a culture environment with solubilized ESM (SESM) surface. Changes in gene expression were investigated in mice lungs and skin after 2- and 4 weeks of oral ESM ingestion. The anti-fibrotic effect of ESM was then investigated in the BLM model and expression of COL3 in the bronchial stroma was investigated. To investigate the relationship between the induction of COL3 expression by ESM ingestion and the amelioration of pulmonary fibrosis, the activation of the mechano-transducer TAZ transcription factor, which senses extracellular matrix stiffness and regulates myofibroblast marker expression, proliferation and migration, was quantified as an indicator of nuclear migration by immunostaining of TAZ in lung fibroblasts. Lung fibroblasts cultured on ESM showed markedly higher COL3, DCN, and MMP2 levels. Oral ESM administration in mice markedly increased COL3 and DCN levels in lung tissues after 2 weeks, and COL3, DCN, and MMP2 levels in the papillary dermis after 4 weeks. To further explore the effects of ESM on the lungs, we used a mouse model of bleomycin-induced fibrosis. In these mice, ESM significantly suppressed fibrosis at 2 weeks and increased the COL3 levels in the bronchioles and DCN levels in the alveoli, which was implicated in the suppression of lung fibrosis. TGF-β induced nuclear translocation of TAZ was not increased when cultured in medium containing SESM. Oral ESM intake may prevent the age-dependent decline of the papillary dermis and pulmonary fibrosis by improving the extracellular environment in skin and lung tissues.

Compartmentalization of alpha-tectorin (TECTA) through microvilli regulates the collagen attachment and the organization of the tectorial membrane

A. Niazi, J. Kim, J. Park, S. Park; Neurobiology, University of Utah, Salt Lake City, UT.

Background: The microvilli are membrane protrusions that are found on the apical surface of some epithelial cells, but their biological function is poorly understood. The tectorial membrane (TM) is an apical extracellular matrix (ECM) in the inner ear that mediates auditory transduction. The developing TM exhibits a highly organized architecture composed of parallel collagen fibrils that are attached to the tip of the microvilli of the cochlear supporting cells. The attachment of elongating collagen fibrils to the tip membrane is crucial for collagen arrangement. Previously, we showed that both surface-tethering and the release of alpha-tectorin (TECTA), a GPI-anchored collagen binding protein, play critical roles in TM morphogenesis by preventing the diffusion of secreted TM components, and mediating matrix elongation, respectively. However, the role of surface shape in the matrix organization and the mechanism by which collagens are attached to a specific membrane compartment were unknown. We identified that transmembrane serine proteases (TMPRSSs) shed TECTA from the cell surface. Noting that surface TECTA is preserved on the tip of the microvilli, we hypothesized that the microvillus structure may restrict TMPRSS sheddase activity from the distal tip, which prompts the preservation of full-length TECTA and collagen attachment sites. **Methods:** To identify the role of TECTA shedding in the matrix organization, we generated Tecta knock-in mice in which the release of TECTA is blocked. In TECTA-R2061S mice, the TMPRSS-mediated cleavage is specifically blocked. Similarly, in TECTA-ZP3 mice, a transmembrane form of TECTA was generated to block the GPI-anchor-dependent cleavage. We studied how these mutations impact the organization of the TM by immunohistochemistry and Transmission electron microscopy (TEM). **Results:** Collagen fibrils are attached to the lateral and base membrane of the microvilli in Tecta-R2061S mice. Furthermore, we observed a significant increase in the microvilli length and extracellular vesicle (EV) density in this mutant. In Tecta-ZP3 mice, the release of TECTA and EV density is dramatically reduced. Also, in Tecta-ZP3 mice, the elongated collagen fibrils

are attached to the distal tips of microvilli but are densely packed and lack crosslinking fibers.
Conclusion: Our findings indicate that the cell surface shape SCs compartmentalizes the release of the TECTA and consequently restrains the collagen attachment site and mediates the specific highly ordered organization of the TM.

The Application of Fibrotic Lung Matrix Derived Hydrogels for *in-vitro* Small Molecule Intervention in Lung Fibrosis

J. Fernandez-Davila[1], D. W. Moore[1], L. R. Rodriguez[1], S. Nathan[2], G. Grant[1], J. L. Moran[3]; [1]Department of Biology, George Mason University, Fairfax, VA, [2]Advanced Lung Disease and Transplant Program, INOVA Fairfax Hospital, Fairfax, VA, [3]Department of Mechanical Engineering, George Mason University, Fairfax, VA.

Idiopathic Pulmonary Fibrosis (IPF) is a disease marked the dysregulated activation and chronic proliferation of lung fibroblasts. With only two FDA approved drugs for this devastating disease, there is an outstanding need for improved *in vitro* model systems to evaluate and identify novel therapeutics. Using decellularized lung tissue donated by patients with IPF, we present and validate a protocol for the generation of a 3D fibrotic hydrogel *in vitro* culture. The culturing of fibroblasts in fibrotic matrix closely recapitulates the cell-to-matrix signaling present in fibrosis and removes complexity of cell cultures on stiff tissue culture plastic. We use this model to explore the effects of small molecule stimulation and inhibition of profibrotic pathways.
IPF lung tissue was decellularized, digested, desalinated, and dehydrated prior to gelation at 37°C. Primary 3D fibroblast cultures were assayed for myofibroblast phenotypes after challenge of TGF-β and the antifibrotic Nintedanib (NTD). This includes quantification of myofibroblast associated gene expression, contractile capacity, and generation of ROS species. Fibroblast-immune cell cross talk is conducted via conditioned media experiments. Media from primary fibroblasts in 3D cultures is added to U937 monocyte cells which are then driven towards macrophage differentiation. Macrophage phenotypes was assayed via QPCR of macrophage polarization genes.
We observed increased rates of contractility in ECM hydrogels seeded with IPF fibroblasts (IPF-F) as compared to normals human lung fibroblasts (NHLF). This contraction was correlated to cell density and increased when stimulated with TGF-β. Expression of genes associated with myofibroblast activation was decreased in all fibroblasts when seeded in hydrogels, as compared to tissue culture plastic. However, even in 3D hydrogel cultures, IPF-F maintained their disease phenotype with increased expression of proliferation and myofibroblast activation genes as compared to NHLF. Treatment of cultures with NTD decreased expression of myofibroblast associated genes and partially mitigated TGF-β driven contraction. Differential expression of cytokines was observed in hydrogel cultures as compared to plastic, with the potential activation of a profibrotic macrophage phenotype in U937 cells treated with hydrogel culture conditioned media.
Overall, our hydrogel is a novel platform to test functional characteristics of activated fibroblasts including contractile forces, cell proliferation, expression of myofibroblast associated genes, generation of oxidative stress, and cytokine stimulation. Furthermore, the application of co-culture assays allows for the exploration of immune cell crosstalk, a key aspect to the amplification of the fibrosis.

B547/P1529

Heat-dependent regulation of collagen metabolism in mouse dermal fibroblasts

T. Nakajima, Y. Ishiuchi-Sato, T. Nedachi; Toyo University, Tokyo, JAPAN.

It has been demonstrated that heat stimulation exerts the activation of Matrix metalloproteinases (MMPs) secreted from skin cells, thereby inducing degradation of collagens in the connective tissues of the skin. On the other hands, it is still unclear detail characteristics of heat-dependent responses of epidermal and dermal cells, including signaling cascades which are activated by heat stimulation as well as the impact of heat on collagen biogenesis. In this study, we analyzed heat-dependent responses of mouse primary cultured dermal fibroblasts (MDFs), especially focused on collagen metabolisms.We cultured MDFs under the different temperature for various times and analyzed the expression of Heat shock protein 70 (HSP70) as an indicator for heat stimulation, and found HSP70 expression was clearly observed when the MDFs were cultured at 41 C for more than 3h. To set more physiological condition, MDFs were stimulated at 41 C for 3 h, then returned cells at normal condition (37 C) and keep culturing for 21 h. We next performed RNA-seq analysis to elucidate gene expression changes during this experimental schedule. The gene expression of major fibrous collagens (Collagen type I and III) was not altered by heat stimulation; however, the gene expression of MMP-2, -3, -14 and collagen fiber synthesis-related protein (BMP1, TLL1) was significantly decreased. Gene ontology analysis suggested that unfolded protein response (UPR) was apparently enhanced in response to heat stimulation. Intriguingly, although UPR activation often correlated with MMPs induction in the other cells, the present study suggested that heat stimulation on MDFs rather reduced these gene expressions.Overall, the present study suggested that the heat stimulation might delay collagen metabolism through down-regulation of BMP1, TLL1, and MMPs in MDFs, as well as exerted UPR to repair and/or remove inappropriate proteins. Further studies on heat-dependent regulation of collagen metabolism and structural changes of collagen fibers will clarify heat-dependent regulation of dermal tissues.

The desmosomal cadherin Desmoglein-2 controls extracellular matrix gene expression via Src and NF-kB signaling.

J. M. Powers, M. M. Mrus, B. T. Mateo, A. D. Dubash; Biology, Furman University, Greenville, SC.

Desmosomes are protein complexes crucial for maintaining cell-cell adhesion and integrity of tissues. These complexes are made up of proteins from three families: transmembrane cadherins (Desmoglein and Desmocollin) link adjacent cells in the extracellular space, armadillo proteins (Plakophilin and Plakoglobin) stabilize the intracellular plaque, and the cytolinker Desmoplakin (DP) connects the plaque to the intermediate filament network. Desmosomal proteins have also been shown to coordinate gene expression pathways required for processes such as proliferation, differentiation and cell migration. In particular, several lines of evidence have linked desmosomal proteins to gene expression of extracellular matrix (ECM) proteins. In our study, we sought to investigate the role of desmosomal cadherins in ECM gene expression. Compared to control A431 cells, Dsg2 knockout cells (generated via CRISPR) demonstrated a dramatic increase in expression of Fibronectin (FN1) mRNA, and minor changes in expression of Collagen 1 (COL1A1) and Collagen 2 (COL2A1) mRNA. An increase in expression of Fibronectin protein levels in Dsg2-deficient cells was also observed via western blot. Increased expression of ECM genes was also observed upon siRNA-mediated knockdown of Dsg2 in both A431 cells and HaCaT keratinocytes, verifying that these changes are not clone-specific or due to off-target CRISPR

effects. An extensive analysis of signaling pathways known to be involved in regulation of ECM gene expression uncovered an important signaling role for Src kinase and the NF-kB transcription factor, as abrogation of either protein (via knockdown or pharmacological inhibition) resulted in a rescue of Dg2KO-mediated increases in FN1 gene expression. Moreover, we have documented a significant increase in localization of NF-kB to the nucleus of Dsg2-deficient cells, indicating an increase in NF-kB transcriptional activity. Taken together, our study highlights a novel role for Dsg2 in mediating ECM gene expression via Src/NF-kB signaling, adding significant insight into the mechanisms by which desmosomal cadherins control the adhesive behavior of cancer cells.

Tension-suppressed degradation of collagen underlie tissue stiffness scaling with fibrillar collagen

K. Saini[1], S. Cho[1], M. Tewari[1], A. Jalil[1], M. Wang[1], M. Vashisth[1], A. Kasznel[1], K. Yamamoto[2], D. Chenoweth[1], D. Discher[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]University of Liverpool, Liverpool, UNITED KINGDOM.

Extremely soft tissues such as embryonic chick hearts or adult mouse brain contain far less collagen than highly stiff adult tissues such as mouse tendons, but cell and molecular mechanisms for such homeostatic differences remain unclear. We hypothesized that cell-generated or exogenous forces combine with strain-suppressed collagen degradation to sculpt extracellular matrix (ECM) levels in tissues. For various mature tissues as well as beating chick hearts and mouse tendons, we find that label-free second harmonic generation (SHG) image intensity from collagen fibrils generally scales non-linearly with tissue stiffness, aligning well with results from cellularized gels of collagen. Chick hearts beating at ~5% strain in a spatiotemporal wave maintain collagen levels until contractile strain is suppressed by myosin-II inhibition; endogenous matrix metalloproteinases (MMPs) then degrade collagens within ~30-60 minutes. Tendons have oriented collagen fibrils but also generally exhibit heterogeneous strains in deformation, with addition of MMP or bacterial collagenase again showing degradation is suppressed at physiological strains (i.e., ~5-8%). Sequestration of collagen cleavage sites by strain is a likely mechanism because molecular permeation and mobility prove strain-independent whereas artificial collagen cross-links accelerate collagen degradation. We conclude that strain-suppressed turnover of collagen underlies tissue stiffness scaling.

PAR-1 induces the TN-C expression in activated microglia in the ischemic brain

Y. Fan[1], X. Feng[1], **C. Chung**[2,1]; [1]Tianjin University, Tianjin, China, [2]Mercer University School of Medicine, Columbus, GA

Stroke is one of the most common causes for mortality and morbidity worldwide. Following acute stroke onset, biochemical and cellular changes induce further brain injuries such as neuroinflammation, cell death, and blood-brain barrier disruption. As the resident immune cells of the central nervous system, microglia rapidly respond to brain insults, including stroke and traumatic brain injury. Evidences suggest that Protease Activated Receptor-1 (PAR-1) mediates neuronal injury in cerebral ischemia. We examined if PAR-1 signaling upregulates the expression of tenascin-C (TNC) in microglia. TNC, an extracellular matrix protein, is considered to be an important inducer in promoting neuroinflammatory cascades and the resultant pathology in stroke. We found that TNC is highly expressed in cultured primary microglia treated with PAR-1 peptide, which can be effectively blocked with PAR-1 antagonist. Upregulation of

TNC exocytosis upon PAR-1 activation in microglia was also observed. To examine the expression of TNC in microglia in the ischemic brain, mice were subjected to 2 hours of transient middle cerebral artery occlusion (MCAO), followed by 12 or 24 hours of reperfusion. Consistent with results from cultured microglia, a high level of expression of TNC was observed in activated microglia in the ischemic brain. These results suggest that PAR-1 signaling plays an important role in neuronal injury in cerebral ischemia via inducing TNC expression and exocytosis in microglia.

B551/P1533

Identification of two COMP C-terminal globular domain epitopes that bind and enhance BMP/TGFbeta growth factors

J. Fraley[1], J. H. N. Yik[1], G.-y. Liu[2], D. R. Haudenschild[1]; [1]University of California, Davis Health, Sacramento, CA, [2]University of California, Davis, Davis, CA

The extracellular matrix (ECM) regulates cellular responses by binding and enhancing TGFβ-superfamily growth factors.The potency and pleiotropic effects of BMP/TGFβ growth factor activity necessitates tight regulation. The ECM plays an active role in growth factor regulation and helps fine-tune cellular responses.One such regulatory ECM component is the cartilage oligomeric matrix protein (COMP), a multi-domain pentameric glycoprotein of bone, cartilage, and most human tissues.We previously identified that the COMP C-terminal globular domain (COMP CTD) bound and enhanced the activity of bone morphogenetic protein-2 (BMP-2) and transforming growth factor beta 1 (TGFβ-1), *in vitro* and *in vivo,* however the exact growth factor binding sites on COMP remain unknown.Therefore, the objective of this study is to identify the interactions sites of the COMP CTD that bind to the TGFβ-superfamily growth factors.A synthetic peptide library of the entire 270aa COMP CTD was developed, consisting of partially overlapping 15aa peptides.Of the 28 COMP CTD peptides tested, we identified two that interfered with rhCOMP binding to immobilized BMP-2 and TGFβ-1 in competitive ELISAs.Peptide YAG corresponds to the sequence YAGFIFGYQDSSSFY, (COMP residues 606-620), and peptide CFS corresponds to the sequence CFSQENIIWANLRYR (COMP residues 726-740).The two sequences were then mapped onto the crystal structure of the COMP CTD, suggesting a potential binding pocket.Since overlapping peptides did not interfere with COMP binding to BMP-2 and TGFβ-1, the potential binding sites were further narrowed down to the inner five residues of each peptide.The inner five residues of peptides YAG and CFS were analyzed using an alanine point mutant screen in a competitive ELISA for their interference of rhCOMP binding to immobilized BMP-2.The results indicated that four residues of the YAG peptide, and one of the CFS peptides as potential sites on COMP where BMP-2 and TGFβ-1 bind.To further confirm YAG and CFS epitope sequences as binding sites on the COMP CTD, antibodies (α-YAG, α-CFS) were developed and tested in a cell-based assay for their function blocking ability. Using a BMP-2 dependent gene transcription luciferase cell line (C33A-2D2), α-YAG and α-CFS significantly blocked rhCOMP enhancement of BMP-2 in a dose dependent manner. Our data suggests that two distinct epitopes in the COMP C-terminal globular domain bind BMP-2 and TGFβ-1. Now, α-YAG and α-CFS will be further tested for their ability to block COMP enhancement of BMP-2 in other quantitative osteogenic assays. Characterization of the COMP binding sites for TGFβ-superfamily growth factors can inform the development of 2nd-generation biologics whereby BMP-2 can be combined with native ECM components to augment clinical outcomes.

A transient cell population in the *Drosophila* gut synthesizes matrix components following basement membrane damage

A. Stricker, K. LaFever, K. Peebles, S. Hutson, A. Page-McCaw; Vanderbilt University, Nashville, TN

Basement membranes are the oldest, most conserved forms of extracellular matrix which serve to separate tissue layers, provide mechanical support, and direct signals to neighboring cells. Additionally, basement membranes are subject to mechanical damage and require dynamic repair mechanisms. Our work utilizes the *Drosophila* adult midgut basement membrane to probe repair dynamics. In *Drosophila*, all major basement membrane components have been conserved but with less redundancy than mammals. Our lab has developed an assay to damage the basement membrane and study the repair process by feeding the flies dextran sodium sulfate (DSS). We have found that many genes required for basement membrane repair are also required to maintain adult basement membranes over time, even without damage, suggesting that continuous synthesis of matrix components is required to maintain and repair the basement membrane. This raises the question of how these processes differ. My data suggests basement membrane damage is actively detected. Following DSS damage, a subset of cells in the *Drosophila* midgut begins transcribing the matrix components collagen IV and the collagen IV crosslinking enzyme, Peroxidasin. We have termed these cells "Matrix Makers." I performed lineage tracing to identify the cellular source and ultimate fate of the Matrix Makers. I found these cells are likely enteroblasts that die or differentiate into short-lived enterocytes once the basement membrane is repaired. In summary, I have identified a transient cell population that synthesizes long-lived matrix components required for basement membrane repair.

MECHANOSENSITIVE TRPV4 channel guides maturation and organization of the bilayered mammary epithelium

T. Kärki[1], C. Guenther[2], **S. Koskimäki**[2], J. Pirhonen[2], K. Rajakylä[3], S. Tojkander[2]; [1]Aalto University, Espoo, Finland, [2]Tampere University, Tampere, Finland, [3]Tampere University of Applied Sciences, Tampere, Finland

Introduction:

Biophysical cues from the cell microenvironment are detected by mechanosensitive components at the cell surface. Such machineries convert physical information into biochemical signaling cascades within cells, subsequently leading to various cellular responses in a stimulus-dependent manner. At the surface of extracellular environment and cell cytoplasm exist several ion channel families that are activated by mechanical signals to direct intracellular events. One of such channels is formed by transient receptor potential cation channel subfamily V member, TRPV4, that is known to act as a mechanosensor in a wide variety of tissues and control ion-influx in a spatio-temporal way.

Materials and Methods:

TRPV4 depletion was conducted on MCF10A or 184A1 mammary epithelial cells (purchased from ATCC) using siRNA. Actin cytoskeleton organization was analyzed from monolayer cultures, alongside with calculation of cell-exerted tractions utilizing traction force microscopy. Maturation markers for both myoepithelial and luminal epithelial cells were screened using immunocytochemistry and western blot analysis. 3D cultures were performed with both MCF10A and 184A1 mammary epithelial cells to analyze the formation and maintenance of mammosphere structures.

Results and Discussion:
Here we report that TRPV4 is prominently expressed in the stem/progenitor cell populations of the mammary epithelium and seemingly important for the lineage-specific differentiation, consequently affecting mechanical features of the mature mammary epithelium. This was evident by the lack of several markers for mature myoepithelial and luminal epithelial cells in TRPV4-depleted cell lines. Interestingly, TRPV4 expression is controlled in a tension-dependent manner, and it also impacts differentiation process dependently on the stiffness of the microenvironment. Furthermore, such cells in a 3D compartment were disabled to maintain normal mammosphere structures and displayed abnormal lumen formation, size of the structures and disrupted cellular junctions.
Conclusion:
Mechanosensitive TRPV4 channel acts as critical player in the homeostasis of normal mammary epithelium through sensing the physical environment and guiding accordingly differentiation and structural organization of the bilayered mammary epithelium.

Autophagy

B555/P1536
WIPI2B/ATG-18 Phosphorylation Regulates Neuronal Autophagosome Biogenesis *in vivo*
H. Tsong, A. Stavoe; University of Texas Hlth Sci Ctr, Houston, TX.

Autophagy is a homeostatic mechanism that cells utilize to clear waste. Autophagy is especially important for neurons because they cannot dilute waste through cell division. However, neurons lose their ability to perform autophagy with age, and the misregulation of autophagy has been implicated in many age-related neurodegenerative diseases (NDDs). Previously, we found that we could restore the rate of autophagosome biogenesis in aged primary murine neurons through the overexpression of WIPI2B, a key autophagy component. Importantly, this rescue is contingent upon the phosphorylation state of WIPI2B. These data suggest that WIPI2B phosphorylation regulates its function in autophagosome biogenesis and that increasing dephosphorylated WIPI2B via protein regulators will upregulate neuronal autophagy. To test this hypothesis, we first verified the role of WIPI2B phosphorylation in neuronal autophagy *in vivo* in *Caenorhabditis elegans*. We generated *C. elegans* strains endogenously expressing phospho-mimetic or phospho-dead ATG-18 (the WIPI2B ortholog). We previously showed that autophagy regulates PVD axon outgrowth cell-autonomously. Using PVD axon length as a simple, visual readout of neuronal autophagy, we determined that worms with phospho-mimetic ATG-18 had longer axons, suggesting defective autophagy, while worms with phospho-dead ATG-18 had normal axon lengths, suggesting functional autophagy. Due to the importance of this phospho-site in autophagy, we used a candidate approach to identify the kinase and phosphatase that regulate ATG-18/WIPI2B phosphorylation. Overexpression of constitutively active CDK-1 in PVD yielded longer PVD axons, suggesting that CDK-1 might regulate neuronal autophagy as a kinase that regulates ATG-18 phosphorylation. Conversely, worms with mutations in a PP2A regulatory subunit SUR-6/B55 displayed longer PVD axons, similarly implicating PP2A in the regulation of neuronal autophagy. Since autophagy misregulation has been implicated in NDDs, a better understanding of how neurons utilize and regulate autophagy will uncover novel therapeutic targets for treating these NDDs.

"Impact of the ER Stress Sensing Protein PERK and Autophagy On Exacerbated Strokes in Alzheimer's Patients "

H. Gudlavalleti, R. Viswanthan, B. Stoveken, H. Deborah, D. Lozano, N. Derosa, s. Weintraub, k. Bieniek, J. Lechleiter; University of Texas Health Science Center - San Antonio, San Antonio, TX.

Patients with Alzheimer's disease are at high risk of stroke and also exhibit increased stroke severity and infarct volume compared to age matched subjects. The role of autophagy in the exacerbation of strokes in these patients is poorly understood. Increased autophagy has been reported as both protective and detrimental, depending at what age stroke occurs. PKR like endoplasmic reticulum (ER) Kinase (PERK) is an early ER stress sensor that activates the unfolded protein response (UPR). Subsequent phosphorylation of eIF2a in this ER stress pathway inhibits general protein translation but can also lead to increased autophagy. PERK variants correlated with an increased risk of Alzheimer's disease exhibit decreased kinase activity and increased turnover rates. We initially investigated the underlying mechanisms of PERK turnover and its impact on autophagy. Our data indicate autophagy / lysosomal inhibition using chloroquine (CQ) treatments (50 uM) of cultured mouse embryonic fibroblasts (MEFs) significantly increased PERK levels over a 20-hour period. In contrast, treatment of cultured MEFs with the proteasomal inhibitor MG-132 (25 uM), did not appear to affect total PERK levels under our conditions. Pharmacologically inhibiting PERK phosphorylation using GSK414 and increasing cell stress with thapsigargin (1 uM) decreased autophagy markers and significantly increased PERK levels. These data suggested non-phosphorylated PERK under stressed conditions decreased PERK degradation due to decreased autophagy. A proteomics analysis of protein extracts from wildtype MEFs and PERK knockout MEFs, treated with and without chloroquine revealed both a loss (5) and gain (2) of autophagic proteins when PERK protein was knocked out. We are currently investigating the role of these PERK-dependent autophagy proteins. An initial analysis of human brain samples from patients with Alzheimer's disease and stroke infarcts showed autophagy markers were increased and PERK levels decreased compared to controls, consistent with our working model. We are also investigating the specific role of PERK-dependent autophagy on stroke severity and volume in AD mouse models. Data from Alzheimer's patients with strokes are being used to guide these experiments. Funded by NIH RF1 **AG058778.**

UnVAILing the mechanisms of noncanonical autophagy signaling in STING-mediated innate immunity

T. Fischer[1], E. Bunker[1], F. Le Guerroue[1], C. Wang[1], A. Werner[2], R. Youle[1]; [1]NINDS/NIH, Bethesda, MD, [2]NIDCR/NIH, Bethesda, MD.

Autophagy machinery play a well-recognized, yet poorly understood, role in host immunity and inflammation. We have recently demonstrated that Stimulator of Interferon Genes (STING), an essential component of innate immune signaling, may confer antiviral defense through an unanticipated mechanism that is distinct from canonical autophagy. STING activation mediates V-ATPase-ATG16L1-induced LC3B (VAIL) lipidation to single membrane vesicles similarly to other noncanonical autophagy signaling in pathogen- and damage-associated responses. We now identify a novel role for ubiquitylation induced by STING in VAIL signaling and reveal key mechanistic details underlying the relationship between ubiquitin, conjugation of LC3B and mammalian ATG8s to membranes, and innate immune signaling. As ubiquitin plays an important role in both autophagy and innate immunity, our

findings position ubiquitylation as a central molecular link between these cellular processes and VAIL signaling mediated by the STING pathway.

Crosstalk between Mitochondrial Quality Control and Antibacterial Pathways in *Mycobacterium tuberculosis* infected Macrophages

S. VERMA[1], S. Sarkar[2], D. Kumar[1]; [1]Cellular Immunology, ICGEB, New Delhi, INDIA, [2]Institute of Cancer and Genomic Sciences, Institute of Biomedical Research, University of Birmingham, UNITED KINGDOM.

Autophagy, the key homeostatic machinery of the cell, has emerged as a critical cellular defense mechanism against intracellular pathogens, including *Mycobacterium tuberculosis (Mtb)*. While autophagy is believed to target invading bacterial pathogens towards lysosome for degradation, virulent *Mtb* is also known to inhibit the maturation of autophagosome into auto-lysosomes. In this study, we explore the role of autophagy adaptors to understand the regulation of the homeostatic and defense arms of autophagy in the infected macrophages. We report here that autophagy adaptors in general, with an exception of NDP52, unexpectedly, had a pro-bacterial role. Depletion of autophagy adaptors, particularly p62/SQSTM1 resulted in excessive redox stress as well as lysosomal targeting of *Mtb*, which enhanced its clearance from the macrophages. We noted that in the absence of autophagy adaptor, mitophagy process gets impaired and results in the activation of alternate compensatory mitochondrial quality control measure i.e. mitochondria-derived vesicle (MDV) biogenesis. The MDVs were trafficked towards the bacterial phagosomes and enhanced the killing of *Mtb*. Thus, we disclose an unexpected crosstalk between the mitochondrial quality control pathway and the host anti-bacterial pathway, which could be further exploited for therapeutics against tuberculosis.

B559/P1540

Discovery of new *Legionella pneumophila* anti-autophagy effector proteins

K. R. Parducho, C. R. Roy; Yale University, New Haven, CT.

Legionella pneumophila is an intracellular bacterial pathogen that secretes over 300 different “effector” proteins into host cells to manipulate various host pathways. The autophagy pathway, which results in the lysosomal degradation of intracellular bacteria, is a target of effector-mediated inhibition. Although multiple effectors have been described that can interfere with autophagy, genetic studies have suggested there remain undiscovered anti-autophagy effectors. To identify these effectors, a *Saccharomyces cerevisiae* library producing individual effector proteins was screened for defects in the transport of GFP-Atg8 to the yeast vacuole, which is a process mediated by autophagy. This screen identified a *L. pneumophila* effector that prevents the starvation-dependent turnover of GFP-Atg8 and p62 in yeast and mammalian cells, respectively. By examining the localization of autophagy-related proteins, cargo and cargo-receptors, it was found that this effector interferes with an early stage of autophagy. Studies are ongoing to determine the biochemical function of this effector and the host target. Determining the function of this *L. pneumophila* effector will provide a better understanding of how bacteria evade autophagic destruction and could provide new insight into autophagy regulation.

DTHIB induces autophagy in human pancreatic cancer

A. Fausey[1,2,3], A. Young[1], S. Ghai[1], **K. Su**[1,2,3]; [1]Department of Cell and Cancer Biology, College of Medicine and Life Sciences, The University of Toledo, Toledo, OH, [2]MD Program, College of Medicine and Life Sciences, The University of Toledo, Toledo, OH, [3]The Medical Student Research Program, College of Medicine and Life Sciences, The University of Toledo, Toledo, OH.

Background: KRAS mutant pancreatic ductal adenocarcinoma (PDAC) is an aggressive cancer with poor prognosis and limited treatment options. Additionally, many malignancies develop chemo-resistance, significantly complicating treatment strategies and highlighting the demand for innovative treatments. The transcription factor Heat-Shock Factor 1 (HSF1) is momentarily activated in response to a variety of cellular stressors, such as temperature fluctuations or an increase in proteotoxic stress. Proteotoxic stress is reduced within the cell by the production of different heat-shock proteins. HSF1 is continuously overexpressed in several malignancies, including KRAS-mutant PDAC, where it promotes malignancy through its transcriptional targets as well as non-transcriptionally through cytosolic protein interactions to maintain protein stability and control cellular proliferation. The intracellular process of autophagy enables the recycling and destruction of cellular organelles and components. The mammalian target of rapamycin complex 1 (mTORC1) is known to suppress autophagy, whereas HSF1 is known to control mTORC1 activity. DTHIB is an HSF1 inhibitor that directly and specifically reduces HSF1 expression. Although DTHIB has significant anticancer efficacy against prostate cancer, its contribution to the emergence of pancreatic cancer is yet unclear. Autophagy plays two distinct roles in cancer, controlling either the growth of tumors or serving as a tumor suppressor. The molecular underpinnings between HSF1 and autophagic induction in PDAC development are not yet determined. Objectives: We hypothesize that inhibiting HSF1 could lead to a autophagic-associated cell death profile in PDAC and serve as a potential therapeutic target for treating human pancreatic cancer. Methods and Results: In the human pancreatic cancer cell line MIA PaCa-2 cells, the HSF1 inhibitor DTHIB dose-dependently induced autophagy which reduced the autophagy marker P62, inhibited mTORC1 activity, and induced LC3 I/II lipidation. In gemcitabine-resistant MIA PaCa-2 cells, DTHIB also elicited autophagy responses. Overexpression of HSF1 partially inhibited DTHIB-induced autophagy. Furthermore, combination with DTHIB and chemotherapy drug gemcitabine synergistically induced MIA PaCa-2 cell death. Conclusion: DTHIB inhibits HSF1 to induce autophagy and cell death in human pancreatic cancer cells.

Cell-type-specific functions for the autophagy receptor p62 in neurons and astrocytes

D. K. Sidibe, C. Miranda, M. H. Stempel, S. L. Maday; University of Pennsylvania, Philadelphia, PA.

Neurons and astrocytes have unique demands in regulating the quality and composition of their proteome. A key regulator of the proteome is autophagy, a lysosomal degradation pathway. Preliminary studies show that autophagy is regulated differently in neurons and astrocytes in paradigms of stress. However, how autophagy is regulated in each cell type to facilitate cell-type-specific functions and stress responses is largely unknown. The objective for this study is to elucidate cell-type-specific functions for the selective autophagy receptor p62 in neurons and astrocytes. P62 facilitates selective forms of autophagy by binding to ubiquitinated substrates and the autophagy marker LC3, thereby incorporating cargo into a forming autophagosome. By selecting specific cargos for degradation, p62 has multiple neuroprotective functions. P62 mitigates proteotoxic stress by targeting ubiquitinated protein

aggregates to autophagy. Additionally, p62 mitigates oxidative stress by targeting Keap1, a negative regulator of the antioxidant transcription factor NRF2, for degradation by autophagy. However, the cell-type-specific function of p62 in neurons and astrocytes is poorly understood. To examine functions of p62 in each cell type, we established a robust system to coculture neurons and astrocytes. This system recapitulates intercellular interactions found *in vivo,* and provides a manipulatable system for defining cell-type-specific p62 function with high resolution. Using our neuron-astrocyte coculture system, I found that metabolic stress increases p62-positive structures in both neurons and astrocytes, but only in neurons do these structures associate with ubiquitin and require ubiquitination for their formation. Strikingly, oxidative stress, which is known to preferentially activate astrocytes, increases p62 levels in astrocytes but not in neurons. These data support the model that p62 has cell-type-specific roles for quality control in neurons and astrocytes. Specifically, p62 may function primarily in selective autophagy in neurons, and in the antioxidant pathway in astrocytes. Intriguingly, ALS-linked mutations in p62 fall within domains that function in selective autophagy or the antioxidant response. I am testing the hypothesis that these mutations may preferentially disrupt neuronal vs. astrocytic function, thus identifying cell-type-specific contributions to ALS.

Macroautophagy and Aging Synergize to Drive Dysfunctional Metabolism in the Alveolar Epithelium of Non-Resolving Lung Fibrosis

L. R. Rodriguez, J. Katzen, A. Murthy, Y. Tomer, T. Dimopoulos, S. Iyer, K. Chavez, V. Abraham, M. F. Beers; University of Pennsylvania, Philadelphia, PA.

Our understanding of the molecular changes in aging cells highlights the role of cell quality control mechanisms such as macroautophagy in age associated diseases. Using *in-vitro* models we first demonstrated that the expression of mutant surfactant protein C (*SFTPC*^{I73T}) in alveolar epithelial type II cells (AT2) yields a block in late macroautophagy further inducing a time dependent metabolic reprogramming and mitochondrial dysfunction. As proof of concept, our inducible murine model of AT2 *SFTPC*^{I73T} expression results in spontaneous non-resolving lung fibrosis, a condition typically seen in humans after the age of 55. Given these observations, we hypothesize that aging synergizes with defects in cell quality control to drive AT2 initiated fibrosis. To test this, we first induced expression of *SFTPC*^{I73T} in old 18-month-old mice and compared the fibrotic phenotype to young 3-month-old *SFTPC*^{I73T} mice followed by characterizing the observed cellular phenotype in an *in-vitro* reductionist model. The murine model is a tamoxifen responsive hypomorph with an excisable cassette in the *SFTPC* locus. A dox-inducible *in vitro SFTPC*^{I73T} expression system was generated in murine lung epithelial cells (MLE-12) and challenged with low dose bleomycin to induce senescence. Characterization of the metabolism in AT2 cells isolated from 3-month-old, 18-month-old, and in induced *Sftpc*^{I73T} MLE-12s was performed by QPCR, immunoblot, flow cytometry, YSI biochemistry, Seahorse^{TM} respirometry, high-resolution microscopy. After 4-weeks, surviving mice underwent lung physiology measurements and endpoint analysis by bronchoalveolar lavage and whole lung collection. In our aged murine model, we observed increased inflammatory cell infiltration and higher mortality versus young mice. Characterization of old *Sftpc*^{I73T} AT2 cells demonstrated that the acquired macroautophagy defects coincide with metabolic reprogramming favoring glycolysis and enhanced lactate secretion. Additionally, a decrease in mitochondrial biogenesis was associated with inhibited mitochondrial respiration. I*n-vitro* studies in the senescent *SFTPC*^{I73T} cell model supported the observed synergism of aging *in vivo* as these cells also demonstrated increased metabolic reprograming marked with increased lactate secretion, decreased

mitochondrial respiratory capacity, and decreased mitochondrial biogenesis. Collectively, these data further highlight the important role of cell quality control, mitochondrial biology, and cellular aging. Given that the AT2 cell serves as a progenitor cell in the distal lung epithelium, these data begin to elucidate an important connection between an aging lung, metabolic reprogramming, and the impaired resolution of lung injury observed in non-resolving lung fibrosis.

Metabolic Regulation of Autophagy

E. Delorme-Axford[1], D. J. Klionsky[2]; [1]Biological Sciences, Oakland University, Rochester, MI, [2]Life Sciences Institute, University of Michigan, Ann Arbor, MI.

The goal of this study is to investigate how autophagy modulates cellular metabolism, and in return, how cellular metabolism affects autophagy activity. Macroautophagy/autophagy is a dynamic pathway of cellular degradation and recycling that is highly conserved from yeast to humans. Basal autophagy is low, but is upregulated during stress conditions, such as nutrient deprivation and various other forms of stress. The classical morphological feature of autophagy is the *de novo* formation of the double-membrane vesicle known as the autophagosome. In humans, perturbation of autophagy (i.e., too much or too little) can have deleterious effects on cell health and survival, contributing to disease pathogenesis. Autophagy is of key importance in the maintenance of cell health through its contribution to both metabolic and quality control mechanisms. Despite the significance and clear connections, the relationship between metabolism and autophagy is not well understood. To address the gap in our understanding of the interplay between autophagy and cellular metabolism, we utilized the yeast *Saccharomyces cerevisiae* to identify and characterize a novel metabolic regulator of autophagy through a targeted genetic screen. Using multiple assays, our studies have demonstrated that the yeast metabolic transcription factor Stb5 functions as a negative regulator of autophagy. Atg1 is a key kinase that promotes autophagy, and Stb5 protein expression decreases significantly in an Atg1-dependent manner when cells are starved for nitrogen. Loss of Stb5 results in the upregulation of select autophagy-related (*ATG*) transcripts under nutrient-replete conditions as demonstrated by real-time quantitative PCR (RT-qPCR). However, the primary effect on autophagy occurs through Stb5-mediated transcription of genes involved in the generation of cellular nicotinamide adenine dinucleotide phosphate/NADPH pools. This work provides insight into the role of Stb5 as a transcription factor that regulates both cellular metabolic responses and autophagy activity. Our findings support a model in which autophagy is stimulated when cellular levels of the metabolite NADPH decrease and may serve to provide biomolecular building blocks for cellular metabolism during nutrient-limiting conditions.

SQST-1/p62 and SKN-1/Nrf2 promote Compartmentalized Cell Elimination under stress

Y. Mohamed, A. Elkhalil, P. Ghose; University of Texas at Arlington, Arlington, TX

Stress responses, such as autophagy, and developmental death programs are critical to cellular quality control. The interplay between autophagy and developmental death programs has been an intriguing question. In particular, how these processes are connected is essentially unknown in morphologically complex cells, which are characterized by distinct compartments, such as the cell body and neurites in neurons. We employ a novel in vivo system to explore this question. In this “tri-partite” killing program, Compartmentalized Cell Elimination, or CCE, three segments of the C. elegans tail-spike cell (TSC) and

the sex-specific CEM neurons die in different ways in the embryo, with the soma and process engulfed by different phagocytes. We examined CCE under heat stress conditions and found CCE takes place normally. From a forward genetic screen we found that mutants for sqst-1, which encodes the C. elegans ortholog of the mammalian SQSTM1/p62, a receptor for selective autophagy, are defective for CCE following stress. Similarly, mutants for uba-1, which encodes the C. elegans ortholog the E1 ubiquitin-ligase enzyme UBA1 that is required for SQSTM1/p62 function, show a similar defect. Interestingly, sqst-1 is not expressed in TSC, but rather in the surrounding phagocytes. Moreover, cell-specific rescue experiments suggest SQST-1 does not function cell autonomously, suggesting a role in phagocytosis. One degradation target of SQSTM1/p62 is KEAP1, a negative regulator of the stress response transcription factor Nrf2. Like sqst-1 mutants, mutants for skn-1, which encodes the C. elegans ortholog of the mammalian Nrf2, also show a similar CCE defect under stress. Both TSC and neighboring phagocytes express skn-1. Interestingly, the p62-Nrf2 axis is linked to preventative therapy for neurodegenerative disease, but a role in stress-induced phagocytosis has not been described. Together, our data suggests autophagy and cellular stress resistance mechanisms bolster a developmental death program of complex cells under stress conditions. We aim to determine whether SKN-1 and SQST-1 act in the same pathway, to determine the transcriptional target of SKN-1, and to genetically assess whether stress-induced CCE is an example of LC3-Associated Phagocytosis (LAP), an autophagy-assisted phagocytic stress response.

The selective autophagy receptor p62 and the heat shock protein HSP27 facilitate lysophagy via the formation of phase-separated condensates

E. Gallagher, E. Holzbaur; University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Lysosomes are membrane-bound organelles that regulate cellular proteostasis. Loss of lysosomal integrity threatens cellular homeostasis and thus initiates the selective autophagy of damaged lysosomes or lysophagy. Lysophagy begins with the ubiquitination of damaged lysosomes. This ubiquitination induces the recruitment of receptors that facilitate the formation of a double-membrane autophagosome that engulfs the damaged lysosome. Proteomic studies have identified several selective autophagy receptors on the surface of damaged endolysosomes, including NDP52, TAX1BP1, and p62/SQSTM1. However, the specific contributions of each of these receptors to lysophagy remains unclear. We used a penta-KO HeLa cell line lacking five well-characterized autophagy receptors, and found that the selective autophagy receptor SQSTM1/p62 is both necessary and sufficient to promote autophagosome formation at damaged lysosomes. We find that p62 is recruited to damaged lysosomes in both HeLa cells and neurons, following lysosomal damage induced either chemically with LLOMe or by a genetically encoded lysosomal photosensitizer. We identify a specific requirement for the Phox and Bem1p (PB1) domain of p62, as loss of the PB1 domain prevents p62 recruitment and inhibits lysophagy. The PB1 domain of p62 facilitates oligomerization and the formation of liquid-like condensates that engulf damaged lysosomes. We demonstrate that the fluidity of these condensates are regulated by the small heat shock protein HSP27. HSP27 is activated by lysosomal damage, and is recruited to damaged lysosomes. Live imaging demonstrates that HSP27 recruitment coincides with autophagosome biogenesis, and that depletion of HSP27 induces p62 aggregation and inhibits lysophagy. Finally, lysosomal dysfunction is particularly injurious to neurons, as evidenced the emerging link between disruption of lysosomal health and neurodegenerative disease. Moreover, mutations in p62 have been associated with Amyotrophic Lateral Sclerosis (ALS). We find that expression of ALS-associated

mutations in p62 impair lysophagy, suggesting that deficits in this pathway may contribute to the cellular pathogenesis of neurodegeneration.

Distinct Pathogenic Mutations in LRRK2 Disrupt Axonal Transport of Autophagosomes

D. Dou[1], C. Boecker[2], J. Goldsmith[1], E. L. F. Holzbaur[1]; [1]Physiology, University of Pennsylvania, Philadelphia, PA, [2]Neurology, University of Gottingen, Gottingen, GERMANY.

Dysfunctional autophagy has been repeatedly implicated in Parkinson's disease (PD) pathogenesis. Leucine-rich repeat kinase 2 (*LRRK2)* mutations are the most common genetic cause of PD and result in hyperactive phosphorylation of the Rab family of GTPases. We hypothesized that LRRK2 hyperactivity contributes to autophagic disruption by causing deficits in autophagosome transport in neuronal axons. To investigate, we live-imaged the autophagosome marker LC3B in axons of human iPSC-derived neurons with knock-in (KI) of the most common LRRK2 mutation, p.G2019S. In wild-type neurons, we observed smooth retrograde transport of autophagosomes, characteristic of physiologic axonal autophagy. In contrast, imaging p.G2019S KI neurons revealed striking increases in autophagosome pausing. Another PD-linked mutation, *LRRK2*-p.R1441H, has been reported to induce even greater magnitude of kinase hyperactivity than p.G2019S. In p.R1441H KI neurons, we observed more severe disruption of autophagosome transport, manifesting as increased pause duration and likelihood of stationary autophagosomes. Thus, magnitude of autophagosome transport deficits may scale with LRRK2 activity. In p.R1441H KI neurons, we also found that overexpression of the small GTPase Arf6, a motor protein regulator, partially rescued the deficits in axonal transport of autophagosomes. Together, our results lead us to propose a model where imbalance between Arf6 and LRRK2-phosphorylated Rabs induces aberrant recruitment of the scaffold protein JIP4 to autophagosomes. This results in an unproductive tug-of-war between molecular motors, disrupting the autophagosomal transport that is tightly linked to neuronal homeostasis. Importantly, autophagosome transport deficits were reversed by LRRK2 kinase inhibitor treatment, further reinforcing LRRK2's status as a promising therapeutic target.

B567/P1548

WIPI2 orchestrates omegasome formation at the plasma membrane by recruiting E-Syt2

D. Campisi, S. Blanchard, T. Wollert; Institut Pasteur, Paris, France

Autophagy is a cellular recycling process that degrades damaged or superfluous cytoplasmic components. The formation of autophagosomes occur at specialized domains of the endoplasmic reticulum (ER), termed omegasomes, from which cup-shaped phagophores emerge. How omegasomes are generated and how they relate to phagophores remain unknown. We found that targeting the phosphatidylinositol (3) phosphate (PI(3)P) binding protein WIPI2 to the plasma membrane (PM) induces the formation of omegasome-like membranes from which phagophores emerge. The process is independent of canonical autophagy inducers including the ULK1 kinase or PI(3)-kinase complexes, suggesting that WIPI2 is a key factor for the induction of omegasomes. The spatiotemporal uncoupling of omegasome formation and canonical autophagy allows us to identify membrane trafficking pathways that contribute lipids for the formation of omegasomes and important molecular regulators of the pathway. We combined confocal imaging and correlative light electron microscopy (CLEM) and found that overexpression of a PM-targeted WIPI2 protein induced the recruitment of extended

synaptotagmin 2 (E-Syt2). E-Syt2 recruitment at the PM formed an expanded and thin cortical ER. I will present our most recent data which suggest that E-Syt2 is a key regulator of omegasome formation.

Clearance of mutant huntingtin inclusion bodies by selective autophagy

A. Folger, K. Frey, Y. Wang; Florida State University, Tallahassee, FL

Abnormal protein aggregation causes neurodegenerative diseases, such as Huntington's disease. This disease is caused by mutations that increase the number of glutamine-encoding trinucleotide repeats in the first exon of the huntingtin (Htt) gene. Mutated Htt exon 1 with polyglutamine expansion is prone to pathological aggregation and forms inclusion bodies. Normally, aggregates of misfolded proteins are cleared by the ubiquitin-proteasome system or autophagy, which alleviates their cytotoxicity. Previous work has elucidated the role of autophagy in the clearance of misfolded proteins, but autophagic clearance of inclusion bodies remains poorly characterized. Here we use mutated Htt with 103 polyglutamine (Htt103QP) as a model substrate to study the autophagic clearance of inclusion bodies in budding yeast. We found that all core autophagy proteins are required for Htt103QP inclusion body autophagy. We further found that the proteins involved in selective autophagy were required for autophagic clearance of Htt103QP inclusion bodies, indicating that this autophagy is selective. Unexpectedly, a known autophagy receptor for mutated Htt, Cue5, was dispensable for inclusion body autophagy, indicating that Cue5 likely promotes the autophagic clearance of mutant Htt aggregates but not inclusion bodies. However, three known selective autophagy receptors were shown to be essential for this inclusion body autophagy, thereby revealing a novel autophagic pathway specific for inclusion bodies. We named this type of autophagy as IBophagy.

B569/P1550

OPA-1 deficiency promotes muscle atrophy through upregulating Phago-MERCs

D. Stephens; Fisk University and Vanderbilt University, Nashville, TN

Autophagy classically operates as a physiological process to degrade cell membrane components, protein aggregates, and damaged organelle, as a mechanism for nutrient breakdown, and as a regulator of cellular architecture. Proper autophagic flux is paramount for both functional skeletal muscle, which maintains support and movement of the skeleton, and metabolism. The function of autophagy as a metabolic controller in muscle has been previously studied; nevertheless, the underlying molecular mechanisms that regulate autophagy in skeletal muscle have merely started to materialize. Notably, mitochondrial dynamics have been linked to autophagy mechanisms. For example, Fibroblasts bearing dominant-negative, mitochondrial dynamics fusion protein, Optic Atrophy Protein 1 mutations showed **increased autophagy and mitophagy in response to uncoupled oxidative phosphorylation**. Remarkably other mitochondria associated structures, such as mitochondrial endoplasmic reticulum contact sites (MERCs) can also regulate autophagy. However, it is not well understood if OPA1 regulates autophagy through mitochondrial endoplasmic reticulum contact sites (MERCs) or an independent pathway. MERCs are enriched with specific proteins and lipids that aid in specialized structural rearrangements such as the formation of autophagosomes. We hypothesized that loss of OPA1 in skeletal muscle increases Phago-MERCS and serves as the platform for autophagosome formation. To investigate the role of OPA-1 on Phago-MERCs, studies were performed in OPA-1 deficient mice, fly, and OPA-1 ablated in murine myotubes. The ablation of OPA-1 in skeletal muscle showed a decrease in soleus, gastrocnemius,

quadriceps, and tibialis anterior muscle weight. Loss of OPA-1 in gastrocnemius muscle showed an increase in the following MERC proteins that are important for Phago-MERC tethering which include: MFN-2 and PACS2. Loss of OPA-1 also increased the Phago-MERC recruiting protein, ATG5. qPCR analysis after the deletion of OPA-1 in 40-week skeletal muscle displayed an increase in MFN-2, LC3B, ATG7, and ATG5 transcripts, while p62 transcripts were shown to decrease. Primary myoblast and myotubes were generated by isolating satellite cells from OPA-1 floxed mice, differentiated, and subsequently the deletion of OPA1 by infecting the cells with adenoviral Cre recombinase. Ablation of OPA-1 in myotubes increased the following MERC proteins: MFN-2, and PACS2. TEM Analysis of OPA-1 deficient skeletal muscle and myotubes had an increase in Phago-MERCs and lysosome structures. Loss of OPA-1 Like in drosophila muscles increases Phago-MERCs. This data suggests that loss of OPA-1 increased Phago-MERCs, which may lead to decreased muscle mass, but a mechanism of action still needs further exploration.

B570/P1551

Defining the mechanisms of dysfunctional ferritinophagy in β-propeller protein-associated neurodegeneration

C. Chen[1], J. P. Chua[2,3], S. C. Stumpf[2,3]; [1]Krieger School of Arts & Sciences, Johns Hopkins University, Baltimore, MD, [2]Department of Neurology, Johns Hopkins Medicine, Baltimore, MD, [3]Institute for Cell Engineering, Johns Hopkins University School of Medicine, Baltimore, MD.

Beta-propeller protein-associated neurodegeneration (BPAN) is a congenital neurodegenerative disorder and subtype of neurodegeneration with brain iron accumulation (NBIA), manifesting with childhood intellectual disability followed by progressive parkinsonism, dystonia, and dementia in adolescence or early adulthood. BPAN is X-linked and caused by mutations in *WDR45*/WIPI4, a critical effector of vesicle maturation in the highly conserved degradation pathway of autophagy. Although prior studies have found that mutations in *WDR45*/WIPI4 lead to impairments in autophagic flux and abnormal accumulation of degradative cargo, the molecular mechanisms underlying brain iron accumulation and neuron-selective degeneration in BPAN remain undefined. In the present study, we evaluate cell type-specific derangements in ferritinophagy, a selective form of autophagy that regulates intracellular iron content and turnover. To do this, we use a novel cell model of BPAN comprised of human induced pluripotent stem cells edited by CRISPR/Cas9 to knock-in a BPAN-related mutation (c.C52>T, p.Gln18X), from which we generate isogenic neurons, astrocytes, and skeletal muscle cells. In comparing mutant against wild-type cells and neurons against non-neurons, we are assessing immunocytochemical, Western, and qPCR analyses of ferritinophagy machinery: ferritin, an essential intracellular carrier of iron, and NCOA4, a selective autophagy receptor for degrading ferritin. We expect that ferritinophagy proteins fail to undergo normal autophagic degradation and are mislocalized in BPAN cells, and that these derangements are most severe in neurons. By clarifying how and to what extent ferritinophagy is dysfunctional in BPAN and on a cell type-specific basis, we will further our understanding of BPAN pathogenesis and the neurotoxic effects of dysfunctional autophagy. In so doing, our studies will provide the basis for investigating novel and neuron-specific mechanisms of rescuing dysferritinophagy and inform treatment strategies for BPAN and other neurodegenerative autophagiopathies.

B571/P1552

FKBP5, a depression-associated gene, mediates autophagy initiation

H. Park[1], S.-Y. Jung[2], J. Chang[2], S. Lee[1]; [1]Inha Universiry, Incheon, Korea, Republic of, [2]Ajou University school of medicine, Suwon, Korea, Republic of

Major depressive disorder (MDD), simply called as depression, is a common but serious psychiatric disorders caused by a combination of genetic and environmental factors. There are many antidepressants that relieve symptoms of depression, but they are ineffective for more than half of patients. Therefore, genetic factors may contribute to individual variation in antidepressant response. However, the molecular mechanisms for the pathophysiology of MDD are not yet fully understood. FK506 binding protein 51 (FKBP51, also known as FKBP5) belongs to a family of immunophilins which regulates stress response as a co-chaperone of HSP90. The scaffolding activity of FKBP5 enables it to play a modulatory role in the immune response, tumorigenesis, cell death, and stress hormone axis. Moreover, single nucleotide polymorphisms (SNPs) in FKBP5, which increase its protein levels, are significantly associated with increased recurrence of depressive episode and response to antidepressants. However, the molecular mechanism for how FKBP5 regulates depressive response remains unclear. It has been recently reported that FKBP5 not only modulates antidepressant response but also interacts with Beclin1, Akt, and PHLPP, which are critical for autophagy, an intracellular degradation system required to maintain cellular homeostasis. To investigate the relationship between FKBP5 and autophagy, we generated FKBP5 knock-out cell lines using a CRISPR/Cas9 system and analyzed them. We found that autophagy initiation step was impaired by a loss of FKBP5. The detailed mechanisms will be shown in the presentation. We hope these findings help us to understand the molecular mechanism of how autophagy is associated with depression.

B572/P1553

IGFBP-3 inhibits mTOR to promote mitochondrial hyperfusion and block mitophagy in cells under hyperosmolar stress

W. L. Stuard, I. J. Trautman, D. M. Robertson; UT Southwestern, Dallas, TX

Purpose: Mucosal epithelial surfaces protect tissues from the external environment and are subject to hyperosmolar stress in many different disease states. We have previously found that the Insulin-like growth factor binding protein-3 (IGFBP-3) protects against hyperosmolar stress-induced mitochondrial damage. The objective of this study is to determine the mechanism whereby IGFBP-3 mediates autophagy and mitophagy in mucosal epithelial cells subject to hyperosmolar stress. **Methods**: Telomerized human corneal epithelial (hTCEpi) cells, human conjunctival epithelial cells (HCjECs), and human bronchial epithelial cells (HBECs) were cultured in serum-free keratinocyte basal media (KBM) at 330 mOsm (control), 450 mOsm KBM, or 450 mOsm KBM with recombinant human (rh)IGFBP-3. Cells were treated with siRNA oligonucleotides targeting TSC1 or rapamycin to constitutively activate or inhibit mTOR. Mitochondrial bioenergetics and mitophagy were analyzed using a seahorse metabolic flux assay, TEM, western blotting, immunofluorescence, and live cell imaging. To test the effects of hyperosmolar stress on the ocular surface *in vivo*, an aqueous deficient mouse model of dry eye disease (DED) was developed by injecting botulinum toxin into the exorbital lacrimal gland. Mice were then treated topically with rhIGFBP-3 or vehicle control eye drops. **Results:** Hyperosmolar stress increased autophagic flux. This was associated with a decrease in p-mTOR. rhIGFBP-3 blocked the increase in autophagic flux at 6 and 24 hours and promoted p-mTOR. At 6 hours, rhIGBFP-3 inhibited autophagic

flux through PINK1 and BNIP3L/NIX. At 24 hours, rhIGFBP-3 selectively blocked BNIP3L/NIX. This was associated with an increase in mitochondrial fusion. There was differential expression of PINK1 and BNIP3L/NIX in the mouse corneal epithelium. Treatment with rhIGFBP-3 blocked mitophagy in our DED mouse model. **Conclusion**: IGFBP-3 blocks the hyperosmolar stress-induced increase in autophagic flux and mitophagy through the activation of mTOR. This occurs through differential regulation of PINK1 and BNIP3L/NIX mitophagy. Further studies are needed to investigate the differential expression PINK1 and BNIP3L/NIX in the corneal epithelium.

Rab9 regulation of autophagic flux is mediated by changes in lysosomal positioning

E. G. Krebs[,1], C. Gomatan, A. Peddireddi, M. Ignacio, S. Shaw, A. M. Strohecker[,1]; The Ohio State University, Columbus, OH

Autophagy is a conserved cellular process that degrades damaged cytoplasmic components and supports metabolism. In the final stages of autophagy, the autophagosome fuses with the lysosome forming a hybrid structure called the autolysosome wherein contents are degraded and returned to the cytoplasm. This step requires autophagosomes and lysosomes to be in proximity. Understanding the molecular mechanisms governing lysosome trafficking in the cell will provide important insights into the regulation of autophagy. A previously executed screen demonstrated that silencing the small GTPase *Rab9* robustly increased autophagic flux, suggesting that RAB9 can negatively regulate the pathway. Similarly, silencing *RAB9* in human NSCLC cell lines via lentiviral shRNAs induces autophagic flux. To directly test the ability of RAB9 to regulate autophagy, we introduced HA tagged vector, -RAB9$^{Wild\ type}$ or its hydrolysis resistant (constitutively active) mutant -RAB9^{Q66L} into HEK293 cells and assessed autophagic flux by western blot. We found that expression of the RAB9^{Q66L} mutant is capable of impairing autophagy induced by multiple stimuli, while expression of RAB9$^{Wild\ type}$ facilitates flux. This suggests that the function of RAB9 is regulated by GTP loading status or ability to cycle. RAB9 has previously been implicated in lysosome positioning in HeLa cells. Thus, we asked whether changes in RAB9-mediated lysosome positioning were responsible for the observed autophagic outcome in our 293 and NSCLC cell lines. Lysosome positioning was profiled in *RAB9* intact or silenced A549 cells under nutrient replete or starvation conditions, using LAMP1 immunofluorescence to visualize lysosomes. We found that silencing *RAB9* in this system results in perinuclear clustering of lysosomes and that this occurred in a dose-dependent manner. We hypothesize that the increased perinuclear localization is responsible for the increased autophagic flux observed in the *RAB9* silenced cells. Ongoing work will test this hypothesis by (i) expressing the RAB9^{Q66L} or RAB9^{S21N}(dominant negative, GDP-bound) mutants in the *RAB9* silenced cells and monitoring lysosome position in the resulting cells and by (ii) identifying the effector interactions that mediate this effect. This work identifies a GTPase-dependent mechanism of regulating autophagic flux via controlling lysosome positioning within the cell.

High glucose and high fat differentially regulate autophagic flux in H9C2 cardiac myoblasts

H. Chen, **Y. Hahn**, B. Silverstein, T. Kobayashi, Y. Huang, S. Kobayashi, Q. Liang; NYIT College of Osteopathic Medicine, Old Westbury, NY

Hyperglycemia and hyperlipidemia are two metabolic disorders that contribute to cardiac damage in diabetic patients. However, the mechanisms underlying cellular responses to these stressors are not

fully defined. Autophagy is a cellular protein degradation pathway that plays a key role in cellular response to various stressful conditions, including diabetes. We previously showed that hyperglycemia inhibited autophagic flux in cultured cardiomyocytes and in the hearts of type 1 diabetic mice, which was a protective response that limited hyperglycemic injury. In the present study, we compared the effects of high glucose and high fatty acid on autophagic flux in H9C2 cardiac myoblasts. H9C2 cardiomyocytes were cultured in DMEM containing either high glucose (30 mM) or high fat (25uM Palmitate-BSA) for 72 or 16 hours, respectively. A cocktail of lysosomal protease inhibitors pepstatin A (25ng/mL) and E64d (5ng/mL) were used to measure autophagic flux. For western blotting, whole-cell lysates were probed for expression of LC3-II protein, a well-established marker for autophagic vacuoles. Autophagic flux was determined by comparing the expression levels of LC3-II with and without protease inhibitors. In the immunofluorescence assays, cells were infected with an adenovirus that encodes an autophagy reporter known as tandem fluorescently tagged mRFP-GFP-LC3. Autophagic flux was determined by comparing the area occupied by mature autolysosomes (red puncta or dots) with and without the inhibitors. The western blot analysis showed that high glucose inhibited, while high fat accelerated autophagic flux, as indicated by the difference in LC3-II levels in the presence and the absence of the lysosomal inhibitors. These results were corroborated in reporter studies as shown by the area or number of puncta. In addition, 3-Methyladenine (3-MA), an inhibitor of autophagosome formation, decreased high fat-induced cell death as shown by propidium iodide staining, suggesting that high fat-induced autophagy was detrimental. Together, our study demonstrated opposite effects of high glucose and high fat on autophagy flux, highlighting the complexity of cellular responses to diabetes-like stressors in H9C2 cells. Future studies will investigate the signaling mechanisms that mediate these differential responses in cardiomyocytes and in the heart.

B575/P1556

Interplay between secretory autophagy and macroautophagy in neurons

S. D. Palumbos, J. Goldsmith, E. L. F. Holzbaur; University of Pennsylvania, Philadelphia, PA

Unlike most cell types, neurons are largely resistant to autophagy induction following starvation or stress. Instead, autophagy primarily functions as a homeostatic mechanism, constitutively degrading damaged proteins and organelles. This reduced capacity for autophagy induction could leave neurons particularly vulnerable to stress, especially considering neurons are post-mitotic, precluding them from clearing damaged proteins and organelles through cell division. Do neurons mobilize additional pathways to discard of damaged material when their capacity for autophagy is overwhelmed? Recent findings suggest that autophagy-dependent degradation and autophagy-dependent secretion can act in coordination to regulate cellular homeostasis in non-neuronal cell types. When autophagosome maturation is impeded, autophagy-dependent secretion of extracellular vesicles (EVs) can be initiated as a mechanism to unburden the degrative machinery. Whether neurons similarly extrude damaged material via autophagy dependent secretion is unclear. We propose that stressed neurons engage autophagy-dependent secretion as an alternate quality control mechanism to dispel cellular waste. This is supported by several preliminary observations. First, we observe that LRRK2 mutant neurons, which exhibit strained degradative autophagy, shunt cargo toward a secretory fate. Additionally, we observe that treating cultured neurons with Bafilomycin A1, effectively blocking lysosomal fusion, prompts the upregulation of secretion. Together, our data suggest that chronically or acutely straining macroautophagy leads neurons to upregulate secretory autophagy. These observations have important implications in neurodegenerative diseases where autophagy is strained, and the expulsion of damaged

proteins or dysfunctional organelles could heighten systemic inflammatory responses. Future directions will further describe interplay between cell-autonomous autophagy and secretory autophagy.

B576/P1557

Atlastin regulates Tor signaling and autophagy in *Drosophila* muscle through alteration of the lysosomal network

S. Srivastav, K. van der Graaf, P. Singh, A. Budi Utama, J. A. McNew, M. Stern; Rice University, Houston, TX

Aim: The hereditary spastic paraplegias (HSPs) represent a family of genetic disorders comprising at least 72 different genes with the common pathology of progressive locomotor deficits and spasticity thought to result from degeneration of upper motor neurons. *atlastin* (*atl, SPG3A*) encodes an ER fusion protein that controls ER morphology, which implicates ER morphology as a causal factor in HSP, but it is not clear how altered ER morphology might result in neurodegeneration.**Method:** Here we use *Drosophila melanogaster* to study the effects of decreased *atl* activity on properties of the larval body wall muscle. Given that one of the primary phenotypes observed in muscle lacking *atl* involves accumulation of aggregates containing poly-ubiquitin (poly-UB), we hypothesize that autophagy flux could be affected. Therefore, different approaches were used to study autophagic flux in muscle lacking *atl*.**Results:** We find that muscle *atl* loss causes accumulation of poly-UB aggregates, most bound to autophagy receptor p62/SQSTM1 (ref(2)p). Muscle *atl* loss also decreases volume and complexity of the lysosomal network as visualized with RFP linked to the lysosomal gene *spinster (spin)* and decreases the number of punctae labelled with LAMP1. To determine effects of these lysosomal deficits on progression through the autophagy pathway, we expressed *ATG8a* tagged with both *GFP* and *mCherry* in a wildtype and *atl* mutant background. We observed numerous punctae with mCherry but not GFP fluorescence in wildtype animals indicating that ATG8 was found mostly in autolysosomes. In contrast, muscles lacking *atl* exhibited a significant number of punctae marked with both mCherry and GFP. This compartment was also labelled with the late endosomal marker Rab7 but not lysosomal marker LAMP1, suggesting that these punctae were most likely amphisomes. We also found that loss of *atl* leads to inability to activate the Tor kinase, perhaps due to the altered lysosomal network.**Conclusion:** We suggest that the accumulation of amphisomes containing cargo in larvae lacking *atl* indicates an inability of autophagosomes to merge with lysosomes, causing autophagosome fusion to be diverted to endosomes. Our results provide new mechanistic insights into the role of Atl, and hence ER morphology, in maintaining cell viability and raise the possibility that certain pathologies in patients with mutations in *SPG3A* might result from altered Tor signaling.

ATG2A Extracts Lipids from ER Exit Sites to Promote Autophagosome Biogenesis

D. Fuller, T. Olivas, Y. Wu, K. Melnyk, P. De Camilli, T. Melia; Yale University, New Haven, CT

Macroautophagy involves the mobilization of millions of lipids in less than ten minutes and requires the establishment of a membrane contact site between a contested donor membrane and the nascent autophagosome. Recent work demonstrated that the essential autophagy protein ATG2A is a bridge-like lipid transport protein that tethers the donor membrane to the early autophagosome to facilitate a rapid transfer of lipids. As ATG2A must interact with the donor membrane to extract lipids, we performed proximity labeling and mass spectrometry to identify proteins on this organelle. Intriguingly,

we found an abundance of ER Exit Site (ERES) proteins which have previously been implicated in autophagosome biogenesis via COPII vesicle fusion. In this body of work, we propose a new model of ERES - autophagosome interaction in which ATG2A competitively interacts with the early secretory pathway by extracting lipids from the ER exit site. We first confirmed colocalization of ATG2A and ERES proteins by live cell imaging and found by co-immunoprecipitation that the N-terminus of ATG2A interacts with ERES proteins. To perturb ATG2A recruitment to the donor membrane, we overexpressed Sar1bH79G, which distorts the ERES membrane. We found that under starvation conditions, ATG2A was occasionally recruited to tubular structures. By CLEM-FIBSEM, we found that these structures corresponded to thin, compact membranes that resembled distorted phagophores. We further found that ATG2A localized on the rim of cup-like structures and along the length of the tubular structures, suggesting a strong curvature preference. Sites of ATG2A localization also contained a high density of membrane contacts with adjacent tubular ER, which could potentially cause this phenotype. To drive autophagosome biogenesis and thereby the association between ATG2A and the donor membrane, we transiently rescued ATG2 DKO cells which contain large compartments filled with pre-autophagosome materials with ATG2A. Under these conditions, ATG2A and ERES proteins strongly colocalize at or near LC3B positive structures. These results, taken together, strongly affirm that ERES function as the donor membrane for autophagosome biogenesis.

A putative disease-causing mutation in autophagy protein ATG3

E. Guinn[1], L. Wang[1], S. Yang[1,2], W. Ji[3], A. Cuentas-Condori[1,2], L. Jeffries[3], V. Knight[4], B. Asomanning[1], M. Khokha[3,5], D. Colón-Ramos[1,2], S. Lakhani[3], T. Melia[1]; [1]Department of Cell Biology, Yale University, New Haven, CT, [2]Department of Neuroscience, Yale University, New Haven, CT, [3]Department of Pediatrics, Yale University, New Haven, CT, [4]Department of Pediatric Neurology, Yale University, New Haven, CT, [5]Department of Genetics, Yale University, New Haven, CT.

Macroautophagy is a degradative cellular process that is upregulated in response to stress. Dysregulation of autophagy and associated pathways are broadly associated with several diseases including cancer, aging, and neurodegeneration. However, since this process is essential for mammalian development, diseases affecting core autophagy genes are very rare. For example, ATG3 is a core autophagy gene driving autophagosome biogenesis; there are no known disease-causing mutations within this gene. However, a patient with an undiagnosed severe neurodevelopmental disease was found to have a point mutation in a single allele of the ATG3 gene. To explore the potential disease-causing impacts of this patient mutation we tested ATG3 function in patient cells, in cell culture models, *in vitro*, and in an animal model. Fibroblasts isolated from the patient display a dysfunctional autophagy response to amino acid starvation. This mutated ATG3 cannot support the conjugation of Atg8 proteins to lipid, the formation of Atg8 puncta nor the lysosome-dependent turnover of Atg8, all suggesting that this mutant is inactive in autophagy. However, in vitro biochemistry reveals the mutant retains the ability to capture Atg8 via a thioester bond, suggesting it is only the final deposition on lipid that is inhibited. ATG3 mediates other conjugations largely independent of autophagy, including the formation of a self-conjugated ATG12-ATG3 complex and the Atg8-ylation of proteins. The patient mutation also fails support the redistribution of endosomes normally driven by ATG12-ATG3, suggesting this pathway is also inhibited. Finally, *C. elegans* with a mutation at this conserved position display significant defects in viability, development, and locomotory behavior that are consistent with autophagy gene knockouts. Thus, this appears to be the first example of an ATG3-dependent disease.

Protein Aggregation, Protein Folding and Phase Separation

B579/P1560

Linking proteostasis and the 12-hour rhythms of nuclear speckle liquid-liquid phase separation dynamics

W. Dion[1], H. Ballance[1], J. Lee[2], Y. Pan[3], S. Irfan[1], C. Edwards[1], M. Sun[1], J. Zhang[1], X. Zhang[4], S. Liu[1], B. Zhu[1]; [1]University of Pittsburgh School of Medicine, Pittsburgh, PA, [2]University of Pittsburgh, Pittsburgh, PA, [3]UPMC Genome Center, Pittsburgh, PA, [4]The Pennsylvania State University, State College, PA.

Organismal health requires a consistent and balanced internal environment known as homeostasis; different physiological processes maintain proper levels of biomolecules at a cellular level. Proteostasis, sustained levels of correctly folded proteins in the endoplasmic reticulum (ER), is maintained by the Unfolded Protein Response (UPR). Excessive misfolded proteins in the ER activate the three branches of the UPR, facilitating adaptive processes to restore a balanced proteome in the cell. XBP1s-dependent ultradian rhythms of ER stress and subsequent UPR-mediated stability are apparent in mammals and produce a 12-hour clock that functions independently of the 24-hour clock or the cell cycle. This 12-hour clock links the liquid-liquid phase separation (LLPS) dynamics of the nuclear speckle (NS) to the UPR through SON, the NS core protein. High SON levels create a diffuse and fluid NS, boost the expression of UPR-associated genes, and improve the cell's ability to clear aggregated proteins. In contrast, low SON levels result in a spherical and stagnant NS, blunt the expression of UPR genes, and weaken the cell's ability to clear insoluble protein aggregates. Furthermore, murine hepatic *Son* levels decrease with age, suggesting that NS LLPS dynamics may change over the course of mammalian lifespan. This link between NS LLPS dynamics and proteostasis identifies a potential target to combat diseases with dysregulated proteostasis.

Investigating TDP-43 Toxicity via Human Suppressor Genes in *Saccharomyces cerevisiae*

C. Alspaugh, E. Hayden, S. Ju, S. Chen, B. Stammen, Q. Zhong; Biological Sciences, Wright State University, Fairborn, OH.

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease, is a neurodegenerative disease that is either inherited (fALS) or occurs sporadically (sALS). A pathogenic hallmark of ALS, similar to other neurodegenerative diseases such as Parkinson's and Alzheimer's, is the mislocalization and aggregation of certain proteins. Over the years, many proteins have been implicated in the pathology of ALS, but one group of proteins has been of recent interest: RNA-binding proteins. One RNA-binding protein of interest is TDP-43, which is found to be toxic, mislocalized, and aggregated in the neurons of patients with ALS. These toxic phenotypes have been recapitulated in the well-conserved budding yeast model. To study the pathology of TDP-43 toxicity, we have conducted genetic screens to uncover human genes that are able to reduce TDP-43 toxicity in yeast. We identified fifty human genes capable of rescuing toxicity and performed growth assays, microscopy, immunoblotting, and protein-protein interaction studies to determine the mechanism of rescue. While these human genes reduced cell death in yeast, there was no alteration in TDP-43 aggregation patterns nor TDP-43 protein levels in the presence of these genes; thus our human gene suppressors must be rescuing toxicity independent of TDP-43 aggregation. By investigating the normal functions of our human suppressor genes, we can begin to

elucidate what other pathways might be at play in TDP-43 toxicity, giving a better scope of TDP-43's role in ALS pathology.

B581/P1562

Composition can buffer protein dynamics within liquid-like condensates.

S. Jelenic[1], J. Bindics[1], P. Czermak[1], B. R. Pillai[1], M. Ruer[2], C. Hoege[2], A. S. Holehouse[3], S. Saha[1]; [1]Institute of Molecular Biotechnology (IMBA), Vienna, AUSTRIA, [2]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, GERMANY, [3]Department of Biochemistry and Molecular Biophysics, Washington University School of Medicine, St. Louis, MO.

Compartmentalization of cellular biochemistry in membrane-less condensates has emerged as a key regulatory principle of many physiological processes. Many of these condensates have a complex composition and form via liquid-liquid phase separation. Rates of biochemical reactions within these condensates depend on diffusion rate of its components. It has been unclear if condensates can deliver robust functional output despite changing conditions e.g. short-term effects of chemical modifications, intrinsic mutational changes, accumulation of high local concentration of sticky molecules.
Here, we address the mechanism that regulates diffusion rate of a scaffold protein (PGL-3) within the liquid-like P granule condensate in adult gonads of *C. elegans*. Scaffold proteins contribute to assembly of most liquid-like condensates in cells and account for a large fraction of the mass within these condensates. The protein PGL-3 is 693 residues long. We found that a folded alpha-helical domain accounting for 65% of the PGL-3 protein drives liquid-liquid phase separation *in vitro*. Using mutational analysis and biophysical perturbations, we generated PGL-3 constructs with reduced alpha-helicity that phase separate into condensates *in vitro* with significantly slower diffusion rates compared to wild-type PGL-3. In contrast, within the P granule condensate (a complex mixture of RNA and >50 proteins) *in vivo*, these PGL-3 constructs diffuse at rates similar to wild-type PGL-3. This suggests that, in liquid-like condensates, composition can buffer against large change in diffusion rates of proteins (hereafter called 'dynamics-buffering').
We investigated the molecular mechanism of dynamics-buffering using *in vitro* reconstitution. It is generally thought that chaperone proteins and/or ATP-dependent RNA helicases are essential to counteract the slow-down of diffusion rate in biomolecular condensates that might result from denaturation of components or inter-polypeptide/RNA chain entanglements. In contrast, we found that weak interactions among two or more components within P granule-like condensates can account for dynamics-buffering. As expected of a buffer, we found that diffusion rate of PGL-3 constructs within condensates remain relatively unchanged regardless of changes in intra-condensate concentration. Once the buffering capacity is exhausted i.e. beyond a threshold intra-condensate concentration, diffusion rate of PGL-3 constructs slow down at higher concentrations.
We speculate that dynamics-buffering of proteins may contribute to robust functional output of cellular liquid-like compartments.

B582/P1563

Oligodendrocyte function in health and disease is regulated by liquid condensate properties of Tubulin Polymerization Promoting Protein

S. Kemal[1], H. Richardson[1], T. McAlear[2], A. Kopach[1], J. Nowacki[1], S. Bechstedt[2], M. Fu[1]; [1]NINDS, NIH, Bethesda, MD, [2]McGill University, Montreal, QC, CANADA.

Axon myelination is carried out by oligodendrocytes, which undergo intense cytoskeletal transformation to carry out this function. We previously showed that Tubulin Polymerization Promoting Protein (TPPP) is a microtubule nucleator that localizes to Golgi outposts in oligodendrocytes. TPPP regulates microtubule polarity and branching, and *Tppp* KO mice have shorter myelin sheaths and are hypomyelinated. TPPP aggregates have been documented alongside α-synuclein inclusions in oligodendrocytes in the neurodegenerative disorder Multiple System Atrophy (MSA). There are currently no therapies for MSA, which leads to death within an average of 9 years from symptom onset. There is a critical need to understand MSA disease etiology to identify viable targets for intervention. We are now investigating the link between TPPP and MSA at the protein, cellular, and organismal level. At the protein level, we made the discovery that recombinant TPPP forms liquid condensates that are functional and robustly nucleate microtubules. TPPP shares many properties common to proteins that undergo liquid-liquid phase separation. First, TPPP contains a prominent N-terminal intrinsically disordered region. Second, TPPP droplets undergo fission and fusion. Third, recombinant TPPP droplets are dynamic in FRAP experiments. At the cellular level, GFP-TPPP expressed in cultured primary rodent oligodendrocytes also exhibit liquid condensate properties by forming droplet-like structures and exhibiting fast FRAP recovery. Surprisingly, overexpression results in aberrant aggregation along the microtubule lattice of GFP-TPPP, which does not recover by FRAP. At the organismal level, MSA patient brains contain widespread perinuclear cytoplasmic TPPP inclusions in oligodendrocytes. We identify a discrete population of TPPP inclusions that are fibril-like, far from the cell body, and colocalize with myelin markers. Contrary to prevailing hypotheses, our data suggest that aggregation initiates at distal sites where TPPP is normally localized to perform microtubule nucleation and subsequently spreads to the perinuclear cytoplasm. Also, we observed many perinuclear TPPP inclusions that lack α-synuclein, suggesting that TPPP aggregation may precede α-synuclein aggregation. Finally, to confirm causality (i.e., TPPP aggregation can cause disease), we performed stereotaxic injection of recombinant TPPP fibrils into wildtype and *Tppp* KO mouse brains. Together, our results showcase the duality of TPPP. Its normal liquid condensate properties allow it to exert precise control over oligodendrocyte microtubule architecture, thus enabling myelin sheath formation. However, these properties increase its propensity to aggregate and contribute to disease pathology.

B583/P1564

RNP condensates decrowd the cytoplasm in stress conditions

Y. Xie, D. Gresham, L. Holt; New York University, New York, NY

The intracellular environment is packed with macromolecules, and this crowded environment has profound impacts on cellular biochemistry. The cytoplasm can be further organized into condensates including ribonucleoprotein (RNP) granules, like P-bodies and stress granules. These RNP granules are crucial in both normal physiology and diseases, such as cancer and neurodegeneration, yet the precise function of these condensates remains elusive. We analyzed the motion of self-assembling fluorescent nanoparticles of 40 nm diameter (40nm-GEMs) as microrheology probes to infer macromolecular

crowding levels. Previous studies in yeast suggested that, upon acute glucose starvation, increased macromolecular crowding and reduced cytoplasmic pH lead to a protective solid-like state of the cytoplasm at the ~100 nm length-scale. Surprisingly, our probes revealed a transient reduction of macromolecular crowding at the 40 nm length-scale in response to acute environmental stresses. Using a combination of mutants, chemical perturbations, and inducible synthetic RNP granules, we found that the collapse of polysomes, and the partitioning of mRNAs into RNP-granules is required for this cytoplasmic decrowding. These findings suggest a new role of RNP granules in modulating the biophysical property of the cytoplasm.

Unexpected, but conserved control of protein self-assembly by translation initiation, in eukaryotes

S. Venkatesan[1], J. J. Lange[1], B. Lerbakken[1], D. Tsuchiya[1], P. Berry[1], S. Swanson[1], Y. Hao[1], L. Florens[1], T. S. Kandola[1], M. Cook[1], B. Slaughter[1], J. Unruh[1], R. Halfmann[1,2]; [1]Stowers Institute for Medical Research, Kansas City, MO, [2]University of Kansas Medical Center, Kansas City, KS

Living proteomes are necessarily far from equilibrium. It is paradoxical, then, that reducing protein influx -- which should promote equilibration -- instead, prolongs life across numerous model systems. Protein aggregation to thermodynamically favored but kinetically limited self-assemblies like amyloids often depletes normal protein function and proteostasis, in turn. We therefore reasoned that kinetic barriers to energetic equilibration of native states to rare but probabilistic amyloid-like states decrease with protein influx.

We used Distributed Amphifluoric FRET to measure kinetic barriers by quantitatively reading out protein self-assembly at single cell resolution, over a range of the query protein's intracellular concentration in vivo. We expressed structurally diverse proteins inducible from a high-copy plasmid in living yeasts at different strengths of translation initiation controlled either globally (pharmacologically) or specifically (uORF or Kozak), while maintaining the same level of query protein expression by controlling plasmid copy number. Remarkably, all reductions in translation initiation hampered seed formation irrespective of neither the query protein structure nor the expression level.

The provision of a pre-existing seed revealed that the proteins remained fully competent for polymerization. Translation, thus, only specifically influences the kinetic barrier to aggregation, and not their ability to aggregate. Various manipulations to enhance polypeptide interaction and residence time on the polysome, such as domain positioning and ribosome collisions, downstream of the coding region of interest, also enhanced aggregation of the query proteins. Single molecule FISH revealed clusters of mRNA in the cytosol, in all experimental manipulations, potentially becoming a pre-requisite for our observations.

We also asked if a tight dodecamer translated equally from two traceable alleles, formed complexes from polypeptides of one allele in strong initiation and from both alleles in poor initiation strengths, and preliminary data agrees.

Finally, our observations are true in both yeast and mammalian cells alike, thereby underscoring the widely conserved nature of this phenomenon. Thus, translation initiation strength potentially dictates the behavior of a wide range of protein classes, across eukaryotes, in strikingly profound manner. We are now exploring both - the underlying physical mechanism, as well as the physiological implications of this phenomenon, via proteomics, mathematical modeling, computational mining of RiboSeq datasets.

Dissecting the mechanics of the Hrd1-centric ERAD system

B. G. Peterson, J. Hwang, J. Russ, J. Schroeder, P. Freddolino, R. D. Baldridge; University of Michigan, Ann Arbor, MI

Endoplasmic reticulum associated degradation (ERAD) is a conserved eukaryotic system that surveils and clears misfolded proteins from the ER. In addition, ERAD regulates key enzymes in biosynthetic pathways and is exploited by a number of infectious agents. We focus on the Hrd1-centric ERAD system that degrades both luminal proteins (ERAD-L) and membrane proteins (ERAD-M) in *S. cerevisiae*. Hrd1-ERAD substrates are recognized, retrotranslocated across the ER membrane to the cytosol, ubiquitinated, extracted from the ERAD system by the Cdc48 complex, and ultimately degraded by the 26S proteasome. Despite its importance in eukaryotic physiology, the mechanics of how this system recognizes, transports, and delivers its substrates to downstream proteins remains unclear. To dissect the function of this system, we conducted total codon mutagenesis on Hrd1 coupled with a fluorescence-based assay to screen for separation of function mutants. We have identified classes of mutants that specifically fail to degrade either ERAD-L or ERAD-M substrates. Using both cell-based and reconstitution biochemical assays, we're interrogating whether the defective degradation results from errors in substrate selection, retrotranslocation, or extraction from the ERAD complex. This work has generated novel insight into how Hrd1 selects, transports, and ubiquitinates its different classes of substrate.

B586/P1567

RAGE Ligands and Protein-Degrading Systems in Animal Models of Neurodegeneration and Normal Senescence

L. A. Lysenko, N. P. Kantserova, N. L. Rendakov; Karelian Research Centre, Russian Academy of Sciences, Petrozavodsk, Russian Federation

The accumulation of irreversibly modified (glycated, carbonylated, aggregated etc.) proteins may result from the deficiency of their clearance pathways including intracellular proteolytic degradation. In murine models of amyloid- and glutamate-induced neurodegeneration, as well as in senile brain, we detected the aggregated abnormal protein deposits, inflammatory responses, oxidative stress, dysregulation of calcium homeostasis, and elevated levels of several S100 calcium-binding proteins. Neurodegeneration and normal ageing were accompanied by a reliable change in concentration, localization, and enzymatic activities of catheptic proteases, decreased proteasome complex assemblage, hyperactivation of calpain-dependent proteolysis, and upregulation of caspase 3. Functionally, lysosomal autophagy and ubiquitin-proteasome systems control protein quality and eliminate damaged ones, and highly selective calpain and caspase systems mediate necrotic and apoptotic pathways of cell death. Senile plaque surroundings express higher levels of the receptor for advanced glycation end-products (RAGE), an immunoglobulin-like cell surface receptor. When bound diverse ligands, such as β-amyloid, advanced glycation end-products (AGEs), transthyretin, and S100 proteins, RAGE appears to initiate several signal transduction cascades resulting in oxidative stress and NF-κB activation. Advanced glycation end-products (AGEs), the proteins, lipids, and nucleic acids modified by reducing carbohydrates, could be consumed with high-temperature cooked meal (exogenous source) and generated in inflamed, ischemic, and oxidatively damaged tissues (endogenous path). We revealed negative correlation of total AGEs level with serum cholecalciferol (vitamin D3) and

endogenous antioxidants, such as GSH system. Moreover, dietary supplementation with natural antioxidants, such as dihydroquecetin, resveratrol, ascorbic acid, occurs to effectively reduce protein glycation, particularly hemoglobin glycation and even heme oxidation in model animals. So, depletion of RAGE ligand pool via dietary antioxidant supply may be considered as a path to decrease chronic inflammation and cell loss. The study was fulfilled as a part of the budgetary task FMEN-2022-0017.

Spatial Temporal Modeling & Bioinformatics

The correlation between cell and nucleus size is explained by an eukaryotic cell growth model

Y. Wu[1], A. Pegoraro[2], D. Weitz[3], P. Janmey[4], S. Sun[1]; [1]Johns Hopkins University, Baltimore, MD, [2]University of Ottawa, Ottawa, ON, CANADA, [3]Harvard University, Boston, MA, [4]University of Pennsylvania, Philadelphia, PA.

In eukaryotes, the cell volume is observed to be strongly correlated with the nuclear volume. The slope of this correlation depends on the cell type, growth condition, and the physical environment of the cell. We develop a computational model of cell growth and proteome increase, incorporating the kinetics of amino acid import, protein/ribosome synthesis and degradation, and active transport of proteins between the cytoplasm and the nucleoplasm. We also include a simple model of ribosome biogenesis and assembly. Results show that the cell volume is tightly correlated with the nuclear volume, and the cytoplasm-nucleoplasm transport rates strongly influence the cell growth rate as well as the cell/nucleus volume ratio (C/N ratio). Ribosome assembly and the ratio of ribosomal proteins to mature ribosomes also influence the cell volume and the cell growth rate. We find that in order to regulate the cell growth rate and the cell/nucleus volume ratio, the cell must optimally control groups of kinetic and transport parameters together, which could explain the quantitative roles of canonical growth pathways. Finally, although not explicitly demonstrated in this work, we point out that it is possible to construct a detailed proteome distribution using our model and RNAseq data, provided that a quantitative cell division mechanism is known.

B590/P1569

Exploring mechanistic rules governing emergent hiPSC colony dynamics using iterative agent-based model development

J. S. Yu[1], .. Allen Institute for Cell Science[1], G. Johnson[1], N. Bagheri[1,2]; [1]Allen Institute for Cell Science, Seattle, WA, [2]University of Washington, Seattle, WA.

The Allen Institute for Cell Science aims to understand the principles by which human induced pluripotent stem cells (hiPSCs) establish and maintain the robust dynamic localization of their cellular structures, and how these cells transition between states during differentiation and disease. hiPS cells grow in epithelial-like colonies where changes in individual-level cell and nuclear shape are tightly coupled to population-level colony dynamics. We interrogate the emergent dynamics of growing hiPSC colonies through the iterative development of cell colony agent-based models (ABMs)—computational modeling frameworks comprising autonomous cell agents guided by biologically-derived rules—in an effort to establish minimal sets of rules that can explain observed states we have previously quantified. We integrate an existing ABM framework (https://github.com/bagherilab/ARCADE) with a 3D Cellular Potts-based representation of both cell and nuclear shape. Initial simulations of simple models with

basic rules guiding cell growth, division, and death are parameterized and validated by comparing simulated distributions of cell and nuclear size to the hiPSC single cell image dataset (https://open.quiltdata.com/b/allencell/tree/aics/hipsc_single_cell_image_dataset). We then systematically evaluate different combinations of rule sets to identify possible explanatory mechanisms underlying observed cell shape distributions. To interrogate and predict colony dynamics with this baseline model, we initialize simulations using the segmentation of nuclei in the first frames of 3D time-lapse videos of growing colonies of mEGFP-tagged laminB1 hiPSCs from the Allen Cell Collection. Cell shapes are approximated from the nuclear shapes using a Voronoi tessellation. Spatial and temporal dynamics of the simulated cell and nuclear sizes, shapes, and positions within the colony are extracted and compared to those observed in the corresponding 3D time-lapse videos. We expect that similarities and differences between simulated and observed colony behavior will provide insight into the underlying mechanisms necessary or sufficient for the emergence of specific dynamics. Iterative model development, which tightly couples model development with experimental observations and expert feedback, provides the opportunity for hypothesis testing and hypothesis generation. The computational framework presented is modular and open-source to facilitate application to diverse systems and collaboration across disciplines.

Temporal and spatial topography of proliferation in cancer

S. Kabraji[1], G. Gaglia[2], D. Rammos[2], Y. Dai[2], A. Verma[2], J. Bergholz[1], W. Wang[1], S. Wang[3], C. Mills[3], M. Chung[3], S. Coy[2], J. Lin[3], R. Jeselsohn[1], O. Metzger[1], E. P. Winer[4], D. Dillon[2], J. J. Zhao[1], P. Sorger[3], S. Santagata[2]; [1]Dana Farber Cancer Institute, Boston, MA, [2]Brigham and Women's Hospital, Boston, MA, [3]Harvard Medical School, Boston, MA, [4]Yale Cancer Center, New Haven, CT.

Cancers are complex ecosystems where intracellular and extracellular signals are integrated to modulate tumor cell proliferation. However, cell-cycle state characteristics, spatial organization, and evolution with perturbation are poorly characterized in tumor tissues. We used multiplexed tissue imaging to develop a robust classifier of proliferation, the multivariate proliferation index (MPI), and applied this to map proliferative and non-proliferative cells in 650 unique tumors across five cancer types. Next, we created a framework for studying cell cycle dynamics using images of fixed tissues, based on time inference. Finally, we used single cell RNA sequencing (scRNAseq) to probe the gene expression programs underlying cell cycle states. The MPI outperforms single markers, like Ki67, when classifying proliferative index across diverse tumor types. Markers of quiescent, stem, and dormant cancer cells identified unique populations of non-proliferating cancer cells. Proliferative and non-proliferative cancer cells are organized across microscopic and macroscopic length scales that are reshaped by therapy. Local clusters of proliferative and non-proliferative tumor cells preferentially neighbor distinct tumor-infiltrating immune cells. In high-dimensional marker space, populations of proliferative cancer cells express canonical patterns of cell cycle protein markers, a property we refer to as "cell cycle coherence". Untreated tumors exist in a continuum of coherence states, ranging from optimal coherence, akin to freely cycling cells in culture, to reduced coherence characterized by either cell cycle polarization or non-canonical marker expression. Coherence can be stereotypically altered by induction and abrogation of mitogen signaling in a HER2-driven model of breast cancer, and with neoadjuvant therapy in patients with localized breast cancer. Microscopic residual tumor cells after HER2 inhibition from patients and tumor models have similarly skewed cell cycle dynamics. scRNAseq of residual tumor cells with skewed cell cycle dynamics suggests that upregulation of the nucleolar stress response is necessary to survive

HER inhibition. In sum, the MPI robustly defines proliferating and non-proliferating cells in breast cancer tissues, with immediate implications for clinical practice and research. The coherence metrics capture the diversity of post-treatment cell cycle states directly in clinical samples from patients with breast cancer, a fundamental step in advancing precision medicine. Replacing binary metrics with multivariate traits provides a quantitative framework to study temporal processes from fixed static images and to investigate the rich spatial biology of human cancers.

Community-driven FAIR data management and reproducibility for the entire image-data life cycle

J. Ryan[1], A. Rigano[2], A. Kang[3], S. C. Ogg[4], J. Lacoste[3], T. Stroh[5], C. M. Brown[6], **C. Strambio-De-Castillia**[2]; [1]Advanced BioImaging Facility - Department of Physiology, McGill University, Montreal, QC, CANADA, [2]Molecular Medicine, University of Massachusetts Medical School, Worcester, MA, [3]MIA Cellavie, Montreal, QC, CANADA, [4]IMAGING AND CHARACTERIZATION CORE LAB, King Abdullah University of Science and Technology, Thuwal, SAUDI ARABIA, [5]Neurology & Neurosurgery, McGill University, Montreal, QC, CANADA, [6]Advanced Bioimaging Facility - Department of Physiology, McGill University, Montreal, QC, CANADA.

Significant advances in spatiotemporal resolution have led to ever-expanding microscopy datasets which, without agreed-upon community guidelines, are challenging to manage, curate, reproduce, quantitatively analyze (including AI-assisted strategies), visualize, publish, and re-use (10.1038/nrd3439-c1; 10.1038/483531a; 10.7554/eLife.67995; 10.7554/eLife.45120/).

As such, biomedical advances crucially depend on the generation of high-quality Findable, Accessible, Interoperable, and Reproducible (FAIR; 10.1038/sdata.2016.18) datasets. This, in turn, requires the seamless integration of community-specified image documentation practices within the Research Data Management (RDM) processing pipelines required to ensure the execution, tracking, and documentation of the entire life cycle of data from sample preparation to publication (i.e., data provenance).

This is important for microscopy, where data interpretation is crucially dependent on easy-to-use RDM software enabling the capture and reporting of knowledge that is collectively termed Image Metadata, and that consists of three key aspects: i) biological context (i.e., organism, growth conditions, sample-type); ii) image acquisition (i.e., microscope hardware/settings/quality-control); and iii) image processing (i.e., software, analysis steps).

To illustrate these points, this presentation will first introduce recently published 4DN-BINA-OME-QUAREP community-driven Image Metadata specifications developed in the context of international bioimaging initiatives (10.1038/s41592-021-01327-9) and how they can be applied to typical light microscopy experiments.

This will be followed by a deep dive into the importance of incorporating robust microscopy quality assessment and reporting procedures in the life cycle of light-microscopy data to ensure rigor, reproducibility, and reusability.

The discussion will identify key stages in the pathway that includes image data acquisition, management, analysis, and dissemination and provide OMERO-based concrete and practical examples of how open-source tools and protocols developed by an international consortium of community initiatives led by QUality Assessment and REProducibility in Light Microscopy (QUAREP-LiMi), are being utilized in close collaboration with Canada Bioimaging, at McGill University and UMass Medical School to capture and report the necessary quality-control metrics and metadata to support the reproducibility

and reusability of image-based datasets.
Finally, the presentation will also introduce the Micro-Meta App and MethodsJ2 software tools that allow researchers to collect detailed microscope hardware and acquisition settings metadata and generates draft methods text for publication.

A Deep Learning Model to Accelerate Molecular Dynamics Simulations of Membrane Fusion for Exocytosis

H. Zhu, D. An, B. O'Shaughnessy; Columbia University, New York City, NY.

Fusion of vesicle and targetmembranes to release neurotransmitters and other contents is central toexocytosis for neurotransmission, hormone secretion and other processes. Thecore components of the cellular fusion machinery are the SNARE proteins. Fusionglycoproteins with mechanistic parallels are used by SARS-CoV-2 and otherenveloped viruses for cell entry.
The mechanisms of membranefusion are poorly understood. A major obstacle is that simulating membranes withtens of thousands of phospholipids and a multiprotein machinery on millisec timescalesis highly computationally demanding. Further, the high complexity makes itdifficult to identify patterns of molecular behavior on the fusion pathway.Previously, we developed ultra coarse-grained molecular dynamics (MD) simulationsof SNARE-driven fusion on msec timescales for the first time (Zeng et al.,2021). However, fusion required lengthy simulation, and intermediate states remainpoorly characterized.
Compared to traditionalanalytical tools, deep learning models are far better adapted to pattern recognitionin complex systems, exploited by applications from image classification tospeech recognition. Here, we developed a deep learning model to accelerate MDmembrane fusion simulations, to compute free energy landscapes and to characterizerarely visited intermediates.
We identified a novelcollective coordinate encoding the probabilistic destiny (unfused, hemifused orfused) of a molecular state on a given timescale, and we used a branchingalgorithm to generate training data. We developed and trained a deep learning basedclassifier to compute the collective variable for a given molecular state, andused the classifier to develop a bias function represented as a deep neural network.This enabled enhanced sampling, calculation of free energies and accelerated computationof fusion times. Our method is applicable to a wide range of molecular systems.
We find vesicle-planarmembrane fusion is driven by SNARE-SNARE entropic forces that press membranestogether and catalyze hemifused connections called stalks, until a stalk expandsinto a hemifusion diaphgragm whose rupture produces fusion by tension-driven formationof a pore. Consistent with measurementsat neuronal synapses, for 8-10 SNAREs mean fusion times are sub-millisecond, decreasingwith number of SNAREs due to increased entropic forces.

Cellular Drift and Diffusion in *Myxococcus xanthus*

K. Gibson[1], C. Grant[1], C. Cotter[2], L. Shimkets[2], H. Schüttler[1]; [1]Physics and Astronomy, University of Georgia, Athens, GA, [2]Microbiology, University of Georgia, Athens, GA.

We apply a novel integral equation (IE) formalism for stochastic cell movements, to examine experimental microcinematography data sets of random cell trajectories, observed in *M. xanthus* populations which exhibit either collective rippling wave or collective aggregation behavior, also known

as fruiting body formation. In terms of our IE-based data analysis, these two types of cell populations are characterized by fundamental differences in their single-cell drift-diffusion dynamics. Specifically, the IE formalism allows us to extract, from the observed cell trajectory data, effective single-cell drift and diffusion coefficients, *C(rho)* and *D(rho)* respectively, including their dependence on the ambient (local) cell density, *rho*. The observed single-cell trajectories are represented in this analysis as a stochastic sequence of straight-line "runs" of random duration, *tau*, speed *v*, and bearing angle *theta*, each run being followed by a "reversal" with random turning angle, *phi*. *C(rho)* and *D(rho)* are then expressed in terms of certain averages over the random sample of observed *(tau, v, phi)*-variables. Several different types of data binning and curve fitting procedures are applied and compared in the course of this IE-based data analysis process. The diffusion coefficient, *D(rho)*, is always positive and thus always acts to disperse accumulations of cells away from higher density regions. The drift coefficient, *C(rho)*, can have either sign and hence can either assist or oppose the diffusive dispersal of cells. In the latter case, the drift tends to drive the random cell motions, on average, in the direction of higher cell density which leads to aggregation under the condition *rho|C(rho)|>D(rho)*. A crucial difference between populations observed to exhibit aggregation *vs.* populations observed to exhibit rippling wave formation is the found in their respective low-density behavior: In the aggregating populations, the drift coefficient always opposes diffusive dispersal, *i.e.*, tends to favor aggregation, at almost all cell densities. By contrast, in rippling populations, the drift coefficient favors diffusive dispersal, *i.e.*, opposes aggregation at low densities, and it favors aggregation only in some narrow intermediate density range.

Biomed Resource Watch: A Knowledge Base of Performance and Issue Information for Cell Lines and Antibodies

K. Lin[1], P. L. Pascual[1], A. E. Bandrowski[1,2], C. Hsu[1], M. Pairish[2], V. Guo[1], M. E. Martone[1], J. S. Grethe[1]; [1]University of California San Diego, La Jolla, CA, [2]SciCrunch, Inc., San Diego, CA.

The NIDDK Information Network (dkNET; dknet.org) is an open community resource portal for researchers supported by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK)[1]. dkNET has developed tools, resources, and training modules to increase the awareness of and enhance scientific rigor and reproducibility. Research Resource Identifiers (RRIDs), unique identifiers for research resources, help improve the identification of research resources in the biomedical literature[2]. Utilizing RRIDs, we developed tools such as Resource Reports to assist researchers in finding and evaluating biomedical research resources such as antibodies, organisms, plasmids, cell lines, biosamples, and software tools for use in their research. Resource Reports provide researchers aggregated resource information, alerts when resources have problems, and validation information. To support these Reports, we have developed a new service, Biomed Resource Watch (BRW, scicrunch.org/ResourceWatch), a knowledge base for aggregating and disseminating known problems and performance information about research resources. We aggregate trustworthy information from authorized sources such as Cellosaurus, which provides information from The International Cell Line Authentication Committee (ICLAC) (example: scicrunch.org/ResourceWatch/Search?q=CVCL_1906). For antibodies, the information is aggregated from sources such as the Antibody Registry, Human Protein Atlas, ENCODE, the Intestinal Stem Cell Consortium(ISCC), and YCharos (example: scicrunch.org/ResourceWatch/Search?q=AB_1078467). We also include information extracted from the literature via natural language processing [Antibody Watch, 3] (example: scicrunch.org/ResourceWatch/Search?q=AB_10013321). BRW provides researchers and curators an

easy-to-use interface to report their claims about a specific resource. As of August 2022, BRW contains the following information: Cellosaurus (14296, 15.92%), Antibody Registry (48513, 54.03%), Antibody Watch (69, 0.08%), and other databases and communities (26918, 29.98%). Researchers can check information about a resource before planning their experiments via Biomed Resource Watch knowledge base-enhanced Resource Reports. This new service aims to help improve efficiency in selecting appropriate resources, enhancing scientific rigor and reproducibility, and promoting a FAIR (Findable, Accessible, Interoperable, Reusable) ecosystem in the biomedical scientific community. Building macromolecular assembly dynamics into cell-scale simulations

S. Guo, **M. E. Johnson**, H. Z. Liu, A. Jhaveri, M. Sang; Biophysics, Johns Hopkins University, Baltimore, MD.

Self-assembly of protein components is ubiquitous across cell biology. Ensuring that such assembly occurs at the right place and the right time is essential for cellular functions. With simulation, we can study the principles governing these processes in diverse conditions in solution and on surfaces. However, these dynamical systems are challenging to study through simulation because they are inherently spatial and structural, and within the cellular environment they are frequently coupled to active, force-responsive, and energy-consuming structures. Here we introduce a variety of new features to our NERDSS software, which builds coarse molecular structure into the reaction-diffusion framework to enable such simulations. With recent applications to dynamics in clathrin-mediated endocytosis, HIV-1 viral lattice assembly, circadian clocks and transcriptional assembly on DNA, simulations have defined mechanisms that recapitulate *in vitro* measurements while providing new quantitative predictions on *in vivo*behavior. With new tools to automate construction of models from PDB structures, we can directly test how assembly of general macromolecular assemblies depends on component stoichiometries, rates, and crucially, to localization on surfaces or DNA substrates. We have further developed python libraries to simplify analysis of our simulation output, improving visualization and comparison to experimental observables. Lastly, we demonstrate how the use of AI methods such as autodifferentiation can be used to accelerate parameter optimization of binding energies and rates.

Defects Within the HIV-1 Immature Lattice Support Dynamic Remodeling and Protease Dimerization

S. Guo, M. E. Johnson; Johns Hopkins University, Baltimore, MD

For HIV virions to become infectious after budding from host cells, they must mature via the activity of the HIV-1 proteases that are embedded in the immature Gag-Pol polyprotein lattice. However, only 5% of the Gag proteins in this lattice carry the proteases, and they are not activated until forming a homo-dimer. The mechanism through which a pair of embedded proteases find one another is unknown. Here, we use reaction-diffusion simulations to assemble a spherical immature lattice with 2/3 coverage of the membrane surface, in good agreement with structures determined by cryoEM. Our simulations show that dynamics of the immature Gag lattice on the membrane is unavoidable due to the missing 1/3 of the spherical protein coat, which allows for Gag-Pol molecules carrying the proteases to detach and

reattach at new places within the lattice. These rebinding events ultimately facilitate dimerization of proteases at timescales of <1 minute. These timescales are achievable for a range of realistic binding energies and rates due to the size of the gap in the lattice and the resultant imperfect contacts along its edge. Our simulations also demonstrate that during assembly, the 5% of lattice proteins that carry proteases is too high to prevent stochastic dimerization events in solution, indicating that prior to budding, dimerization events are either 'lost' to diffusion or are actively inhibited to prevent early protease activation. We find that the speed of dimerization events is largely insensitive to diffusion, which is almost exclusively restricted to occurring efficiently along the 2D surface. Both Gag-Gag interaction stability and diffusion influence the large-scale autocorrelation times of the lattice. Both the simulated and experimentally measured correlation functions from iPALM measurements support diffusive and remodeled dynamics of the immature lattice on the membrane. These dynamics are likely essential for proper maturation, and quantifying the stability of the associated lattice is thus a key step in understanding formation of infectious viruses.

B598/P1577

Interactome models incorporating diverse data sources predict cell-line differences in protein complexes

G. R. Wilkins, Jr, R. F. Murphy, J. Lugo-Martinez; Biological Sciences, Carnegie Mellon University, Pittsburgh, PA.

The formation of protein complexes is governed by the set of expressed proteins and regulated by cellular conditions. Most prior work on measuring and predicting protein complexes has been either based on data for a specific cell type or generalized without considering cell type. We have therefore sought to model variation in complexes across cell types. We began by developing improved models for complex prediction, extending the set of proteins for which complexes can be predicted. These models started by predicting protein-protein interactions using dramatically expanded sets of features and a new technique, "Ensemble Learning using Complete Feature Subsets," that we developed to better handle missing features. For a previously described dataset derived from known complexes in the CORUM database, we achieved a predictive accuracy of 0.81 compared to 0.61 and 0.63 in previous studies. We then clustered high-confidence predicted pairs into putative complexes using graph-based techniques and observed high agreement between many of our predictions and those in the STRING database. Evaluation of our predicted complexes using F-score-based comparison metrics yielded a score of 0.528, much higher than the scores of 0.302 and 0.157 obtained in previous work. Using cell line-specific versions of these models, we ranked complexes by the difference in predicted probability of occurrence between pairs of cell lines. We found that 94% of known CORUM complexes had a probability difference of less than 0.1 (and 88% less than 0.05), which is expected since most currently identified complexes are involved in cell housekeeping and would not be expected to be different between cell lines. By contrast, we identified 201 complexes, not previously identified in CORUM, that had predicted probability differences greater than 0.1 between two of the cell lines. A number of these complexes, but not all, have been previously identified in specific circumstances. For example, one complex was identified as elevated in adolescent schizophrenic brains. Our results establish the potential impact of cell type on complex assembly and exemplify the need for capturing cellular diversity in models of the interactome.

CZ CELLxGENE Discover is an online analytical platform and the largest repository of standardized single-cell data.

P. E. Garcia-Nieto, S. Chambers, H. Thomas, B. Raymor, M. Lombardo, B. Aevermann, K. Liang, M. Czerwinski, S. Badajoz, C. Megill, T. Smith, M. Dunitz, D. Hegeman, A. Mani, T. Huang, K. Katsuya, E. Bezzi, B. Martin, A. Tolopko, A. Tarashansky, N. Gloria, A. Infeld, M. Urisko, J. Cool, A. Carr; Chan Zuckerberg Initiative, Redwood City, CA.

CZ CELLxGENE Discover (cellxgene.cziscience.com) is a free-to-use online data portal hosting a growing corpus of more than 400 single-cell datasets with over 24 million unique cells from human and mouse. The portal hosts single-cell data from modalities that include gene expression, chromatin accessibility, DNA methylation, and spatial transcriptomics. All data are standardized to include raw and normalized counts, and annotated using an ontological shared vocabulary for cell and gene metadata.
Data are easily searchable and can be downloaded in multiple formats via web or by programmatic API calls. Additionally we deploy UI-based analytical tools for exploration of single datasets that do not require download. We will showcase the main tools hosted in the portal. First, the CELLxGENE explorer which displays an interactive 2-dimensional representation of cells in a dataset and allows users to color cells by gene activity or metadata (e.g. cell type, disease, technical features, etc.), subset and analyze subgroups of cells, perform differential gene expression and create scatter plots of gene expression. Second, scExpression which allows querying the expression of any gene across all human and mouse cell types available in the concatenated data from the portal.
CELLxGENE is intended for community use and contributions. By supporting multiple modalities and data generated by labs around the world, the CELLxGENE suite of tools and data aims to maximize rapid use of data. To date, we support data from over dozens of labs and consortia such as the Tabula projects, LungMap, BICCN, Allen Institute for Brain Science, KPMP and the Human Cell Atlas. New contributions are welcome, the CELLxGENE team actively supports curation of data, and we work to ensure that self-curation is easy.
We are continuously improving the usability of CELLxGENE and adding new features tailored to the needs of cell and computational biologists. Groups interested in submitting their own data can contact the CELLxGENE team at cellxgene@chanzuckerberg.com to explore whether your data would be a good fit for CELLxGENE.

Structural basis for CTPS regulation

C. Guo; ShanghaiTech University, Shanghai, CHINA.

CTP synthase catalyzes the final step of de novo pyrimidine biosynthesis. As for the importance of its product CTP, CTPS was considered as a potential target for viral, protozoal, and *Mycobacterium tuberculosis* infections, as well as for cancer and immunosuppression. CTPS can accurately recognize and interact with all four basic nucleotides ATP, UTP, CTP, GTP, and is also regulated by transient internal gas tunnels, multi ligand interactions, different proteomes, different oligomers and post-translational modifications. Because of the complexity of its regulation mechanism, CTPS is considered as a classic exemplar of protein regulation. In the past decades, through X-ray crystallography and biochemical experiments, people have learned a lot about its regulation. Cryo-EM is a rapidly developing technology in recent years. Through rapid freezing technology, the state of protein in solution can be largely

retained. It is very suitable for structural analysis of dynamic and large proteins. With this technology, we obtained a series of high-resolution structures of CTPS proteins, which provided a structural basis for the study of CTPS regulation.

Long term consequences of early life adversity on neural architecture: A brain-wide cell biological perspective

T. W. Uselman[1], R. E. Jacobs[2], E. L. Bearer[1,3]; [1]Pathology, University of New Mexico - Health Sciences Center, Albuquerque, NM, [2]Zilka Neurogenetic Institute, Keck School of Medicine, University of Southern California, Los Angeles, CA, [3]Biology and Biological Engineering, California Institute of Technology, Pasadena, CA.

Early life adversity (ELA) correlates with vulnerability to neuropsychiatric disorders later in life. That psychotropic drugs target monoamine reuptake transporters points to the noradrenergic system (NS) as one of the contributing factors. Yet how ELA influences brain biology to heighten risk and what roles NS might play remain a mystery. We hypothesize that one mechanism is defective development of NS anatomy which shifts brain network coordination. To investigate impacts of ELA we coupled longitudinal magnetic resonance imaging (MRI) with optical microscopy to map brain-wide neural activity and the NS in a preclinical model for ELA. Limited bedding, a fragmented maternal care protocol, was provided to dams with pups from postnatal day 2-9. Pups with or without ELA (n=24) were aged 10 weeks in normal housing and then subjected to longitudinal manganese-enhanced MRI, which can be paired with video recordings of movements. Images and videos were captured before, immediately and long after acute exposure to ethological threat (TMT, 2,3,5-Trimethyl-3-thiazoline). At conclusion of longitudinal imaging, mice were sacrificed, brains perfusion fixed, embedded, serially sectioned and immunohistologically stained for norepinephrine transporter (NET) or for immediate early gene cFos, to delineate NS anatomy or to confirm neural activity. MR images were aligned and normalized prior to statistical parametric mapping (SPM), segmentation, and network analysis. Recordings were analyzed with Noldus Ethovision. which revealed that ELA increased exploration at baseline. TMT provoked increased defensive-avoidance with or without ELA, attesting to its expected effect. By comparison of SPMs of cohorts with or without ELA, we found that ELA heightened baseline neural activity in ventral pallidum, and decreased in prefrontal cortex and thalamus. Network analysis found ELA decreased the coordination of neural activity between many brain regions and shifted network topology. NET-staining identified shifts in distal NS termini in the nucleus accumbens and prefrontal cortex, correlating with ELA-induced changes to neural activity. Together our data suggest that ELA reconfigures brain-wide neural activity and may do so in part through developmental defects of NS anatomy. Future work will study roles of NS activity in ELA brain-states via chemogenetic DREADD modulation of NS neuron activity. Support: RO1MH096093, Harvey Family Endowment, UNM BBHI.

Mass spectrometry signal quantification using supervised deep learning

C. Gohel[1], A. Swartz[2], G. Rahnavard[1]; [1]The George Washington University, Washington, DC, [2]University of Washington, Seattle, WA

Mass spectrometry (MS) is an important and often used tool for detecting the intensity of small and large molecules (metabolites and proteins) in molecular biology experiments. Small molecules can be

further used as biomarkers for characterizing and investigating human health and disease underlying biological activities. Liquid Chromatography and Gas Chromatography processing steps are used ahead of MS analysis to separate molecules using retention time. However, molecules whose mass-to-charge ratio overlap are often ignored by detection software. One approach for the annotation of molecules with overlapped retention times is to manually assign start and end times to molecules that overlap. For this, an expert must review output curves from the mass spectrometer and locate the start and stop times of the signal of interest. To assist this, we have developed and evaluated massLens, an automated pipeline software that integrates the curve from the start to the stop time. massLens accurately identifies the quantity of the molecule that generates a given signal. Determining the quantity of each molecule in the sample is the ultimate goal of the MS analysis.

B603/P1582

Learning Representations of 3D Intracellular Structures and their Organization using Deep Generative Models

G. Pires[1], R. Vasan[1], . Allen Institute for Cell Science[1], J. Theriot[2], T. Knijnenburg[1]; [1]Allen Institute for Cell Science, Seattle, WA, [2]University of Washington and Howard Hughes Medical Institute, Seattle, WA

The Allen Institute for Cell Science aims to understand the principles by which human induced pluripotent stem cells (hiPSCs) establish and maintain robust dynamic localization of cellular structures, and how they transition between states during differentiation and disease. Our approach is rooted in large-scale imaging experiments followed by quantitation and modeling. To describe high-dimensional, rich 3D images using interpretable latent representations, we are investigating the use of deep generative models, namely the variational auto-encoder (VAE). The VAE is a deep learning framework composed of two networks: the encoder, which takes the input data and produces a lower-dimensional representation; and the decoder, which takes the latent representation produced by the encoder and attempts to reconstruct the original input as faithfully as possible. Our work consists of an exploration of what choices of encoder/decoder architectures, inductive biases, and data modalities best suit the modeling of different components of the cell, as well as their inter-relationships. This formulation exhibits several benefits over classical methods. Specifically, it can be extended to handle any type of input data modality; it can leverage non-linearities to expand the set of learnable representations; it can incorporate inductive biases to exploit a priori knowledge about the underlying phenomena (e.g. symmetry), or to impose certain properties in the resulting representations (e.g. disentanglement). For example: Can we exploit symmetries, like XY rotational equivariance, to disregard non-meaningful sources of variation? What are good data modalities to use for more fluid structures, like the nucleolus, or for network-like structures, like the mitochondria? Can we capture quantitative aspects of organelle interactions in our learned representations? We attempt to address (narrower versions of) these questions using our large-scale hiPSC image dataset (available for access and download at allencell.org), which comprises over 200,000 high resolution 3D images of single cells in hiPSC lines.

B604/P1583

Magnetic levitation-based viable cell enrichment minimizes isolation-induced inflammatory response signaling in mammalian immune cells

D. Wakhloo, M. Margalef, A. Kale, S. Brodie, C. Stevens, G. Facer, K. Travers, J. McKinney; LevitasBio, Menlo Park, CA

Isolation of single cells from tissue with minimal transcriptional profile changes is critical to elucidating the link between gene expression and disease. Widely used enrichment methodologies can exert undue stress on cells, altering their native transcriptomic profiles. This method-related dysregulation of genes and/or pathways often masks more biologically-relevant gene expression profiles and can be misinterpreted as a consequence of disease. Certain cell types such as brain resident microglia and the immune fraction of Dissociated Tumor Cells (DTC) are highly sensitive to stress or other stimuli, which triggers increased inflammatory responses due to cell handling. Here, we report on a novel, gentle, quick, label-free enrichment procedure that harnesses magnetic levitation to efficiently isolate a higher percentage of microglial cells from fresh rodent brains without inflicting significant cell stress. Magnetic levitation-enriched samples yield more homeostatic microglia and fewer proliferating and inflammatory microglia as compared to cells isolated by flow cytometry. Expression of genes associated with inflammatory pathways was increased (2-6 fold) in flow-processed cells compared to the magnetically-levitated cells, suggesting that flow cytometry workflows significantly alter the transcriptomic profile of these cells. Similar results were observed in the immune cell component of DTC samples, where certain inflammatory pathways were found to be upregulated when flow cytometry was used to enrich for viable cells compared to magnetic levitation. These changes in gene expression may be misinterpreted as disease-related phenotypes. In addition to significantly lowering the expression of inflammation-related genes, magnetic levitation-enriched cells had higher quality sequencing metrics after scRNAseq. Median genes per cell, fraction reads per cell, and median UMI per cell were all higher in magnetically-levitated samples. A concomitant decrease in mitochondrial content per cell was also observed. In conclusion, using two different tissue types, we unequivocally demonstrate the effectiveness of Levitation Technology to isolate and enrich cells in their native transcriptomic state, enabling researchers to study disease-related pathways and/or targets that reflect their true biology, not stress-induced activity.

Physical Approaches to Cell Biology 1

Characterizing Mixing in Cytoplasmic Streaming During Motility in Amoeba Chaos

U. Diaz[1], M. Das[2], W. Marshall[1]; [1]University of California San Francisco, San Francisco, CA, [2]Rochester Institute of Technology, Rochester, NY.

The cytoplasm is a dynamic fluid where cellular building blocks and components are continuously mixing. Cytoplasmic mixing is important for transporting intracellular material ranging from nucleotides and proteins to full organelles. Although diffusion is sufficient to drive cytoplasmic mixing in relatively small cell types, large cell types rely on active transport mechanisms to facilitate cytoplasmic mixing. In large ameboid and neutrophil cell types, cytoplasmic streaming is coupled to membrane deformations formed in motility. However, it remains unclear how well material mixes within cytoplasmic flows during motility. In addition, it is also unclear whether these cytoplasmic flows are laminar or turbulent in

nature, especially considering the low Reynolds number of the cytoplasm. In relatively small volumes of viscous fluids at very low Reynolds number, such as the cytoplasm, it is hard to obtain significant mixing simply from streaming. Here we examine whether cellular activity and shape-change may facilitate chaotic mixing of the cytoplasm.
Chaos carolinensis is an excellent model system to study mixing in cytoplasmic flows during motility thanks to its large size, which makes it highly amenable to microinjection and micro-surgery. To visualize cytoplasmic flows, we microinject two fluorescent beads into the cytoplasm of each amoeba and use fluorescence time lapse microscopy to track the movement of individual beads very accurately across long periods of time (up to 12 hours). To describe mixing we use an automated pipeline to find timepoints where the two bead trajectories come very close to each other, then characterize the separation of the particle trajectories with time via power law curve fits of the inter-particle separation and estimate Lyapunov exponents. We also study mean square displacements of individual beads with time to identify regimes of diffusive and active transport. To perturb amoeba motility we modulate temperature, substrate thickness, and use perturbations against the integrity of the uropod, an actin based contractile structure at the posterior end of the cell. In our work we describe how temperature, substrate thickness, and uropod integrity influence mixing in cytoplasmic flows during active motility in the giant amoeba Chaos carolinensis.

Isometric size-scaling of cell surface components in mammalian cells

T. P. Miettinen, W. Wu, S. R. Manalis; Koch Institute for Integrative Cancer Research, Massachusetts Institute of Technology, Cambridge, MA.

The surface area of a cell and the components of the plasma membrane set the maximum limit to cell's ability to uptake nutrients, secrete components and deform. In animal cells, the complicated ultrastructure of the plasma membrane causes cell surface area to be high and difficult to quantify. Despite common assumptions about surface-to-volume scaling, little is known about how animal cell surface area and components scale with increasing cell size. Here, we combine single-cell measurements of cell size with surface-specific detection of plasma membrane proteome in near-spherical mammalian cells to examine the size-scaling of cell surface area and components. We find that freely proliferating cells exhibit near-isometric size-scaling of overall plasma membrane proteome that is independent of the cell cycle. This near-isometric size-scaling of plasma membrane proteome is maintained despite large size increases during polyploidization. On transcriptional level, single cells scale their plasma membrane protein transcripts proportionally to cell size. However, individual surface proteins display a range of scaling phenotypes that arise post-transcriptionally. The isometric scaling of overall plasma membrane proteome is made possible by an increasingly folded plasma membrane ultrastructure in larger cells. This isometric scaling of plasma membrane proteome may function as a design principle that reduces regulatory complexity and cell size-dependency of cell extravasation, while ensuring sufficient membrane area for nutrient uptake and cell division that is largely independent of cell size.

Mesoscale molecular assembly is favored by crowded active matter in the cell

T. Shu[1], J. Alberts[2], W. Burrell[3], D. Sang[1], M. Viana[4], M. Heidenreich[5], S. Rafelski[4], E. Levy[5], G. Hocky[6], L. Holt[1]; [1]Institute for System Genetics, NYU Langone Health, New York City, NY, [2]Department of Biology, Center for Cell Dynamics, University of Washington, Seattle, WA, [3]Department of Biology, NYU, New York City, NY, [4]Allen Institute for Cell Science, Seattle, WA, [5]Department of Structural Biology, Weizmann Institute of Science, Rehovot, ISRAEL, [6]Department of Chemistry, NYU, New York City, NY.

Cells are extremely crowded at the mesoscale, with up to 40% of the cell volume taken up by macromolecules. Moreover, the intracellular environment is in a state of non-equilibrium due to energy-dependent active processes. This crowded and active cellular environment can impact both molecular diffusion and interactions, and these effects are length-scale dependent. Many biochemical processes in the cell involve assembly of hundreds of proteins, at length-scales from nanometers up to microns. We set out to investigate the impact of the active, crowded cellular environment on these mesoscale molecular assembly processes, using liquid-liquid phase separation (LLPS) as an easily observable example. To simplify this problem, we leveraged a synthetic engineered experimental model system that condenses into a mesoscale assembly from two geometrically defined nanoscale protein components in the cytoplasm, which can be expressed in both S. cerevisiae yeast and mammalian Hela cells. We then developed two independent simulation platforms to allow microscopic interpretations of our experimental results through the framework of graph theory. We discovered that macromolecular crowding increases the kon rate of biochemical bond formation, shifts the critical point for LLPS, affects the kinetics of initial condensate formation, and stabilizes the condensed state. In addition, reducing cellular activity experimentally through ATP depletion or actin network disruption inhibits the growth of mesoscale assembly while increasing effective temperature from active processes in simulations promoted the coarsening of liquid droplets. These changes in condensate dynamics were directly related to changes in mesoscale diffusion. Finally, using poly(A)-binding protein (Pab1) in yeast, a marker protein for stress granule, we found that modulating phase separation through osmotic compression promotes yeast fitness during prolonged heat stress and its effect was compromised under Pab1 mutation that impedes phase separation. Our work highlights the importance of the cellular environment for mesoscale molecular diffusion and assembly.

B608/P1587

Membrane compression from exocytosis of synaptic vesicle fusion triggers ultrafast endocytosis

J. Liu[1], H. Jing[1], S. Raychaudhuri[1], T. Ogunmowo[1], G. Kusick[1], T. Ha[1], E. Chapman[2], S. Watanabe[1]; [1]Johns Hopkins University, Baltimore, MD, [2]University of Wisconsin-Madison, Madison, WI

Compensatory endocytosis keeps the surface area of secretory cells constant following exocytosis. At chemical synapses, clathrin-independent ultrafast endocytosis maintains such homeostasis. This endocytic pathway is temporally and spatially coupled to exocytosis, initiating within 50 ms at the region immediately next to where vesicles fuse: the active zone. How synaptic vesicle exocytosis induces ultrafast endocytosis is unknown. Here, we demonstrate that actin filaments are enriched in the region surrounding active zone at mouse hippocampal synapses and that the membrane area conservation due to this actin corral is necessary for exo-endocytic coupling. Simulations suggest that flattening of fused vesicles exerts lateral membrane pressure in the plasma membrane against the actin corral, resulting in rapid formation of endocytic pits at the border between the active zone and the surrounding actin-

enriched region. Consistent with our simulations, ultrafast endocytosis does not initiate when actin organization is disrupted, either pharmacologically or by ablation of the actin-binding protein Epsin1. These data suggest that endocytosis is mechanically coupled to exocytosis at synapses.

Vast heterogeneity in cytoplasmic diffusion rates revealed by nanorheology and Doppelgänger simulations

A. T. Molines[1], R. M. Garner[2], J. A. Theriot[3], F. Chang[4]; [1]Cell and Tissue Biology, University of California San Francisco, San Francisco, CA, [2]Systems Biology, Harvard Medical School, Boston, MA, [3]Department of Biology, University of Washington, Seattle, WA, [4]Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA.

The cytoplasm is a complex, crowded, actively-driven environment whose biophysical characteristics modulate critical cellular processes such as cytoskeletal dynamics, phase separation, and stem-cell fate. Little is known about the variance in these cytoplasmic properties. Here, we employed particle-tracking nano-rheology on genetically encoded multimeric 40-nm nanoparticles (GEMs) to measure diffusion within the cytoplasm of the fission yeast Schizosaccharomyces pombe. We found that the apparent diffusion coefficients of individual GEM particles varied over a 400-fold range, while the average particle diffusivity for each individual cell spanned a 10-fold range. To determine the origin of this heterogeneity, we developed a Doppelgänger Simulation approach that uses stochastic simulations of GEM diffusion that replicate the experimental statistics on a particle-by-particle basis, such that each experimental track and cell had a one-to-one correspondence with their simulated counterpart. These simulations showed that the large intra- and inter-cellular variations in diffusivity could not be explained by experimental variability but could only be reproduced with stochastic models that assume an equally wide intra- and inter-cellular variation in cytoplasmic viscosity. To probe the origin of this variation, we found that the variance in GEM diffusivity was largely independent of factors such as temperature, cytoskeletal effects, cell cycle stage and spatial locations, but was magnified by hyperosmotic shocks. Taken together, our results provide a striking demonstration that the cytoplasm is not “well-mixed” but represents a highly heterogeneous environment in which subcellular components at the 40-nm size-scale experience dramatically different effective viscosities within an individual cell, as well as in different cells in the population. These findings carry significant implications for the origins and regulation of biological noise at cellular and subcellular levels.

B610/P1589

Coupling between Membrane Protein Condensates and Ordered Membrane Domains

H. Wang[1], S. Chan[1], S. Dey[1], I. Castello-Serrano[1], J. Ditlev[2], M. Rosen[3], K. Levental[1], I. Levental[1]; [1]University of Virginia, Charlottesville, VA, [2]University of Toronto, Toronto, ON, Canada, [3]University of Texas Southwestern Medical Center, Dallas, TX

Liquid-liquid phase separation of membrane proteins have been observed in many cellular machineries, including LAT/Grb2/Sos1 condensates formed at the membrane of immunological synapse and PSD95/SnyGAP/Homer3/Shank3 condensates at the membrane of neurological synapse. The presence of a membrane can influence condensate formation and conversely, condensates may influence membrane organization. Specifically, the condensate-forming protein linker for actication of T-cells (LAT) associates with membrane domains known as lipid rafts, whose formation is guided by liquid-liquid

phase behavior. Thus, while LAT has the potential to act as the biophysical and functional linker between 3D protein condensates and 2D lipid domains, such coupling not been widely studied. Here we provide evidence that LAT condensates can induce and stabilize lipid domains, and in turn that raft domains can nucleate and stabilize LAT condensates. First, reconstituted LAT condensates formed exclusively in Lo domains on phase-separated supported membrane bilayers, and their location and morphology were dictated by condensates. Protein condensates could induce phase separation in biomimetic giant unilamellar vesicles (GUV), with liquid ordered (Lo) domains being recruited to condensates. Inversely, phase separated membranes concentrate LAT molecules in Lo regions, facilitating condensate formation. Moreover, we found that protein condensation could change their raft affinity: when monomeric LAT was included in both ordered and disordered domains, LAT condensates were still exclusively observed in ordered domains. Finally, these mechanisms were confirmed in living T-cells, where activation induces protein condensates that associate with and stabilize raft-like membrane domains. This coupling of lipid and protein assembly was essential T-cell activation. Altogether, we conclude that LAT protein condensates are thermodynamically coupled to ordered membrane domains to regulate the organization of T-cell membranes that facilitates immune cell signal transduction.

Post-injury hydraulic fracturing drives fissure formation in the zebrafish basal epidermal cell layer

M. Sathe[1], A. S. Kennard[2], E. C. Labuz[1], C. K. Prinz[1], J. A. Theriot[1]; [1]Biology, University of Washington/Howard Hughes Medical Institute, Seattle, WA, [2]Biology, University of Massachusetts, Amherst, MA.

The skin epithelium acts as the barrier between an organism's internal and external environments. In zebrafish and other freshwater organisms, this barrier function requires withstanding a large osmotic pressure differential. Here we show that, following acute injury, the larval zebrafish epidermis undergoes a dramatic fissuring process that resembles hydraulic fracturing, driven by the influx of external fluid. The fissuring starts in the basal epidermal layer nearest to the wound, and then propagates at a constant rate through the tissue spanning over one hundred micrometers. Interestingly, the basal cells of the skin still remain connected via thin tethers after fissuring while the outermost superficial epidermal layer remains intact. Fissuring is completely inhibited when larvae are wounded in an isotonic external media, suggesting that osmotic pressure gradients drive fissure. Additionally, fissuring partially depends on myosin II activity, as its inhibition reduces fissure propagation away from the wound. During and after fissuring, the basal layer forms large macropinosomes (with cross-sectional areas ranging from 1-10 μm^2), presumably to clear the excess fluid. We conclude that excess external fluid entry through the wound and subsequent closure of the wound through actomyosin purse string contraction in the superficial cell layer causes fluid pressure buildup in the extracellular space of the zebrafish epidermis. This excess fluid pressure causes tissue to fissure, and eventually the fluid is cleared through macropinocytosis.

In vivo*nanorheology reveals a novel role for the outer nuclear membrane KASH protein ANC-1 in regulating cytoplasmic macromolecular crowding in*Caenorhabditis elegans

G. Luxton[1], H. Hao[1], S. Kalra[1], X. Ding[1], E. F. Gregory[1], L. J. Holt[2], D. A. Starr[1]; [1]Molecular and Cellular Biology, University of California, Davis, Davis, CA, [2]Institute for Systems Genetics, New York University School of Medicine, New York, NY.

Macromolecular crowding considerably influences biochemical reaction rates and the physical properties of intracellular environments. Recent advances have made progress on how crowding is modulated in individual cultured cells by regulating ribosome concentrations. However, the mechanisms that regulate molecular crowding throughout development in multicellular *in vivo* contexts are largely unexplored. We used genetically encoded multimeric nanoparticles (GEMs) to study the physical properties of the cell interior within developing tissues of the multicellular organism, *C. elegans*. GEMs are homomultimeric scaffolds fused to a green fluorescent protein that self-assemble into bright, stable particles 40 nm in diameter. To use GEMs to perform single-particle tracking nanorheology experiments *in vivo*, we engineered *C. elegans* strains stably expressing 40 nm GEMs under the control of tissue-specific promoters in the hypodermis, intestine, and neurons. GEMs exhibited tissue-specific effective diffusion coefficients. We observed more immobile GEMs in the hypodermis and intestine than we observed in neurons or previously reported in individual yeast, or mammalian tissue culture cells. Previous nanorheology studies performed in cultured mammalian cells identified the conserved nuclear envelope-spanning linker of nucleoskeleton and cytoskeleton (LINC) complex as a key determinant of cellular mechanical stiffness. We asked if LINC complex components were required to regulate macromolecular crowding and cellular mechanics in *C. elegans*. The effective GEM diffusion coefficients were considerably increased in *C. elegans* intestinal or hypodermal cells lacking the KASH protein ANC-1. In contrast, no significant effect on GEM mobility was observed in strains null for the SUN protein UNC-84, or harboring muscular dystrophy-associated mutations in the nuclear lamin protein, LMN-1. Furthermore, we demonstrate that ANC-1 is required for the homogeneous cytoplasmic distribution of ribosomes *in vivo*. Collectively, these results establish a LINC complex-independent role for ANC-1 in controlling the mesoscale biophysical properties of the cytoplasm *in vivo* across several different tissues.

B613/P1592

The uniformity and stability of cellular mass density in mammalian cell culture

X. Liu, S. Oh, M. W. Kirschner; Harvard Medical School, Boston, MA.

Cell dry mass is the sum of the biosynthesis and degradation activities that act on a time scale of hours, whereas cell volume can be instantaneously altered by external osmotic stress in minutes. How the two are coupled is a fundamental question in cell size control. It has been proposed that cell volume is proportional to cell dry mass during growth and proliferation, resulting in a constant cellular mass density defined as cell dry mass dividing by cell volume. However, the goodness of the proportionality and its stability against perturbations has never been characterized. Here, using Normalized stimulated Raman Imaging (NoRI), we systematically investigated the uniformity of mass density in three cultured mammalian cell lines and their response to pharmaceutical and physiological perturbations. We found a remarkably narrow mass density distribution within and among cell lines, independent of the cell cycle. Furthermore, we found that cellular mass density can be modulated directly by extracellular osmolytes or membrane tension but is highly resistant to the inhibition of protein synthesis or degradation,

suggesting the existence of feedback controls to maintain mass density homeostasis. These findings shed light on the understanding of how and why mass density changes during the transition of cell physiological states and pave the road to discovering molecular mechanisms.

How Cells Program Mineral Shape in Sea Cucumbers - Part 1

P. Vyas, C. Brannon, L. Formery, C. Lowe, M. Prakash; Bioengineering, Stanford University, Stanford, CA.

Biomineralization is ubiquitous in both unicellular and multicellular living systems and has remained elusive for several centuries due to limitations in the simultaneous understanding of both physical and biomolecular processes. Specifically, in holothurians, biomineralization occurs in the form of discrete ~100 um length scale structures called ossicles that diversify in shapes not only across holothurian species but even within an individual animal. To understand the fundamental processes enabling cellular cooperation at multi-cell length scales during the growth of ossicles, we directly observe them through live and fixed microscopy techniques. We establish that these structures grow from individual crystalline seeds inside a multi-cell syncytial complex with the biomineralized phase completely covered with a membrane-coated cytoplasmic sheath. We demonstrate that the initial seed transforms into a fully formed holed structure through 4 key steps - instability in the seed, tip extension, tip splitting, and merging of two tips. Through large-scale statistics on microCT data, we probe the robustness of the processes described. Throughout the growth, we demonstrate that cytoplasmic and membranous activity restricted to the surface of the biomineralized phase rather than motility of participating cell bodies regulate the material transport and directional growth of the structure. By observing distinct developmental niches within the animal we demonstrate differential symmetry breaking and seed cell-cluster dispersion as the structure grows, which acts as an additional layer of control over the fundamental growth processes. The system thus serves as a unique playground merging non-equilibrium solidification growth in chemical soups and classical branching morphogenesis in living systems.

The role of hair pigmentation in thermoregulation and heat adsorption

G. A. Jimenez-Jordan[1], J. Roldan-Kalil[2], J. Alves[1], M. Inyushin[1]; [1]University of Central Del Caribe-School of Medicine, Bayamon, PR, [2]University of Puerto Rico Medical Sciences Campus, San Juan, PR

Studies show that men find women with blonde hair more attractive on average and women find men with dark hair more attractive on average[1]. This shows the social importance of hair color in human social interactions. It has also been historically key for camouflage and protection against predators in early human development[2]. However, hair phenotype has another important function, which is its role in protection from light and thermoregulation. This function has not been studied in detail in comparison to the previous ones discussed and it may be the most important one in terms of human physiology. The difference of temperature adsorption between different types of pigmentation of hair holds a lot of answers to many questions when it comes to the reasons why humans form distinct patterns of hair phenotypes. Melanin is the main pigment in hair, it has a propensity to bind metals and it is present in specialized organelles called melanosomes[3]. Using Transmission Electronic Microscopy (TEM), melanin with adsorbed metal ions is visible as dark spots that are quantifiable for the three types of hair pigmentation (blonde, brown, black) that are being studied. Low energy blue (441 nm) and green (532 nm) lasers were used to study the temperature change between irradiated and the unirradiated

hair shaft in samples of different hair types. It was determined that different hair pigmentations have significant differences in melanin granule quantities and in the changes in heat that occur when lasers are shone at the strands. It was determined that black hair has the most amount of melanin granules, followed by brown hair, and lastly blonde hair. Blue light adsorption also follows the same trend, with black hair absorbing the most, followed by brown hair and lastly blonde hair, while green light equally adsorbed by brown and black hair. Conclusion and discussion: These results show the reason why different hair pigmentations are common in different parts of the world. They provide a quantifiable explanation of why most people in sun-deprived areas, such as Scandinavia, have blonde hair. On the other hand, these results are consistent with the opposite effect, why most people located close to the Equator have dark, black hair. This study demonstrates the role of hair pigmentation in human physiology and evolution utilizing TEM microscopy and Infrared Thermal microscopy.

Computational Extraction of Cytoplasm Oscillations in Slime Mold *Physarum polycephalum*

P. Chudinov; UCSF, San Francisco, CA

Physarum polycephalum is a single cellular slime mold that is famously capable of solving complex optimization problems. The mechanisms of decision-making in the slime mold have been actively studied in the past 2 decades, but we still do not completely understand of exact decision-making process of the cell. Our initial data suggested that cytoplasmic oscillations are involved in Physarum's change of movement direction behavior, yet verification with fluorescence microscopy poses a challenge due to the phototoxicity. We propose a novel imaging method to extract cell parameters such as weight centroid, cytoplasm oscillation frequency and local plasmodium thickness estimate which provide an insight into fluid mechanics of the cytoplasm. The approach consists of bright field microscopy with even amount of light across the cell body (to avoid phototoxicity) followed by a computational pipeline - segmentation and pixel intensity analysis. Using this method we can see changes in cytoplasm oscillation patterns at decision-making points.

B617/P1596

Physical principles behind strong sensitivity of temperature receptors

R. Chou[1,2], Q.-X. Jiang[3,4]; [1]Case Western Reserve University, Cleveland, OH, [2]University of Buffalo, Buffalo, NY, [3]University At Buffalo, SUNY, Buffalo, NY, [4]University of Florida, Gainesville, FL

Temperature is a ubiquitous environmental variable for all cellular processes. Living organisms have evolved specific mechanisms for temperature sensing in order to seek optimal inhabiting temperatures and avoid danger from noxious heat or frigid cold. One of the mechanisms in mammals involves a group of ion channels, thermal transient receptor potential (thermoTRP) channels, which act as sensors of ambient temperatures in peripheral sensory neurons. Functions of these channels necessitate exquisite temperature sensitivity, but the underlying mechanisms remain elusive. Thermodynamics implies that thermoTRP opening by temperature requires energetic changes in the regime of hundreds of kcal/mol. Such a change far exceeds what most enzymatic reactions can provide, which usually is in the range of 5-

30 kcal/mol. Thus, one central question on temperature receptors has been on how they attain the large energetics needed for their physiological functions. In this work we introduce differential scanning calorimetry (DSC) to directly measure energetic changes accompanying temperature-induced conformational transitions in a group of prototype heat-sensitive receptors. The DSC scans unravel that thermoTRPs undergo thermal transitions at an energy scale that is significantly larger than what was inferred from functional measurements, and reaches the regime of (partial) protein unfolding. Thermodynamic analysis reveals that the thermoTRPs bear intrinsic thermal instability and that their heat-induced opening represents an early event of protein unfolding. Our findings suggest that coupling functional transitions to (partial) protein denaturation may represent a general physical principle for living cells to achieve exceedingly high temperature sensitivity.

B618/P1597

Hydrodynamic forces during microtubule aster movement

T. Mitchison, L. Bai; Harvard Medical School, Boston, MA

The cytoplasm of animal cells is a complex material that can be though of as a gel made of entangled cytoskeleton and endomembrane networks percolated by a sol made of water, small molecules and macromolecules that span a large range of sizes. If these components move collectively, continuum approximations such bulk viscoelasticity may suffice to describe the mechanics. If the sol moves relative to the gel, counterintuitive phenomena may occur whose description requires more complex physical models. We previously used a poroelastic formalism to account for slow equilibration of hydrostatic pressure gradients across tissue culture cells, driven by actomyosin or osmotic forces, and proposed an effective pore size of approximately 30nm for the network component of cytoplasm (PMID: 17921219, PMID: 19690051). Our current focus is on centrosome positioning during early cleavage divisions in frog eggs. After mitosis, microtubule asters move apart in response to pulling forces from dynein and actomyosin. Current models typically assume that asters are rigid objects moving through a static, viscous liquid. Our observations in frog egg extract, which is undiluted, living cytoplasm, showed that all the cytoplasmic networks inside asters move collectively. When asters moved rapidly over dynein attached to a glass surface, they advected a small molecule probe, and presumably also water. Whether advection of water also occurs at physiological rates of aster movement in eggs is unknown, but it seems likely given the large size of asters and small effective pore size of cytoplasm. These observations suggest that a realistic model of aster movement must take hydrodynamic forces into account. Preliminary results from microneedle perturbation of egg extract indicate that F-actin is the predominant elastic element, even inside asters where microtubules instruct spatial organization. We propose that F-actin networks, percolated by large macromolecule complexes such as ribosomes and glycogen, determine the effective pore size of animal cell cytoplasm. This pore size is small enough to advect water during changes in cell shape or internal organization, which must be considered in physical models.

B619/P1598

Tracking Chromatin Across Temporal Scales Shows Variation in Dynamics in Response to DNA Damage

F. Iqbal, J. Liu; IUPUI, Indianapolis, IN

The movement of chromatin in human cells is highly complicated. Such movement is dependent on the molecular size of the chromatin domain and time lag of Single Particle Tracking (SPT) measurements. It

is unclear why such behavior exists. Most theoretical models which are mainly based on the polymer model fail to explain this phenomenon. We have proposed a single molecule imaging strategy that can track the dynamics of single nucleosomes in the human cell. By varying the temporal scale of imaging, our observations show that two types of motion are present in chromatin dynamics: a fast local fluctuation of the nucleosome, and a slow chromatin chain movement. A theoretical model that was developed from ChromoShake validated this conclusion. We also investigated the response to DNA damage from the nucleosomes by varying temporal scales. It was noted that bleomycin (BLM) induces the accelerated motion of nucleosomes at short time scale (interval ~ 30 ms), while the motion of nucleosomes at long time scale (interval ~seconds) is reduced. This disparity discloses that the DNA damage accelerates the local chromatin motion, while slows down the chromatin chain movement.

Metal ion doping of melanin compounds enhances xray absorption

S. A. Baranowitz[1], L. Malone[2], M. F. Kiani[3]; [1]Epitek, Marlton, NJ, [2]Drexel University, Philadelphia, PA, [3]Temple University, Philadelphia, PA

Melanin is a biopigment widespread in animals and humans. It has been shown to absorb ultraviolet light, x-rays, and gamma rays. Lead shields are the most common protection against x-rays. Since lead is extremely toxic, non-toxic alternatives would be desirable to protect against radiological damage. The objective of this study is to compare the x-ray absorption of metal ion doped melanin compounds to lead controls. The melanin was extracted from a natural source, cuttlefish ink. Three metal ion doped melanin compounds were tested: bismuth - synthetic melanin (disk A), bismuth - natural melanin (disk B) and silver - synthetic melanin (disk C). Each compound's absorption was tested and compared to lead samples of the same size. Both the bismuth - synthetic melanin and the bismuth- natural melanin had absorption not substantially different than the lead controls.

Force-induced site-specific enzymatic cleavage of DNA probes reveals serial mechanical engagement boosts T cell activation

J. Rogers, R. Ma, Y. Hu, K. Salaita; Emory University, Atlanta, GA.

T cells use their T cell receptors (TCRs) to identify antigens presented on the surface of virtually all cell types in structures called peptide-major histocompatibility complexes (pMHCs). The interaction between a TCR and pMHC is critical for the identification and eradication of virally infected or cancerous cells. A mystery in the field concerns how the weak affinity between the pMHC and TCR can be highly sensitive and discriminatory. To explain how TCR-pMHC interactions initiate potent signaling, models of TCR triggering have been introduced, which include the serial engagement and the mechanosensory models. Mechanical forces and the number of engagements between the TCR and pMHC are factors that have each individually been linked to TCR triggering; however, the extent of their contributions toward T cell activation in tandem remains poorly understood. Herein, we introduce **f**orce-ind**u**ced **s**ite-specific **e**nzymatic cleavage of DNA (FUSE DNA) probes, which allows the tension *duration* along the TCR-pMHC bond to be controlled experimentally. With FUSE DNA, the tension duration can be tuned by varying the concentration of a restriction endonuclease, which is responsible for selectively cleaving mechanically sampled DNA probes. This new capability provides a method to study how molecular mechanisms, such as TCR tension and serial engagement, contribute to TCR triggering. First, we show

this assay can visualize and disrupt mechanical interactions greater than 7.1 pN between OT-1 TCRs and anti-CD3ε. The average lifetime of the FUSE DNA probe (τ_p) was determined to be 1.6 min at 1000 U/mL of restriction endonuclease *AseI* and can be increased by decreasing the nuclease concentration. We define this lifetime as the average tension duration experienced by a TCR. T cells challenged with probes presenting ovalbumin (OVA) pMHC demonstrated dampened expression of pYZAP70 in the presence of the *AseI* endonuclease, thus demonstrating the perturbation of TCR mechanotransduction. This activation differential was exacerbated at lower antigen densities, wherein the largest decline in activation was observed with single molecule densities of pMHC. Finally, T cells experience a greater level of activation as the average tension duration increases, which leads to the conclusion that TCRs must serially, mechanically engage with pMHCs to boost subsequent activation. These results also demonstrate the potential for FUSE DNA to investigate the role of force duration in more general mechanosensitive pathways, such as Notch signaling and integrin-ligand interactions.

Evaluating airway ALI model fabrication methods and comparing differentiation potential of primary and hTERT-immortalized epithelial cells.

K. Tyo, F. Tian; ATCC, Gaithersburg, MD.

Human respiratory research encompasses a variety of fields including drug development, disease modeling, and toxicology testing. Despite the availability of traditional in vitro airway models, there is a persistent concern with their lack of physiological relevance to the human lung. Within the past decade, several advanced in vitro airway models have been constructed, which promises to provide more relevant applications in human respiratory research. However, the numerous variables associated in the generation of these advanced models can cause incomplete or inconsistent differentiation, resulting in research delays or cost overruns. In these studies, we showcase an optimal method of fabricating airway models consisting of human bronchial tracheal epithelial cells (HBECs) grown in collagen-coated 24-well plate inserts and cultured under air-liquid interface for 5 weeks. Model generation using different lots of primary HBECs as well as hTERT-immortalized HBECs were compared. In addition, various commercial media designed to promote epithelial differentiation were evaluated. Next, primary HBECs from ATCC and other commercial companies were evaluated and compared on epithelial differentiation and model morphology using optimized processes validated during the first phase of the study. All airway models were evaluated via weekly microscopy and transepithelial/transendothelial electrical resistivity measurements. Additionally, H&E and alcian blue imaging and MUC5AC and α-tubulin immunohistochemical analysis from histological samples of mature airway models were generated. These studies elucidate techniques and procedures to reliably generate 3D airway models with consistent full epithelial differentiation across replicates using both ATCC and other commercial primary HBECs.

RNase L Acts as a Regeneration Repressor

N. Islam[1], **C. S. Kirby**[1], E. Wier[2], A. Li[2], M. P. Alphonse[2], E. Sweren[2], G. Wang[2], D. Kim[3], H. Liu[2], S. Reddy[4], L. Miller[2], J. Yu[5], W. Huang[6], J. W. Jones[5], S. Lee[1], S. Kim[1], M. Kane[5], R. H. Silverman[7], L. A. Garza[2]; [1]Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, [2]Department of Dermatology, Johns Hopkins University School of Medicine, Baltimore, MD, [3]Department of Biochemical Engineering, Dongseo University, Busan, KOREA, REPUBLIC OF, [4]Department of Plastic Surgery, Johns Hopkins University School of Medicine, Baltimore, MD, [5]Department of Pharmaceutical Sciences, University of Maryland School of Pharmacy, Baltimore, MD, [6]School of Biomedical Sciences, University of Queensland, St. Lucia, AUSTRALIA, [7]Department of Cancer Biology, Cleveland Clinic, Cleveland, OH.

Mammalian tissue injury response is usually characterized by fibrosis and scarring rather than functional regeneration. This limited regenerative capacity in mammals could reflect a loss of pro-regeneration programs or active suppression by genes functioning akin to tumor suppressors. To uncover programs governing regeneration in mammals, we performed comprehensive transcriptome screening in human subjects after laser rejuvenation treatment and cross-referenced these transcripts to those found in mice with enhanced Wound Induced Hair Neogenesis (WIHN), a rare example of mammalian organogenesis. We find the anti-viral endoribonuclease RNase L to be a powerful suppressor of regeneration. Rnasel-/- mice exhibit a remarkable regenerative capacity with elevated WIHN ($n=10$, $p<0.0001$) through enhanced IL-36α ($n=3$, $p<0.01$). Consistent with the known role of RNase L to stimulate caspase-1, we find that pharmacologic inhibition of caspases promotes regeneration ($n=3$ versus 4, $p<0.001$) in a novel IL-36-dependent manner ($n=4$, n.s.). This occurs by a potential negative feedback loop, where Rnase L activated Caspase-1 inhibits the pro-regenerative dsRNA-TLR3 pathway through the cleavage of TRIF. Additionally, these responses are not limited to skin but extend to other organs, such as the colon ($n=4$, $p<0.05$), suggesting that suppression of regeneration is a fundamental characteristic of epithelial wound healing. Taken together, this work suggests that RNase L functions as a regeneration repressor gene in a functional tradeoff that prioritizes host antiviral abilities and as a potential target to enhance healing in multiple epithelial organs, perhaps even during viral infection.

An Unbiased Characterization of Epithelial Monolayer Development in Culture

N. Dawney[1], C. Cammarota[2], Q. Jia[1], A. Shipley[1], J. Glichowski[2], T. Finegan[3], D. Bergstralh[1,2]; [1]Department of Biology, University of Rochester, Rochester, NY, [2]Department of Physics and Astronomy, University of Rochester, Rochester, NY, [3]Department of Physics and BioInspired Institute, Syracuse University, Syracuse, NY.

Epithelial tissues are the most common tissue type, and the function of these tissues is frequently linked to a monolayered cell architecture. Our work aims to address the question of how epithelial monolayers form, and in particular how they develop organization with respect to the apical-basal axis (meaning tissue depth). We have developed a computational tool, *A*utomated *L*ayer *An*alysis (ALAn), that characterizes epithelial architecture in this axis. We find that that MDCK and MCF-7 cell lines, which can develop polarized monolayers in culture, form four distinct architectures with different structural characteristics and material properties. Three of these architectures (termed Immature, Intermediate and Mature) are organized, whereas the fourth (termed Disorganized) is a category of exclusion. We find

that epithelial architecture in the apical-basal axis is governed by multiple factors, including but not limited to cell density. Interestingly, we find cells are capable of reorganization in the apical-basal axis to form monolayers from cell aggregates. This behavior is governed by substrate availability; upon seeding, cells quickly land and spread to cover the substrate, preventing new cells forming substrate connections. Our results show that monolayers grown in culture can vary substantially, and highlight the importance of taking all three dimensions into account when analyzing experimental results.

Whole-embryo analysis of local cell arrangement links differential cadherin expression to specific tissue architecture

M. Brambach[1,2], D. Gilmour[1]; [1]Department of Molecular Life Sciences, University of Zurich, Zurich, SWITZERLAND, [2]Life Science Zurich Graduate School, Zurich, SWITZERLAND.

Tissue architecture, the three-dimensional arrangement of cells, is a key feature of tissues that enables their functions. While it has been extensively studied how tissues are specified molecularly and consequently how morphogenic processes are induced, it is still largely unclear how cells generate their local arrangement. Many modern omics approaches require that samples are dissociated, and thus dispose of this tissue-architectural information, with the result that general mechanisms that link the organisation of cells in tissues to patterned gene expression remain elusive.
Here we use a quantitative morphometric approach to investigate how cells generate and maintain specific tissue architectures on a whole-organism scale. We use *in toto* light sheet microscopy of zebrafish embryos and nuclear segmentation to characterise individual cells based on the organisation of their tissue neighbourhood. This uncovers that the complexity of tissue architecture can be reduced to two broad classes: regular, low-density organisation and a more irregular, high-density configuration. To understand how these different types of architecture emerge, we define the expression patterns of the most abundantly expressed cadherin family members and classify them based on the organisation of their constituent cells. This reveals a striking correspondence to tissue architecture, with cadherins of the 'Cdh1 class' correlating with a regular, low-density organisation whereas cadherins of the 'Cdh2 class' correlate with irregular, high-density tissues. Time course analysis demonstrates that these two modes of organisation exist throughout early development and that downregulation of Cdh2 coincides with cells transitioning between architectural modes. Targeted perturbations of cadherin expression support a model where differential cadherin expression underlies the architectural diversity of tissues.

The LINC complex controls global breast acini architecture through connections to the actin cytoskeleton

M. Rayer[1], K. Mui[1], A. Nickerson[2], T. P. Lele[3], G. G. Gundersen[1]; [1]cell and pathology, Columbia University, New York, NY, [2]Division of Genes & Development, Department of Pediatrics,, University of Massachusetts Medical School, Worcester, MA, [3]Department of Biomedical Engineering, Department of Chemical Engineering, Department of Translationa, Texas A & M, College Station, TX.

Lumen formation of a glandular epithelium is essential for normal breast function, and its absence is a hallmark of cancer. Recently, dominant negative approaches revealed that the linker of nucleoskeleton and cytoskeleton (LINC) complex is required for proper formation and maintenance of acinar lumens in breast epithelia grown in 3D culture (Zhang Q et al., *Curr Biol* 2019). The LINC complex is downregulated

in breast tumors (Matsumoto A et al., *Cancer Medicine,* 2015), and we confirmed that this was an acute response to transformation using the inducible Src-ER MCF-10A cell system. To test whether downregulation of the LINC complex affects normal breast acinar architecture in 3D culture. We knocked down specific LINC complex components. This revealed that SUN1, SUN2 and nesprin-2, but not nesprin-1 were required for proper formation of a lumen in breast epithelial acini. In nesprin-2 depleted cells, re-expression of the actin binding domain of nesprin-2G, but not its microtubule motor binding domain, rescued normal acini formation. The formins FHOD1 and FHOD3 interact with nesprin-2 in fibroblasts and muscle cells to enhance actin coupling to the LINC complex (Kutscheidt, S et al, *Nature Cell Biol* 2014; Antoku S et al, *Dev Cell* 2019). We found that knockdown of either FHOD 1 or FHOD3 also prevented normal acini formation. By confocal microscopy of fixed or living breast acini, we identified a small zone of F-actin accumulation in close proximity to the nucleus on the basal side of the epithelium. We have generated a nesprin-2 degron to test whether nesprin-2 is also required to maintain normal epithelial architecture. Our results show that specific LINC complex components mediate the connection of nuclei to actin filaments in breast epithelial and that disrupting this connection results in abnormal acinar architecture, a hallmark of cancer.

B628/P1606

Pulsed Apical Constriction during Embryogenesis Is Driven by Self-Assembled and Intrinsically Disordered Actomyosin Networks

H. Zhu, T. Zhu, B. O'Shaughnessy; Columbia University, New York City, NY.

During embryogenesis, cells exert active forces to sculpt tissues into complex shapes that are precursors of organs and other specialized structures. Apical constriction is a conserved cell deformation mode that contracts and folds tissues. In many organisms, apical constriction is driven by contractile pulses generated by apical actomyosin cellular networks (Martin and Goldstein, 2014). These actomyosin networks have radial polarity: formins and actin filament barbed ends localize to the peripheral cell-cell junctions of the apical surface, while actin filaments point inwards with their pointed ends and myosin II localizing to the medial apical zone (Mason et al., 2013).

The mechanism of network formation and pulsed contraction is unclear. In Drosophila, medial-apical accumulation of upstream regulators such as RhoA determine the radial polarity, and RhoA may be the pacemaker for the pulsed network contractions (Mason et al., 2016). However, other studies suggest mechanical feedback from myosin to upstream signaling molecules drives radial polarity and pulsing (Munjal et al., 2015).

Here we built a detailed, molecularly explicit simulation of apical actomyosin networks in Drosophila embryos, incorporating polymerizing actin filaments, myosin II clusters, formins and actin crosslinkers, with amounts constrained by experiment. In simulations, myosin clusters and actin filaments spontaneously self-assembled into a disordered network with radial geometry. Myosin bundled actin filaments, and myosin density was greatest in the medial apical region, consistent with the observed myosin coalescence during apical constriction (Martin et al., 2009).

Interestingly, simulations exhibited spontaneous stochastic pulsing, with cyclic accumulation of actin filaments and myosin in the medial apical zone, reminiscent of cyclic bridging instabilities in fission yeast cytokinetic actomyosin rings with deficient actin severing activity (Cheffings et al., 2019). However, in simulations incorporating a RhoA pacemaker that regulated myosin on- and off-kinetics, pulsed contractions were far stronger.

Our results suggest actomyosin networks driving apical constriction use mechanical forces to self-

organize, that their intrinsic disorder leads to spontaneous stochastic pulsing, and an upstream pacemaker may render the pulsing dynamics far stronger and more coherent.

B629/P1607

Actomyosin Pulsing Protects Embryo Tissue Folding from Unavoidable Fluctuations due to Inherent Stochasticity in Cellular Systems

H. Zhu, B. O'Shaughnessy; Columbia University, New York City, NY.

A feature common to many morphogenetic processes across diverse organisms is pulsatile time-dependence of actomyosin contractile structures and contraction response. During embryogenesis myosin patterning with pulsatile time-dependence generates contractile stresses that reshape tissue into the precursors of organs and other structures, but the function of pulsing is not understood. *Drosophila* ventral furrow formation is a classic example, when tissue contraction and folding are driven by coordinated apical constriction of ventral cells, driven by apical actomyosin networks with pulsatile time-dependence (Martin et al., 2009). Without myosin pulsing, tissue contraction is inhomogeneous, with failure of tissue folding and furrowing, as observed in embryos with C-GAP depletion (Mason et al., 2016) or in myosin phosphomimetic mutants (Vasquez et al., 2014). Why furrowing requires pulsing is unexplained.

Here we used biophysical modeling and analysis of extensive experimental data to show pulsing protects tissue folding from unavoidable stochastic fluctuations in cellular myosin. Such variations are inherent to cells and multicellular organisms, and originate in stochasticity of upstream regulating networks and other processes. During Drosophila ventral furrow formation, myosin levels have large fluctuations from cell to cell (Heer et al., 2017). We show that the multicell contraction profile across tissue is highly sensitive to these cell-scale myosin fluctuations about the envelope, and when frozen in time they disrupt ventral furrowing in Drosophila, as seen experimentally (Mason et al., 2016; Vasquez et al., 2014). However, with pulsatile time-dependence the fluctuations are effectively time-averaged and dramatically weakened by a low-pass filter mechanism, and furrowing is rescued as observed in wild type embryos (Martin et al., 2009). We also explain why pulsing fails to rescue furrowing in Twist-depleted embryos (Xie and Martin, 2015): since a myosin envelope fails to ramp up, fluctuations are unopposed by tissue-scale envelope curvature that contracts cells and folds tissue. In conclusion, myosin pulsing is a low pass filter mechanism protecting tissue folding from unavoidable fluctuations in myosin due to the inherent stochasticity of upstream regulatory networks and other processes.

B630/P1608

Exploring the dynamic mechanical interactions of extruding cells and their neighbors: Do apoptotic cells leave? or are they pushed?

S. Anjum[1], Y. Atieh[2], G. T. Eisenhoffer[2], L. A. Davidson[1]; [1]Bioengineering, University of Pittsburgh, Pittsburgh, PA, [2]Genetics, University of Texas MD Anderson Cancer Center, Houston, TX.

Epithelial tissue homeostasis is necessary to maintain barrier function and to prevent the onset and progression of cancer. Damaged or dying cells are removed from epithelial tissues by the process of extrusion. The epithelium of larval zebrafish enables experimentally controlled cell death that allows apoptotic cell extrusion to be visualized *in vivo* and in real time. In these experiments, cells exhibit stochastic area oscillations before being removed from the tissue. Extrusion is thought to be driven by both cell-autonomous and non-autonomous processes that are difficult to test by traditional

experimental techniques alone. Furthermore, cell and tissue-scale mechanics are frequently assumed to be coupled, but these interactions are difficult to test *in vivo*. To address these issues, we develop and present a cell-based model that can capture the dynamics of oscillations prior to cell extrusion using amplitude, duration, and areas of contractile activity measured from *in vivo* live imaging. Starting with mechanically interacting cell centroids, we trigger extrusion of a single cell by reducing its interactions with neighbors such that the area change and ultimate extrusion of the triggered cell match rates of cell extrusion observed in living epithelia. To capture the dynamics associated with extrusion, we move centroids over time and tessellate them. To represent changes in cell area found experimentally, we develop a hybrid weighted Voronoi tessellation method capable of encoding the magnitude of cell-cell mechanical interactions into cell areas. Time-sequences of simulated epithelial tissues are then segmented to identify cell boundaries from which we analyze local and global shape changes. Now we can vary biophysical programs of both extruding and neighbor cells such as frequency and amplitude of area oscillations, as well as tissue-wide viscosity and confinement. To query autonomy, we can keep the properties of either an extruding cell, or its local neighborhood fixed over time. Our results demonstrate that cell autonomous properties dominate rates of cell area loss even as surrounding cells oscillate in area. This model illustrates how kinetic programs of cell oscillation and extrusion can be mechanically coupled to tissue-level stability and highlights the power of combining modeling and experimentation to characterize cellular and tissue mechanics.

B631/P1609

Revealing the cellular mechanisms of tracheal-esophageal separation through live imaging

R. Yan, C. Tabin; Department of Genetics, Harvard Medical School, Boston, MA.

The respiratory system of humans and other amniotes derives from the foregut during early embryonic development. Initially emerging as a pair of buds attached to the ventral side of the foregut tube, the respiratory system separates from the digestive tract through the septation of the trachea from the esophagus in concert with the elongation of the bronchi. In humans, defects in foregut patterning can disrupt this process, leading to congenital malformations impacting 1 in 3,000 newborns. Contrasting the current knowledge about the genetic components of tracheal-esophageal separation (TES), its cellular mechanisms, including what determines the narrowing of the epithelium and how the tracheal-esophageal junction moves anteriorly over time, remain largely elusive. To solve these questions, we developed explant culture systems for embryonic chick and mouse foreguts to recapitulate TES ex vivo, which allowed us to observe the cellular dynamics at unprecedented spatiotemporal resolution as well as to perturb the cellular pathways with pharmacological treatments. We identified actomyosin contraction as an essential component of TES, driving the bilateral indentation of the epithelial tube by the surrounding mesenchyme. As the opposite epithelial layers join, the junctional cells lose their apicobasal polarities and undergo apoptosis, further facilitating the mesenchymal invasion to split the foregut tube into the esophagus and trachea. Pharmacological inhibition of actomyosin contractility or apoptosis precludes TES and thus the formation of the trachea in explants. Our results reveal the essential cellular processes for TES, whose dysregulation potentially causes tracheal-esophageal malformations in patients. Combining ex vivo culture and quantitative live imaging, we are further investigating the physicochemical underpinnings of the cellular dynamics during normal and pathophysiological TES.

Decoding morphogenic instruction by Notch receptors

M. White, K. Jacobs, T. Singh, **M. L. Kutys**; Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA.

The coordination of genetic programs and the physical organization of cells sculpt developing tissues, drive regeneration and, when dysregulated, facilitate disease. Exchange of chemical and mechanical information at cell-cell interfaces necessarily coordinates these processes, though molecular details remain unclear. The ubiquitously important Notch pathway mediates cell-to-cell communication in a variety of tissues across developmental stages. Interestingly, recent work from our group and others have contributed to an emerging model where Notch receptor activation has the capacity to regulate both cell mechanics and transcriptional changes. Here, by employing an organotypic tissue-engineered model of human mammary ducts in combination with genetic approaches to specifically isolate the cortical and transcriptional arms of Notch signaling, we demonstrate that deletion of *NOTCH1* results in the morphogenic dysregulation of duct tissue architecture that is not observed with loss of Notch1 transcriptional activity. Live cell imaging reveals that loss of Notch1 cortical signaling leads to defects in epithelial polarization, adherens junctions and actin organization, and proliferation, which ultimately impairs tissue architecture through lumen filling and duct occlusion. Mechanistically, we identify that as epithelia reach confluence and initiate apical-basal polarization, Notch1 localizes to lateral membrane contacts via previously unappreciated protein-protein interactions. Lateral contact localization and complex assembly is coincident with proteolytic activation of Notch1, which occurs without any downstream transcriptional change, yet is necessary for epithelial cell-cell adhesion, polarity maintenance, and growth arrest. Further, we demonstrate the increase in cell proliferation and putative impaired contact inhibition in Notch1 knockout cells are driven by the aberrant internalization and signaling of EGFR. Together, these results establish new roles and mechanisms by which cortical Notch1 signaling influences the homeostatic maintenance of epithelial tissues.

Elucidating the role of copper and ATP7A in skeletal myogenesis

T. J. Whitlow, 1st Gen, Y. Zhang, N. J. Ferguson, A. M. Perez, H. Patel, J. Link, E. Larson, A. T. Mezzell, K. E. Vest; Molecular Genetics, Biochemistry, and Microbiology, UNIVERSITY OF CINCINATTI MED. SCHOOL, Cincinnati, OH.

Copper (Cu) is an important trace nutrient that functions as an enzyme cofactor and signaling molecule. Cu is also toxic, so intracellular Cu must be regulated by transporter and chaperone proteins. The trans-Golgi Cu transporter ATP7A provides Cu to secreted cuproenzymes and exports Cu when levels are high. Thus, ATP7A is a major determiner of intracellular Cu levels. Though the basic mechanisms of Cu handling are known, the tissue specific functions are less understood. Skeletal muscle accounts for approximately 23% of total systemic Cu and is required for movement, breathing, and swallowing. Skeletal muscle is a post-mitotic tissue comprised of multi-nucleated myofibers that can be regenerated by an associated pool of stem cells. Few studies have focused on ATP7A in muscle stem cells and muscle regeneration. Our previous work showed that total Cu, ATP7A protein, and *Atp7a* mRNA stability increase during muscle cell differentiation (myogenesis). Thus, we hypothesized that ATP7A is important for myogenesis. Proliferating C2C12 cells, an immortalized muscle cell line, and primary myoblasts can be induced to form multinucleated myotubes in a process that resembles in vivo myogenesis. We found

that ATP7A deficiency impairs myotube formation in both, suggesting that it is a critical component of myogenesis. ATP7A loads copper onto secreted cuproenzymes and also pumps copper directly out of the cell as the primary copper detoxification pathway. Using BCS-mediated Cu chelation, we determined that the differentiation defect from ATP7A loss was not due to copper overload. This led us to hypothesize that the primary role of ATP7A is to provide copper to secreted enzymes. We determined that co-differentiating ATP7A knockdown cells with wild type cells in trans-wells rescues myotube formation. We then sought to determine which secreted cuproenzyme is necessary for myogenesis. Previous literature suggests that the amine oxidase lysyl oxidase (LOX) is required for myogenesis. We found that knocking down ATP7A reduced LOX activity, and that addition of recombinant LOX rescues differentiation in ATP7A knockdown cells. These results confirm that ATP7A is important for providing Cu to secreted factors that are required for differentiation thus adding to our knowledge of tissue specific Cu requirements.

B634/P1612

Stage specific copper prioritization during muscle cell differentiation

A. M. Perez, Y. Zhang, T. J. Whitlow, K. E. Vest; Molecular Genetics, Biochemistry, and Microbiology, University of Cincinnati, Cincinnati, OH.

Copper (Cu) is an essential trace nutrient that acts as a cofactor in enzymes required for fundamental processes like energy production. Cu can be toxic and therefore must be tightly regulated. The primary importer of Cu into the cell is CTR1. In the cytoplasm, Cu can be bound by intracellular Cu proteins, bound by small molecule metabolites in labile Cu pools, exported via ATP7A, or imported into mitochondria. Mitochondrial Cu is important for oxidative phosphorylation (OXPHOS) for both energy generation and metabolite synthesis. Cu enters the mitochondrial matrix via the transport protein SLC25A3 before transport to the IMS. Impairment of any of these pathways can lead to systemic or cellular Cu deficiency or overload and cause diseases with tissue specific defects, which are poorly understood. Skeletal muscle is a regenerative tissue that contains ~23% of total Cu, which is largely attributed to the function of Cu in OXPHOS. However, the function of Cu in muscle regeneration is poorly understood. Skeletal muscle is made up of bundles of multinucleated myofibers. Residing along the myofibers are satellite cells (SC), adult stem cells that drive muscle regeneration. Skeletal muscle regeneration, known as myogenesis, requires activation, proliferation, and differentiation of SC. This process requires coordinated activity of intracellular and extracellular signaling pathways. Our published and unpublished data suggest that Cu is required for muscle cell differentiation and that ATP7A-mediated Cu export to secreted enzymes is required at the intermediate stages of myogenesis. However, the importance of mitochondrial Cud during myogenesis is not known. We hypothesized that mitochondrial Cu needed in mature skeletal muscle rather than for myogenesis. Using siRNAs, we knocked down *Slc25a3* in C2C12 myoblasts and found that myotube formation is not affected. This result suggests that although we know that mitochondrial Cu is required for OXPHOS, it is not required for differentiation of C2C12 myoblasts. Our future studies will focus on understanding when mitochondrial Cu is loaded during myogenesis and how it is delivered from CTR1 to mitochondria.

Evaluating neuroprotective effects of sulforaphane in a VPA-induced autism model

R. Bessetti[1], V. Koonce[1], A. Papariello[1], C. Camacho[1], K. McCoy[2], K. Litwa[1]; [1]East Carolina University/Anatomy and Cell Biology, Greenville, NC, [2]Florida Atlantic University, Boca Raton, FL.

In the last decade, U.S. Autism Spectrum Disorder (ASD) diagnoses have increased. Pregnant women are commonly exposed to environmental factors that can increase the likelihood of offspring developing an ASD. A potential avenue for reducing the adverse effects of environmental contaminants is to enhance the body's own detoxification and antioxidant pathways, ultimately reducing cellular oxidative stress. NF-E2-related factor 2 (Nrf2) is a transcription factor thatpromotes the expression of cytoprotective and antioxidant genes. The phytochemical, sulforaphane (SFN), potently activates the Nrf2 pathway by decreasing Nrf2 proteasomal degradation mediated by Keap1 (Kelch-like ECH-associated protein 1). Our investigation aims to test the hypothesis that SFN will protect developing neural circuits from the detrimental effects of environmental contaminants. We generated a human fetal brain model of chemically-induced autism by exposing human cortical spheroids (HCSs) to the anti-epileptic drug valproic acid (VPA). Fetal exposure to the VPA has been linked to an increased risk of developing an ASD in humans and autism-like behavior in rodents. At a molecular level, VPA functions as an inhibitor of histone deacetylases and is known to increase oxidative stress. In HCSs, either VPA or SFN alone impair synapse formation. Whereas in combination, they restore synapse formation. Nrf2 nuclear translocation is increase by both VPA and SFN. We are also using CRISPR interference to establish whether sulforaphane's effects are mediated via the Nrf2 pathway. We have successfully used this technology to decrease Nrf2 expression in HCSs. Based on these findings, we are currently testing the hypothesis that synapse formation requires a delicate balance between oxidative stress and antioxidant buffering. Our data supports that sulforaphane can restore synapse formation and oxidative homeostasis in the presence of environmental stressors.

B636/P1614

Organ size and shape control by potassium-channel mediated bioelectricity in zebrafish

G. Zhang; Comparative Pathobilogy, Purdue University, West Lafayette, IN.

Organ size determination and growth regulation are critical in animal embryogenesis and larva growth. Vertebrate limbs and fins have been served as a model for studying this fundamental question. The zebrafish fin development has been extensively studied. However, the signals that determine fin size and shapes remain largely unexplored. We identified two long-fin zebrafish mutants of inwardly rectifying potassium channel (*kir*) genes. These mutants show allometric growth during the larva stage and significant longer fins in adults in a genetically dominant manner. We mapped a viral DNA insertion into the noncoding region of the two *kir* genes, and this insertion led to a transient and ectopic expression in somite, from which the fin ray progenitors originate. Moreover, we showed that ectopic expression of additional *kir* genes in the somite of transgenic zebrafish phenocopied the long-fin phenotype in a gene dosage-sensitive manner. Furthermore, this long-finned phenotype was only able to be reversed by a CRISPR-induced *kir* gene loss-of-function mutation in an allelic-specific manner. Taken together, our results reveal that potassium-channel mediated bioelectricity is an emerging vital regulator for fin size determination in zebrafish.

B637/P1615

Multiscale mechanical reinforcement for the propagation of a morphogenetic process

S. Weng, R. J. Huebner, C. C. Devitt, B. Nyaoga, J. R. Alvarado, J. B. Wallingford; University of Texas At Austin, Austin, TX.

Force propagation integrates cell intercalation and tissue-scale convergent extension

Convergent extension (CE) is an evolutionary conserved morphogenetic process by which repeated polarized cell intercalations drive convergence in one axis and elongation of the tissue in an orthogonal direction. We recently showed that the poorly characterized catenin Arvcf is largely dispensable for cell intercalation but is absolutely required for mechanically effective CE. Here, we explore the mechanisms by which Arvcf links cellular behaviors and tissue-scale shape change, using new methods for image-based mechanical assessment at different scales. We found that Arvcf-dependent converging forces were required to fully resolve individual cell intercalation events and that local converging forces can propagate in the direction of tissue extension. These data suggest a multiscale mechanical feedforward loop underpinning the propagation of CE across the tissue. By contrast, in the absence of Arvcf, converging forces were reduced and cells took on aberrant packing configurations that effectively blocked force propagation. Together, these data are significant for providing new biomechanical and cell biological insights into a fundamental morphogenetic process that is implicated in human neural tube defects and skeletal dysplasia.

B638/P1616

The spindle orienting machinery requires activation, not just localization

T. M. Finegan, K. E. Neville, D. T. Bergstralh; Department of Biology, University of Rochester, Rochester, NY.

The orientation of the mitotic spindle at metaphase determines the placement of the daughter cells. Spindle orientation in animals typically relies on an evolutionarily conserved biological machine comprised of at least four proteins - called Partner of Inscuteable (Pins), Gαi, Mushroom body defective (Mud), and Dynein in flies - that exert a pulling force on astral microtubules and reels the spindle into alignment. The canonical model for spindle orientation holds that the direction of pulling is determined by asymmetric placement of this machinery at the cell cortex. In most cell types, this placement is thought to be mediated by Pins, and a substantial body of literature is therefore devoted to identifying polarized cues that govern localized cortical enrichment of Pins. In *Drosophila* neuroblasts, for example, this cue is thought to be Inscuteable, which helps recruit Pins to the apical cell surface. In this study we revisit the canonical model. We find that spindle orientation in the follicular epithelium requires not only Pins localization but also activation, which relies on direct interaction between Pins and the multifunctional protein Discs large. This mechanism is distinct from the one mediated by Inscuteable, which we find also has an activating step. Together our results show that the canonical model is incomplete. Local enrichment of Pins is not sufficient to determine spindle orientation; an activation step is also necessary.

B639/P1617

The tricellular junction protein tricellulin is involved in multiciliated cell epithelial insertion during Xenopus skin development

C. Savvidou, K. Miti, N. Christodoulou, P. A. Skourides; UNIVERSITY OF CYPRUS, Nicosia, Cyprus

Epithelial cell insertion is a crucial process necessary for early embryo development and tissue homeostasis. To accomplish this, cells become polarized, move apically anchoring at the epithelial tight junctions, and subsequently remodel these junctions generating an apical surface. Multiciliated cell (MCC) intercalation into the epidermis during *Xenopus laevis* embryogenesis can be used as a model system to understand the cellular and molecular mechanisms orchestrating cell insertion into an epithelium. Previous studies have revealed that MCCs anchor preferentially at the contacts of three epithelial cells, a structure known as tricellular junction (TCj). Lipolysis-stimulated lipoprotein receptor (LSR) and tricellulin (Marveld2) are the two main components of vertebrate tricellular junctions. LSR was recently shown to be necessary for MCCs insertion into the skin epithelium. However, the role of tricellulin during MCC intercalation has not been addressed. Here our aim is to elucidate the role of tricellulin in MCC radial intercalation. Our data show that tricellulin has a crucial role during MCCs epithelial insertion. Specifically, we show that the majority of MCCs expressing dominant negative constructs of tricellulin fail to emerge at the surface of the epithelium. The few cells which do emerge display severe ciliogenesis defects. Analysis of the apical actomyosin network in MCCs expressing the tricellulin mutant constructs suggests that the cell intercalation and ciliogenesis defects stem from defective apical actin organization. Overall, our findings reveal a novel role of tricellulin in MCCs radial intercalation which can serve as the basis for future studies aiming to examine the role of tricellular junction proteins in the insertion of cells into an epithelium in development and disease.

B640/P1618

PSPC1 deficiency retards angiogenesis by downregulating VEGFR2 and Dll4/Notch1 signaling

C. Y. Chang, S. S. Lee, Y. S. Jou; Institute of Biomedical Sciences, Academia Sinica, Taiwan, Taipei, Taiwan

Paraspeckle component 1 (PSPC1) has been known to be the contextual determinant of pro-metastatic switches of TGFβ and subcellular translocations of oncogenic proteins in tumor progression. PSPC1 was expressed during early developmental stage in multiple tissues. However, the biological functions of PSPC1 during development remain largely unknown. Here, we generated *Pspc1* knockout (*Pspc1* KO) mice and discovered the impacts of PSPC1 in development. *Pspc1* KO mice showed dilated hearts with smaller size, decreased reticulocyte number, reduced height of intestinal villus, abnormal cerebellar foliation, and increased lipid drop in adipocyte tissue, and about 75% *Pspc1* KO mice died in early postnatal stage. Among multiple *Pspc1* tissue-specific knockout mice, endothelial-specific *Pspc1* knockout (*Pspc1* Tie2-cKO) mice had higher postnatal death rate and resembled the smaller heart size phenotype of *Pspc1* KO mice. In *Pspc1* Tie2-cKO heart, retarded coronary vasculature was detected. In retinal angiogenesis assay, the vessel progression was significantly retarded with diminished endothelial cell proliferation and filopodia formation in *Pspc1* Tie2-cKO mice. Moreover, knockdown of *Pspc1* in mouse endothelial MS1 cells significantly abolished angiogenic sprouting in 3D fibrin gel bead assay. By transcriptome analysis, knockdown of *Pspc1* significantly downregulated Dll4 and VEGFR2 mRNA levels, and also the Dll4/Notch1 and receptor tyrosine kinase signaling pathways. By Western blots assay, knockdown of *Pspc1* largely reduced the VEGFR2 phosphorylation and Notch1 activation respectively stimulated by VEGF treatment and increasing cell density. Interestingly, *Pspc1* knockdown induces the

tip cell gene expressing signature in MS1 cells. Together, our results indicated that expression of *Pspc1* is required for angiogenic sprouting, especially in tip cell induction, vasculature development and heart morphogenesis of mouse.

B641/P1619

Using multiphoton fluorescence lifetime imaging to visualize NADH/FAD endogenous autofluorescence in *Drosophila* early embryogenesis

M. España, A. C. Paré, K. Quinn; University of Arkansas, Fayetteville, AR

Tissue remodeling occurs in the context of both normal development and wound healing. By studying tissue remodeling events across a range of organisms--notably convergent extension (CE) during head-to-tail axis elongation--researchers have identified conserved contractile and adhesive proteins that alter cell morphology. In addition, the processes that drive CE share striking similarities at the molecular level with epithelial wound healing, and many view epithelial regeneration as a reactivation of normal developmental mechanisms. Notably, wound healing is also dependent on mitochondrial dynamics (i.e., fusion and fission) and the production of reactive oxygen species. It is therefore compelling to think that changes in cellular metabolism or mitochondrial signaling may be necessary to drive the dynamic cellular processes of CE, although this has not been demonstrated *in vivo*. One of the premier models for studying CE is the *Drosophila* embryo, because 1) cell movements are easy to visualize, 2) CE occurs rapidly over the course of 30 minutes, and 3) tissue remodeling occurs in the absence of cell division (which complicates analysis in other systems). To address whether there are changes in cellular metabolism over the course of CE in living embryos, we are using non-destructive multiphoton microscopy and fluorescence lifetime imaging (FLIM) to visualize the endogenous autofluorescence of mitochondrial cofactors before, during, and after CE. We are also using fractal image analysis to probe mitochondrial network architecture to ask whether mitochondrial dynamics are correlated with CE. These experiments will reveal the role of cellular bioenergetics during tissue remodeling in the context of normal development, and may contribute to our understanding of the cellular basis of wound healing and CE-based birth defects, such as spina bifida.

Visualization of cytoskeletal proteins reveals the architecture of the cortical actomyosin network driving apical constriction in C. elegans

P. Zhang, **T. N. Medwig-Kinney**, B. Goldstein; University of North Carolina At Chapel Hill, Chapel Hill, NC

Apical constriction results in cell shape changes that drive key morphogenetic events during development, including Drosophila ventral furrow formation, C. elegans gastrulation, and vertebrate neural tube formation. Apical constriction is primarily driven by contraction of apical actomyosin networks. It has been reported that the actomyosin networks of the epithelial cells within the ventral furrow of Drosophila exhibit a radial sarcomere-like pattern, where nonmuscle myosin II, myosin-activating kinase, and pointed end-capping proteins all exhibit enrichment in the center of the apical domain. To determine if this is a broadly conserved actin architecture during apical constriction, we examined actomyosin dynamics during C. elegans gastrulation, in which two endodermal precursor cells internalize from the surface of the embryo. We observed enrichment of nonmuscle myosin (NMY-2) and a myosin regulatory light-chain kinase (MRCK-1) in the apical cortex, as expected. However, we did not observe enrichment of NMY-2 or MRCK-1 in the center of the apical domain; instead, both proteins

exhibited punctate localization throughout the apical cortex. To visualize the polarity of actin filaments, we used CRISPR to generate endogenously tagged alleles of several capping proteins and focused on those that were readily visible in the endoderm precursors. CAP-1, a barbed-end capping protein, was enriched at cell-cell contacts, consistent with what was observed in Drosophila. However, UNC-94, a pointed-end capping protein, was not enriched in the center of the apical cortex and instead showed a more diffuse pattern throughout the apical cortex. Our observations suggest that C. elegans endoderm precursors employ a mixed-polarity actin network with myosin and a myosin activator distributed throughout this network, in contrast to the polarized actomyosin network reported in Drosophila epithelial cells. Taken together, these results suggest that diverse strategies of actomyosin organization are used in animal cells to accomplish apical constriction.

Investigating horizontal cell ultra-structure through 3-D electron microscopy in the pure-rodskate retina

Y. Yusuf, I. Anastassov; San Francisco State University, San Francisco, CA

The overall goal of this project is to determine what molecular and structural adaptations have allowed the pure-rod skate (L. erinacea) retina to achieve functionality over a full range of brightness conditions. The visual systems of most vertebrate species have two different kinds ofphotoreceptors: rods and cones. Vertebrates can distinguish color and bright light by combining and comparing signals from cones sensitive to different wavelengths of light. Rods are sensitive to low light levels and drive vision in dim light.

L. erinacea only possesses rods, which can function across large ranges of light intensity. We aim to understand how the skate retina achieves functional duality with a monotypic photoreceptor population. Specifically, we aim to describe how the diversity of horizontal cells (i.e., a downstream partner of rods and cones) and their structural characteristics contribute to the ability of the skate retina to transmit visual information across vastly different levels of illumination. We analyze differences between internal and external horizontal cells (IHC and EHC, respectively) by using serial section EM data to obtain 3D representations of cell structure and cell connectivity.

SB-3DEM was performed on skate retina; the dataset analyzed here was from adult animals with width=57.344µm, height=315.392µm, and depth=34.79µm. Voxel size was 7x7x70nm.

Preliminary 3-D reconstructions of an IHC show a length of ~55.41µm, while reconstructions of an EHC show a length of 54.14µm. Volume and surface for both cells appear to be significantly different from each other, with IHCs having a larger surface area (~1755µm 2) and a smallervolume (~2173 µm 3), and EHCs having a smaller surface area (~1566µm 2) and larger volume (~3963 µm 3). Additional reconstructions of connections of each cell type to rods is ongoing, but preliminary data suggests EHCs contact significantly more rods than IHCs.

Large differences in structural characteristics between IHCs and EHCs suggest a possible division along functional lines. Given that in mixed rod-cone retinas, horizontal cells contact rods or cones very selectively, we hypothesize that IHCs and EHCs also contact rods selectively. However, we propose that this selectivity is based on the numbers and functional range of the contacted rods within the dendritic field of each type of horizontal cell.

Investigating cell type specific modes of Wnt dispersal *in vivo*

M. Favichia[1], B. Goldstein[2], A. M. Pani[1]; [1]University of Virginia, Charlottesville, VA, [2]University of North Carolina at Chapel Hill, Chapel Hill, NC

Wnts are secreted signaling proteins with essential roles in development, homeostasis, and disease. How Wnt signaling is regulated in space and time is a key question in developmental and cell biology. Wnt ligands can move between cells to activate signaling across a range of distances, and in different contexts Wnts can utilize distinct mechanisms to disperse between cells. However, the cell-biological bases for Wnt dispersal in living animals remain unknown in many cases, and the extent to which dispersal mechanisms vary by cell type, organism, and/or ligand remain uncertain. We are using *C. elegans* as a tractable system for *in vivo* cell biology that is amenable to live imaging and rapid genome engineering. *In vivo* imaging of multiple endogenously tagged Wnts and architectures of Wnt-expressing cells revealed cell-type specific modes of Wnt transport during larval development and a potentially novel mechanism for long-range Wnt signaling. Live imaging of two Wnt homologs, CWN-1 and EGL-20, revealed two scenarios where we hypothesize that neurons, or neuron-like cells, utilize different transport processes to deliver Wnt proteins over long distances to non-neuronal cells. We observed that CWN-1 is highly expressed in Canal Associated Neuron (CAN) cells during larval development, and endogenously tagged CWN-1 localizes to mobile punctae within the bipolar, axon-like CAN projections. Time-lapse imaging revealed anterograde transport for CWN-1 punctae in CAN cells at speeds consistent with kinesin motor proteins. However, CWN-1 appears to spread between cells by extracellular diffusion during embryonic development, which provides an example of cell-type specific Wnt dispersal mechanisms. To test the extent to which Wnt transport in neurons may generally resemble CWN-1 tranport in CAN, we examined Wnt/EGL-20 transport in *egl-20*-expressing neurons with projections to the ventral nerve cord. We observed that endogenous EGL-20 accumulates on cells adjacent to axons of *egl-20*-expressing neurons, and EGL-20 distribution in neighboring cells tracks outgrowth of these axons during development. However, we did not observe clear EGL-20 punctae in axons, which suggests the mode of transport differs from CWN-1 transport in CAN. To test whether differences in transport depend on cell type vs. ligand, we expressed EGL-20::mNG in CANs using a short fragment of the *cwn-1* promoter. Transgenically expressed EGL-20 localized to punctae in CAN cell extensions similar to endogenous CWN-1, which indicates that transport modes for these proteins in their endogenous contexts likely depends on cell type rather than properties of the different ligands. We are currently investigating how CWN-1 is trafficked and secreted from CAN and the functions for Wnt signaling from these cells.

B645/P1623

Urotensin-II-related peptides, Urp1 and Urp2, control zebrafish spine morphology

E. E. Bearce; University of Oregon, Eugene, OR

The spine provides structure and support to the body, yet how it develops its characteristic morphology as the organism grows is little understood. This is underscored by the commonality of conditions in which the spine curves abnormally such as scoliosis, kyphosis and lordosis. Understanding the origin of such spinal curves has been challenging in part due to the lack of appropriate animal models. Recently, zebrafish have emerged as promising tools with which to understand the origin of spinal curves. Using zebrafish, we demonstrate that the Urotensin II-related peptides (URPs), Urp1 and Urp2, are essential

for maintaining spine morphology. Urp1 and Urp2 are 10-amino acid cyclic peptides expressed by neurons lining the central canal of the spinal cord. Upon combined genetic loss of Urp1 and Urp2, adolescent-onset planar curves manifested in the caudal region of the spine, akin to a lordosis-like condition. Highly similar curves were caused by mutation of Uts2r3, an URP receptor. Quantitative comparisons revealed that Urotensin-associated curves were distinct from other zebrafish spinal curve mutants that more closely reflected idiopathic scoliosis or kyphosis. Last, we found that the Reissner fiber, a proteinaceous thread that sits in the central canal and has been implicated in the control of spine morphology, breaks down prior to curve formation in an idiopathic scoliosis model but was unperturbed by loss of Uts2r3. This suggests a Reissner fiber-independent mechanism of curvature in Urotensin-deficient mutants. Overall, our results show that Urp1 and Urp2 control zebrafish spine morphology and establish new animal models of lordosis-like curves.

The role of Pericentrin in Kupffer's vesicle (KV) formation

Y. WU[1], K. Rasmussen[1], L.-E. Jao[2], H. Hehnly[1]; [1]Syracuse University, Syracuse, NY, [2]University of California Davis School of Medicine, Sacramento, CA

Human diseases such as dwarfism, mental disorders, and ciliopathies are linked to loss-of-function mutations in the centrosome gene, Pericentrin. Pericentrin is a largely conserved centrosome-localized coiled-coil protein that serves as a multifunctional scaffold for protein anchoring (Delaval and Doxsey, 2009). Pericentrin has been linked to regulating cilia formation, spindle assembly and positioning, centrosome positioning, and tissue morphogenesis. Correct spindle positioning, followed by strategic placement of the cytokinetic bridge within the confines of a developing tissue, can ultimately determine where daughter cells are positioned. A report from our lab identified that cell division, specifically the final stage of cell division, cytokinetic bridge placement and cleavage, could potentially be employed for lumen formation *in vivo* (Rathbun et al., 2020). In our current work, we again took advantage of Danio rerio's (zebrafish) left-right organizer, the Kupffer's vesicle (KV), to test the role of Pericentrin in directing KV cell patterning events. To do this, we compared wild-type ($pcnt^{+/+}$) to $pcnt^{-/-}$ as well as $pcnt^{+/-}$ embryos. KV development requires a population of migratory-like progenitor cells (15-20 cells) to potentially proliferate, then self-assemble into a rosette-like structure. This structure then transitions into a cyst of ciliated cells with a fluid-filled lumen located at the base of the notochord (approximately 100-200 cells in total). Our studies identified that $pcnt^{-/-}$ as well as $pcnt^{+/-}$ embryos have significantly fewer cilia and a decreased lumen area compared to the control animals ($pcnt^{+/+}$). To determine if this was due to defects in mitotic progression, we first needed to better characterize the mitotic and post-mitotic population of KV cells under control conditions. Interestingly, we not only identified a significant mitotic (phospho-Histone3B$^+$) and post-mitotic (BrdU$^+$) population of KV cells, but also that both populations were enriched towards the notochord. This finding suggests that mitotic activity is spatially confined during KV development. A significant decrease in KV cells number was found in $pcnt^{+/-}$ embryos compared to control. This finding suggests that the loss of Pericentrin results in KV cell proliferation defects. Our future directions are to carefully characterize $pcnt^{+/-}$ and $pcnt^{-/-}$ KV cell mitotic behavior and organization during KV development, and further characterize downstream developmental defects that may occur (e.g., congenital heart defects, laterality defects, and overall size differences).

Embryogenesis

Optogenetic rescue of a patterning mutant

H. E. Johnson[1], N. J. V. Djabrayan[2], S. Y. Shvartsman[3], J. E. Toettcher[4]; [1]Biological Sciences, The University of Hong Kong, Hong Kong, HONG KONG, [2]Visiting Assistant Professor, Clark University, Boston, MA, [3]Chemical and Biological Engineering, Princeton University, Princeton, NJ, [4]Molecular Biology, Princeton University, Princeton, NJ.

Animal embryos are partitioned into spatial domains by successive patterns of intracellular signaling and gene expression. Yet in most cases it is unknown which pattern features are required to support normal development. In one such example early in *Drosophila* development, receptor tyrosine kinase (RTK) activity leads to an evolving gradient of Erk activity, patterns gene expression, and the specification of tissues / morphogenic movements. The ideal experiment to determine the required features of signaling would be to abolish this signaling to create a “blank canvas” and “paint” arbitrary signaling patterns back onto it. To accomplish this, we developed a light-inducible system activate Erk in early Drosophila embryo and expressed it in a mutant background devoid of a forementioned RTK signaling. In this background, we systematically test the requirements of early embryo Erk signaling for cell fates, gene expression, and the formation of a viable embryo. Surprisingly, we find that the embryo is quite robust to spatial perturbations in the signal, as simple all-or-none light inputs were able to completely rescue normal embryogenesis, generating viable larvae and fertile adults from an otherwise-lethal genetic mutant. Systematically varying illumination parameters further revealed that at least three distinct developmental programs are triggered at different signaling thresholds and that the morphogenetic movements of gastrulation are robust to a 3-fold variation in the posterior pattern width. These results have opened the door to studies using these techniques to reveal the role of more complex signaling dynamics during development. Through live imaging of signaling biosensors, we have begun to map intricate signaling dynamics during development. We are now extending these optogenetic techniques to these complex developmental events and signaling dynamics to understand their function.

How conserved signaling pathways build the unique tardigrade body

K. L. Heikes[1], B. Goldstein[2]; [1]Genetics and Molecular Biology, UNC Chapel Hill, Chapel Hill, NC, [2]Biology, UNC Chapel Hill, Chapel Hill, NC.

Embryonic development depends on precise communication between cells to establish patterns, such as germ layers and tissue morphology. Most knowledge of developmental patterning mechanisms stems from studies using only a small number of model systems. Emerging models provide means to explore how the same signaling pathways are used to construct organisms of diverse shapes. The tardigrade *Hypsibius exemplaris* is one such system. Although tools to study *H. exemplaris* are limited, methods do exist for fluorescence in situ hybridization (FISH). We studied the Bone Morphogenetic Protein (BMP) and Fibroblast Growth Factor (FGF) pathways at 24 hours post laying, using FISH to reveal expression patterns of *H. exemplaris* homologs to build a picture of where these pathways function. We found that the BMP receptors thickveins (*tkv*) and punt (*put*) are ubiquitously expressed, which suggests that most cells are receptive to BMP signaling. The BMP ligand decapentaplegic (*dpp*) is enriched in a set of cells laterally along the left and right sides of the embryo in the outermost (presumptive ectoderm) layer of

cells, and the BMP antagonist short gastrulation (*sog*) is enriched in a similar pattern. We examined *dpp* and *sog* in combination using double FISH and found that the *dpp* pattern is more dorsal than the *sog* pattern. Applying knowledge of BMP signaling from other systems, we hypothesized that BMP signaling functions laterally in *H. exemplaris* to either establish ectodermal fate, pattern the cuticle, pattern the limbs, or a combination of these roles. We also examined expression of the FGF ligand (*fgf8*) and the most highly expressed FGF receptor (*fgfr1*). We found that *fgf8* is expressed in the outermost layer of cells in a striped pattern, likely overlapping with the posterior end of each segment boundary, and *fgfr1* is expressed in a more internal layer of cells, overlapping with the regions where the presumptive endomesodermal pouches form within each segment. We hypothesized that FGF signaling specifies the fate of the cells in these pouches. We will address these hypotheses using chemical inhibitors of BMP and FGF signaling to see how disruption of these pathways impacts development. This work collectively sheds light on how the unique tardigrade body develops and expands our knowledge of the ways conserved signaling pathways are used to build diverse organisms.

ATF6 responses to ER stress under high temperature during early porcine embryonic development

M. SUN, X. Cui; Chungbuk National University, Cheongju, KOREA, REPUBLIC OF.

Activating transcription factor 6 (ATF6), one of three sensor proteins in the endoplasmic reticulum (ER), is an important regulator in the ER stress-induced apoptosis pathway. ATF6 resides in the ER and upon activation is translocated to the Golgi apparatus, where it is cleaved by site-1-protease (S1P) to generate an amino-terminal cytoplasmic fragment. Although recent studies have made some progress in elucidating the regulatory mechanisms of ATF6, the function of ATF6 during early porcine embryonic development under high temperature remains unclear. In this study, zygotes were divided into 3 groups: control, high temperature (HT) group, and HT+ATF6 knockdown group. The results showed that ATF6 is expressed at all stages during embryonic development, with ATF6 clustered around the nucleus at 2- and 4-cell stages and localized in the nucleus at BL stage. Meanwhile, the HT decreased blastocyst rate, and increased levels of ATF6 protein expression and lead to a nuclear localization of ATF6 upon induction of 4-cell stage. Next, the expression level of ATF6 was knocked down in embryos by microinjection of ATF6 dsRNA, and the results showed that the reduction of ER marker Calnexin expression, Ca^{2+} release and abnormal ER distribution caused by HT can be alleviated by reducing ATF6 expression. In addition, ATF6 knockdown also reduced the level of embryonic apoptosis mediated by elevated AIFM2 expression in heat-exposed embryos. In conclusion, the results suggest that ATF6 is an important mediator of HT-induced ER stress as well as apoptosis during early porcine embryonic development. Key words: ATF6; embryo; high temperature; ER stress; apoptosis

Effect of YBX1 on Early Embryonic Development in Pigs

W. Jiang, X. Cui; Chungbuk National University, Cheongju, KOREA, REPUBLIC OF.

Y-box binding proteins, including YBX1, are a group of proteins found in bacteria, plants, and animals. YBX1 is a member of the family of DNA- and RNA-binding proteins, that plays vital roles in multiple aspects, including RNA stabilization, translational repression, and transcriptional regulation, but its roles remain less known during pre-implantation development. In this study, to investigate the function of YBX1 and its mechanism of action in porcine embryo development, YBX1 was knocked down by

microinjecting double-stranded RNA of YBX1 at the 1-cell stage. YBX1 was located in the cytoplasm during embryo development. The mRNA level of *YBX1* was increased from 4-cell stage to blastocyst but it was significantly decreased in YBX1 knockdown embryos compared with the control. Moreover, the percentage of blastocysts was decreased in following YBX1 knockdown compared with the control. Defecting YBX1 expression decreased the level of m^6A, METTL3, and YTHDF2 at 4-cells and blastocyst. Additionally, YBX1 depletion reduced histone modification (H3K9ac and H3K4me2) at 4-cells. YBX1 knockdown increased the unfolded protein response and endoplasmic reticulum stress. In conclusion, YBX1 is essential for early embryo development by regulating mRNA stability and translation.

B651/P1629

GRP78 is Required for the Stabilization of MC4R in Porcine Embryos

G. Heo, X. S. Cui; ChungBuk National University, Seowon-gu, Cheongju-si, Chungcheongbuk-do, KOREA, REPUBLIC OF.

GRP78(Glucose-Regulated Protein 78) is a protein known to be overexpressed in the context of glucose deficiency. Currently, many studies have been conducted on the increase in expression of GRP78 due to Endoplasmic Reticulum (ER) stress. However, there are no studies examining the role of GRP78 in germ cells, particularly porcine embryos. Therefore, the purpose of this study was to investigate the role of GRP78 in porcine embryonic development. HA15, an inhibitor of GRP78, was added to the culture medium and embryos were cultured for 7 days. Inhibition of GRP78 reduced the activity of MC4R and subsequently decreased the activity of Gαs, a type of G protein. As evidence, it was confirmed that the amount of cAMP was decreased in porcine blastocyst in which GRP78 was inhibited. Also, CDK1, CDK2, p-ERK 1/2, and APC/C are proteins related to cell division, and their expression was reduced in the HA15-added group compared to the control. As expected, the expression of p-DRP1 was increased in GRP78-inhibited blastocyst. PGC1α and SIRT1, which induce mitochondrial biogenesis, were decreased in porcine embryos lacking GRP78. Furthermore, inhibition of GRP78 led to mitochondrial dysfunction including decreasing ATP content, mitochondrial membrane potential, and active mitochondria. In conclusion, GRP78 is essential for the development of porcine embryos due to GRP78 regulates the G protein-coupled receptor pathway and cell proliferation by contributing to the internalization and stabilization of MC4R and it also helps to maintain the function of mitochondria.

B652/P1630

Effect of Zscan4 on porcine embryonic development

X. Li, X. Cui; Chungbuk National University, Cheongju, KOREA, REPUBLIC OF.

Zinc finger and SCAN domain containing 4 (Zscan4) is a DNA-binding protein which involved in the regulation of telomere elongation and genomic stability in mouse embryos and embryonic stem cells. However, the effect of Zsacn4 on telomere length in porcine preimplantation embryos remains less known. In this study, to investigate the function and underlying mechanism of Zscan4 in porcine embryo development, Zscan4 was knocked down by microinjection of dsRNA and Dnmt1 was inhibited by the inhibitor at the 1-cell stage. Zscan4 was highly expressed at the 4-cell and 5-8-cell stage of porcine embryos. The percentage of 5-8 cell stage embryos and blastocyst were decreased in Zscan4 knockdown group compared to control. Notably, depleting Zscan4 induced the protein expression level of Dnmt1 as well as DNA methylation (5mC) at the 4-cell stage. Meanwhile, the expression levels of Tet2 and H3K9me3 were decreased following Zscan4 knockdown. The q-PCR results showed that Zscan4

knockdown led to decrease of *Trf1* mRNA expression level and the shorten telomere length compared to control. In addition, the Hinokitiol, a kind of Dnmt1 inhibitor, was used to reduce DNA hypermethylation in Zscan4 knockdown embryos. Dnmt1 inhibition rescued the blastocyst defects caused by Zscan4 knockdown. In conclusion, Zscan4 is essential for maintain of telomere length and genomic stability by regulating Dnmt1 expression during early porcine embryonic development.

B653/P1631

Alpha-lipoic acid Attenuates Heat stress-induced Oxidative Stress in Porcine Embryos

S. Lee, X. Cui; Chungbuk National University, Cheongju, KOREA, REPUBLIC OF.

Heat stress (HS) is one of the long-standing barriers that animals face in the living environment and has deleterious effects on reproductive performance and may ultimately lead to infertility. Alpha-lipoic acid (ALA) is a strong antioxidant synthesized by plants and animals, known as a cofactor for mitochondrial bioenergetic enzymes. Previous studies have shown that ALA has a protective effect on oxidative stress and endoplasmic reticulum stress caused by heat damage in mammalian reproductive system. However, the mechanism of ALA in HS-induced early porcine embryonic development has not been investigated. In this study, parthenogenetically activated porcine zygotes were divided into 3 groups: control, high temperature (HT) group (42℃ for 11 h, treated from 24 h to 35 h after activation), and ALA+HT group (with 10 μmol/L ALA). The results showed that HT treatment significantly reduced the rate of blastocyst compared to the control. Addition of ALA partially recovered the rate of blastocyst and improved the quality of blastocyst, which indicating large in diameter of blastocyst, more total cell numbers, and lower number of TUNEL positive cells in blastocysts were detected by ALA treatment compared to the HT group. Moreover, supplementation of ALA significantly reduced reactive oxygen species level and higher glutathione level, suggesting ALA reduced oxidative stress induced by HS. This study showed that the mRNA expression of heat shock protein 70 (*HSP70*), heat shock protein 40 (*HSP 40*), and the protein level of heat shock factor 1 (HSF1) were increased in ALA+HT group compared to HT group. Collectively, this study revealed that supplementation of ALA ameliorates the HS-induced oxidative stress by increasing the expression of heat shock response genes, which eventually improve the quality of HS-induced porcine embryo.

Keyword: Temperature, Alpha-lipoic acid, Oxidative stress, Heat shock protein

Nascent Transcriptome Reveals Orchestration of Zygotic Genome Activation in Early Embryogenesis

H. Chen[1], M. C. Good[1,2]; [1]Department of Cell and Developmental Biology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, [2]Department of Bioengineering, School of Engineering and Applied Science, University of Pennsylvania, Philadelphia, PA.

Early embryo development requires maternal-to-zygotic transition, during which transcriptionally silent nuclei begin widespread gene expression during zygotic genome activation (ZGA). ZGA is vital for early cell fating and germ layer specification, and ZGA timing is regulated by multiple mechanisms. However, controversies remain about whether these mechanisms are interrelated and vary among species and whether the timing of germ layer-specific gene activation is temporally ordered. In some embryonic models, widespread ZGA onset is spatiotemporally graded, yet it is unclear whether the transcriptome follows this pattern. A major challenge in addressing these questions is to accurately measure the timing of each gene activation. Here, we metabolically label and identify the nascent transcriptome using 5-

ethynyl uridine (EU) in *Xenopus* blastula embryos. We find that EU-RNA-seq outperforms total RNA-seq in detecting the ZGA transcriptome, which is dominated by transcription from maternal-zygotic genes, enabling improved ZGA timing determination. We uncover discrete spatiotemporal patterns for individual gene activation, a majority following a spatial pattern of ZGA that is correlated with a cell-size gradient. We further reveal that transcription necessitates a period of developmental progression and that ZGA can be precociously induced by cycloheximide, potentially through elongation of interphase. Finally, most ectodermal genes are activated earlier than endodermal genes, suggesting a temporal orchestration of germ layer-specific genes, potentially linked to the spatially graded pattern of ZGA. Together, our study provides fundamental new insights into the composition and dynamics of the ZGA transcriptome, mechanisms regulating ZGA timing, and its role in the onset of early cell fating.

B655/P1633

A Natural Cell-size Gradient Dictates Patterning of Genome Activation and Vertebrate Early Development

W. Qian[1,2], H. Chen[1], M. C. Good[1,2,3]; [1]Department of Cell and Developmental Biology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, [2]Cell and Molecular Biology Graduate Program, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, [3]Department of Bioengineering, School of Engineering and Applied Science, University of Pennsylvania, Philadelphia, PA.

Early embryogenesis features cell division without growth. After rapid reduction in cell volume, the cell size or the DNA-to-cytoplasm ratio plays a pivotal role in thresholding the onset of zygotic genome activation (ZGA) in multiple species. However, the functional importance of the pattern of cell size in early development is largely unknown. To address this question, we use the early *Xenopus* embryo because it contains a natural gradient of cell size along the animal-vegetal (AV) axis, varying over 1000-fold in volumes between the smallest cells at the animal pole and the largest cells at the vegetal pole. This variation displays a cell-size-dependent spatial pattern of ZGA onset, which initiates transcription first at the animal pole and delays in the vegetal pole. Here we leverage a temperature-gradient controller to alter the cell-size gradient in the early *Xenopus* embryo by changing cell division rate along the AV axis. Interestingly, we discover that ZGA onset inversely correlates with the cell size regardless of the location of cells in space, corroborating a critical role of a cell-size threshold in regulating ZGA. We further characterize the phenotypes of the embryos with an inverted cell-size gradient along the AV axis, depending on the extent of inversion. Strikingly, extremely inverted embryos lyse before the gastrula stage, potentially linked to an incongruous ZGA pattern caused by the inversion of the cell-size gradient. Moreover, targeted transcriptional inhibition at the animal pole, where ZGA firstly occurs in a normal embryo, phenocopies the embryonic lysis, suggesting a critical role of a natural cell-size gradient in early development depending on the proper spatiotemporal order of zygotic transcription. Finally, moderately inverted embryos show defects in eyes and heads at the tadpole stage, which are ectodermal tissues derived from the animal pole. Together, our study reveals the considerable significance of cell-size gradient in coordinating genome activation in space and shaping early embryo development.

Arvcf catenin links subcellular actomyosin dynamics to tissue scale force production during vertebrate axis extension.

R. J. Huebner, S. Weng, C. Lee, S. Sarıkaya, O. Papoulas, R. M. Cox, E. M. Marcotte, J. B. Wallingford; The University of Texas at Austin, Austin, TX.

Anterior-posterior (head-tail) axis extension is an early and essential step in animal development and this process requires the coordinated movement of proteins, cells, and whole tissues. Thus, a challenge to understanding axis extension is connecting events that occur across these various length scales. Here we describe how a poorly characterized adhesion effector, Arvcf catenin, controls head-to-tail axis extension during gastrulation in *Xenopus laevis*. We find that Arvcf is required for extension of the intact embryo but surprisingly is not required for extension of isolated tissues. Next, we determined that the organism scale phenotype results from a modest defect in tissue scale force production that was only observable when the tissue experienced external resistance (e.g., surrounding tissues in the animal). Finally, we link the tissue scale force defect to a dampening of the pulsatile recruitment of cell adhesion and cytoskeletal proteins to membranes. These results not only provide a comprehensive understanding of ARVCF function during axis extension but also provide insight into how a cellular scale defect in adhesion results in an organism scale failure in development.

Filopodia-mediated morphogenic cytokinesis underlies *C. elegans* embryonic handedness

Y. Xiong, K. Sugioka; University of British Columbia, Vancouver, BC, Canada

Chirality is one of the fundamental molecular and cellular properties that controls animal morphogenesis. In organisms with bilateral symmetries, molecular and cellular chirality specify the larger scale organismal handedness, wherein organ's relative positioning and shape exhibit left-right asymmetry. In *Caenorhabditis elegans* and pond snails, body handedness is first specified during early embryonic cell division in a CYK-1/Formin-dependent manner (Middelkoop *et al.*, PNAS, 2021; Davison *et al.*, Curr. Biol., 2016; Kuroda *et al.*, Sci. Rep., 2016). However, the mechanism underlying cell division-dependent chiral morphogenesis remains elusive. Here, we found that the contractile ring tilting and filopodia-dependent ring-cell surface coupling underly chiral morphogenesis in *C. elegans*. *C. elegans* organismal handedness is specified during cytokinesis of ABa and ABp blastomeres at the 4-cell stage. Division axes of ABa and ABp are orthogonal to the anterior-posterior axis until early anaphase, but they tilt due to the clockwise rotation during cytokinesis. To identify the intrinsic and extrinsic cues that regulate chiral morphogenesis, we performed the blastomere isolation assay to eliminate and reconstitute cell-cell interactions. We found that adhesion between ABa and ABp is sufficient for chiral morphogenesis and that the attachment of adhesive polystyrene bead to either ABa or ABp induced the clockwise cell rotation. Consistently, the contractile rings of ABa and ABp in intact embryos undergo clockwise rotation relative to the ABa-ABp boundary, resulting in non-parallel alignment of the two rings. Furthermore, we found the Formin-dependent formation of interlocking filopodia at the ABa-ABp boundary. Interestingly, filopodia extending from ABp is pulled by the ABa contractile ring and vice versa. Because of the non-parallel ring alignment, ABa and ABp contractile rings pull ABp and ABa cell surfaces toward the anterior right and posterior left, respectively, leading to chiral blastomere arrangement. Our results reveal the novel contractile ring-dependent morphogenesis mechanism critical for shaping the embryonic body plan.

B658/P1636

Role of mechanical forces during morphogenesis of the left-right organizer

E. M. Retzlaff[1], P. C. Sanematsu[2,3], J. D. Amack[1], M. L. Manning[2]; [1]Cell and Developmental Biology, SUNY Upstate Medical University Library - Syracuse, NY, Syracuse, NY, [2]Department of Physics, Syracuse University, Syracuse, NY, [3]BioInspired Syracuse: Institute of Material and Living Systems, Syracuse, NY.

In vertebrates, several internal organs develop asymmetries along the left-right (LR) body axis. Defects in LR asymmetry result in a broad spectrum of clinical complications. A transient structure referred to as the 'left-right organizer' (LRO) directs LR patterning of vertebrate embryos. During morphogenesis of the zebrafish embryo's LRO, which is called Kupffer's vesicle, LRO cells bearing motile cilia undergo regional shape changes along the anterior-posterior (AP) axis. Anterior cells take on columnar shapes that allow tight packing, whereas posterior cells become cuboidal-like and more widely spaced apart. These shape changes create an AP asymmetric concentration of beating cilia that is critical for establishing LR asymmetric fluid flows and patterning cues. However, the mechanisms that control LRO cell shape changes are not understood. We are using a combination of quantitative live imaging and 3-dimensional (3D) computational modeling to test the hypothesis that coordinated biophysical forces provide a mechanism that regulates LRO cell shape changes. During early somite stages when the embryonic AP axis extends, we find that the LRO moves faster towards the posterior of the embryo than surrounding cells, possibly being 'pushed' by convergence and extension of cells in the rod-like notochord. 3D modeling simulations indicate mechanical drag forces generated as the LRO moves through the surrounding tissue can drive LRO cell shape changes. To experimentally test the impact of these forces on LRO cell shapes *in vivo*, we use light-activated small molecules to alter actomyosin contractility in selected cells surrounding the LRO. This optical approach allows spatial and temporal of control of mechanical properties of tissues involved in generating 'pushing' and drag forces that can be used to systematically define the role of extrinsic mechanical forces on LRO morphogenesis and function. This work is supported by NIH grant R01HD099031.

Mouse nodal immotile cilia sense bending direction for left-right determination: Mechanical regulation in initiation of symmetry breaking

T. A. Katoh[1], T. Omori[2], K. Mizuno[3], T. Itabashi[4], A. H. Iwane[4], T. Ishikawa[2], Y. Okada[5,6], T. Nishizaka[7], H. Hamada[1]; [1]RIKEN Center for Biosystems Dynamics Research (BDR), Kobe, JAPAN, [2]Grad. Sch. Eng., Tohoku Univ., Sendai, JAPAN, [3]Fac. Med. Sci., Univ. of Fukui, Fukui, JAPAN, [4]RIKEN Center for Biosystems Dynamics Research (BDR), Hiroshima, JAPAN, [5]RIKEN Center for Biosystems Dynamics Research (BDR), Osaka, JAPAN, [6]Grad. Sch. Med., Grad. Sch. Sci., UBI, WPI-IRCN, The Univ. of Tokyo, Tokyo, JAPAN, [7]Fac. Sci., Gakushuin Univ., Tokyo, JAPAN.

How is the left-right (L-R) asymmetry of a mammalian body determined? Cilia at the ventral node of mouse early embryos play an essential role in symmetry breaking. While motile cilia located at the central region of the node generate the leftward nodal flow, immotile cilia located at the periphery of the node sense flow-dependent signals, and only L-side ones are activated. The cation channel Pkd2 localized at immotile cilia is required for sensing the flow and triggers *Dand5* mRNA decay, however, it has long remained elusive how cilia sense the flow and why only the L-side ones are activated. **Asymmetric passive deformation along the dorsoventral axis in response to the flow:** How immotile

cilia behave in response to the nodal flow *in vivo*: High-speed imaging revealed low-frequency motion is important for symmetry breaking. Thus, the steady-state deformation of cilia was examined under controlling nodal flow by UV laser. The shape of the same cilium in the presence or absence of the flow were observed by 3-D high-resolution microscopy: the L-side cilia showed ventral bending (5.0±9.2°; *n*=21), whereas the R-side ones showed dorsal bending (4.2±7.4°; *n*=18). **Mechanical stimuli to immotile cilium trigger *Dand5* mRNA degradation and Ca^{2+} transient:** We next tested whether immotile cilia of *iv/iv* embryos (which lack nodal flow) respond to mechanical force with the use of optical tweezers. Significant degradation of *Dand5* mRNA was induced at 2h after the mechanical stimulation (53±21%; *n*=28), while it was not detected with *Pkd2*$^{-/-}$ embryo (110±14%; *n*=7). The cytoplasmic Ca^{2+} frequency is increased significantly from 0.83±0.71 to 1.39±1.65 spikes/min (*n*=42) in response to mechanical stimuli. **Immotile cilia sense bending direction in a manner dependent on polarized localization of Pkd2:** We found that the localization of the Pkd2 channel, a candidate of mechanosensitive channel, was significantly biased toward the dorsal side (0.54±0.12; *n*=50), which could explain how cilia sense the direction. In the presence of the nodal flow, the ventral bending of the L-side cilium imposes a strain of 0.014±0.013 (*n*=8) to the dorsal side of them, which is sufficient to activate dorsally localized Pkd2 and trigger the Ca^{2+} response. In contrast, strain at the R-side cilium is 0.000±0.001 (*n*=8), would not support a response. Indeed, the induction of Ca^{2+} transients was observed preferentially by mechanical stimuli directed toward the ventral side. These observations explain the differential response of immotile cilia to the directional flow [1]. **Reference:** [1] Katoh, Takanobu A., et al. "Immotile cilia of the mouse node sense a fluid flow-induced mechanical force for left-right symmetry breaking." *bioRxiv* (2022).

Identifying the role of SOX9 in neural crest EMT

H. R. Menendez, 1st; Anatomy, Physiology, and Cell Biology, University of California, Davis, Davis, CA.

Neural crest cells (NCC) are a population of stem-like, transient, multipotent cells in developing vertebrate embryos. These cells begin as tightly adherent epithelial cells and then undergo an epithelial to mesenchymal transition (EMT) where they invade distant tissues and differentiate. NCCs become more than 30 different tissue and cell types in adults including craniofacial bone and cartilage and the peripheral and enteric nervous systems. Sox9 is a definitive NC marker that plays a role in NCC development and EMT; however, the functional mechanism by which SOX9 regulates NC EMT and migration remains unknown. Our work aims to define the level of functional conservation between SOX9 and other NC gene regulatory network (GRN) markers across species. We will additionally identify how perturbations of SOX9 alter the expression of other NC GRN markersand the formation of craniofacial structures. Using Gallus gallus and Coturnix japonica, my work uses SOX9 perturbations prior to NC EMT to identify the necessity and sufficiency of SOX9 to drive NC behaviors and embryonic craniofacial development. I hypothesize that Sox9 expression is activated by PAX7 and SOX10 transcription factors and that SOX9 drives NC migration by regulating the expression of genes coding for cadherin proteins involved in EMT. Using a combination of gain and loss of function experiments followed by immunohistochemistry and histological analysis, my findings show that a reduction of SOX9 stunts NC migration distance, but SOX9 alone is not sufficient to drive differences in migration. Overall, my project will illuminate the role that SOX9 plays in NC cell development, migration, and craniofacial morphogenesis.

The role of signaling sensitivity in congenital heart defects and heterotaxy

J. H. Kong[1], C. B. Young[2], G. Pusapati[3], F. H. Espinoza[3], C. B. Patel[3], J. F. Bazan[4], T. M. Gunn[5], C. W. Lo[6], R. Rohatgi[1]; [1]Biochemistry and Stanford Cardiovascular Institute, Stanford University, Stanford, CA, [2]Princeton University, Princeton, NJ, [3]Stanford University, Stanford, CA, [4]ħ Bioconsulting llc, Stillwater, MN, [5]McLaughlin Research Institute, Great Falls, MT, [6]University of Pittsburgh, Pittsburgh, PA.

Hedgehog signaling is essential for the development of many tissues and organs. Hedgehog ligands are morphogens and thus direct cell fate decisions in a manner dependent on signaling strength. Precise regulation of this signaling strength is critical for embryonic development, as even modest disruptions in the signaling amplitude can result in severe birth defects. Previous studies have shown that signaling strength is influenced by both the morphogen concentration and the duration of morphogen exposure. However, an equally important layer of regulation remains unrecognized and understudied -- How does a target cell regulate its sensitivity to a morphogen? The central focus of our research examines the mechanisms that modulate a cell's sensitivity to extracellular morphogens. Initially, genome-wide CRISPR screens were used to identify a novel protein complex (the MMM complex) that suppresses sensitivity to Hedgehog ligands. The MMM complex consists of three proteins: the tetraspan MOSMO, single-pass transmembrane protein MEGF8, and E3 ligase MGRN1. We discovered that the MMM complex is a membrane-tethered ubiquitination complex that promotes the degradation of the Hedgehog pathway transducer Smoothened. Remarkably, developing embryos are exquisitely sensitive to mutations in the MMM complex and the gradual loss of functional MMM alleles corresponds with a gradual increase in the prevalence of left-right patterning defects and severe heart malformations. Overall, our work has identified a novel cellular pathway that regulates morphogen signaling sensitivity and provides insight into the mechanisms and complex genetics that underlie defects in left-right patterning and heart development.

An epigenetic factor *KANSL1* is involved in neural progenitor proliferation in the adult mouse brain

B. Jeon[1], T. Ford[2]; [1]Kent State University, Kent, OH, [2]Department of Biological Sciences, Kent State University, Kent, OH.

KAT8 regulatory NSL complex subunit 1 (KANSL1) is a component of a chromatin remodeling complex and plays a role in histone modifications such as methylation and acetylation. While KANSL1 dysfunction is associated with neurodevelopmental conditions, its neurobiological function in the brain remains unclear. We found a significant decrease in neural progenitor proliferation in the hippocampal dentate gyrus of *Kansl1* heterozygous knockout mice compared to wild type controls. In addition to the impairment in the hippocampus, progenitor proliferation in the subventricular zone appeared to be disrupted in *Kansl1* knockout mice as the olfactory bulb size was markedly reduced compared to the control bulb size. The number of dividing progenitors identified by BrdU tracing or phospho-histone H3 immunostaining was reduced in the mutant mice. We also examined neurodevelopmental behaviors in *Kansl1* knockout mice and found learning and memory impairments. The Morris water maze test revealed that *Kansl1* mutant mice spent more time in locating the hidden platform over the learning period than control mice. The probe trial at the end of the learning process showed defective memory maintenance or retrieval in the mutant mice. Our results demonstrate a critical role of KANSL1 in brain

cell proliferation and shed light on the potential link between neurodevelopmental pathology and abnormal neurogenesis mediated by chromatin remodeler dysfunction.

Connexin Function in Zebrafish Lens Development

T. Liang, S. Y. Choi; Biomedical Sciences, Chonnam National University Medical School, Hwasun 58128, KOREA, REPUBLIC OF.

A functional visual system is essential for species such as humans and zebrafish, in which vision is the primary sensory pathway for seeking food. Zebrafish is frequently used in ophthalmology research because of its amenability to genetic manipulation and easy assessment of visual function. There are two types of cells in zebrafish lens: lens epithelial cells (LECs) and lens fiber cells (LFCs). LECs form a monolayer covering the spherical LFCs, and an organelles-free zone begins in the center when the lens becomes a functional optical element in the visual pathway. Gap junctions are intercellular channels that mediate the transfer of small molecules between adjacent cells, and Connexins are vertebrate-specific gap junction proteins. Thirty-nine zebrafish *connexin* genes have been reported to date. We have screened 30 zebrafish *connexins* for lens-specific expression and found that *cx23, cx44.1, cx48.5,* and *cx50.5* were expressed in developing zebrafish lens. To explore roles for these Connexins in the development of zebrafish lens, we downregulated expression of these genes using CRISPR/Cas9 technology.Whole mount in situ hybridization (WISH) using *cx23, cx44.1, cx48.5,* and *cx50.5* riboprobes showed that all four *connexins* were expressed in primary LFCs and LECs at one day post-fertilization (dpf). *cx23, cx44.1,* and *cx48.5* were expressed at both LFCs and LECs at 2-5 dpf, whereas *cx50.5* was expressed only in LFCs at 2-5 dpf. In addition, the *cx44.1* and *cx48.5* crispants showed reduced lens size than control at 1-5 dpf, whereas *cx23* and *cx50.5* did not. Generation of mutant zebrafish lacking these genes, either alone or in combination, is ongoing. In conclusion, *cx44.1* and *cx48.5* may play a vital role in the development of the zebrafish lens.

Dysregulated trophoblast invasion and differentiation in Preeclampsia results from a reactive oxygen species-mediated endoplasmic reticulum stress pathway

I. Mukherjee[1,2], S. Singh[1], J. B. Sharma[3], S. Biswas[4], R. Dhar[1], S. Karmakar[1]; [1]Department of Biochemistry, All India Institute of Medical Sciences, New Delhi, INDIA, [2]Amity Institute of Biotechnology, Amity University, Noida, Uttar Pradesh, INDIA, [3]Department of Obstetrics & Gynecology, All India Institute of Medical Sciences, New Delhi, INDIA, [4]Amity Institute of Molecular Medicine & Stem Cell Research, Amity University, Noida, Uttar Pradesh, INDIA.

Pre-eclampsia (PE) is a leading cause of maternal and fetal mortality and morbidity. This high-risk condition needs close monitoring, possibly an early delivery if beyond 34 weeks as per ACOG guidelines. PE is a pregnancy-related disorder having trophoblast-mediated poor vascular modification with inadequate perfusion resulting in insufficient uterine blood flow, which in turn induces hypoxia leading to placental ischemic-reperfusion injury. This results in reactive oxygen species (ROS) mediated oxidative stress (OS) and tissue injury. PE is often associated with placental pathology defects possibly resulting from ROS-driven aberrant differentiation-invasion program, details of which are largely unknown. Therefore, we aimed to delineate the molecular pathogenesis of ROS on trophoblast and its effect on placenta function. Post-delivery placenta with paired blood samples was collected from 25 clinically

established PE patients and 20 healthy subjects for making organoids. To recapitulate the ROS-mediated effect, trophoblast-derived cell line HTR-8/SV neo and BeWo were treated with a sub-lethal dose of H_2O_2 *in vitro*. Cell viability was determined, and the impact of ROS was confirmed by estimating lipid peroxidation. Elaborate transcriptomic and GSEA analyses were performed to identify the differentially expressed genes (DEGs) between exposed and control groups. Electron microscopy (EM) based ultrastructural changes in placental tissues were studied. Results showed OS significantly affected the differentiation and syncytialization in trophoblasts, both of which are crucial placental functions. ROS also severely enhanced the invasiveness and motility of these cells as evident from the Boyden chamber assay. TEM showed ROS-driven signatures of intracellular injury as swollen endoplasmic reticulum (ER), cell membrane damage, reduction of glycogen granules, and mitochondrial disintegration. Interestingly, these were also found abundantly in PE organoids, thereby validating our ex-vivo PE model. ROS also induced the classical unfolded protein response (UPR) in trophoblasts through the engagement of the BiP-XBP1s axis which was in accordance with the endoplasmic reticulum (ER) stress response reported earlier. Our findings elucidated the molecular pathogenesis in PE subjected to OS that has profoundly influenced trophoblast differentiation and invasion. We are currently validating these in our organoids to explain the effect of ROS on transcription and to modulate the function of uterine immune cells, thereby affecting the cytokine milieu at the feto-placental unit. Our study will be helpful for mechanistic details and future intervention for the basic scientists and clinicians for effective disease management.

Role of CHD7 in radiation-induced fetal malformations

A. Noda, K. Muramoto, S. Mishima; Radiation Effects Research Foundation, Hiroshima City, Japan

In the process of studying the biological effects of unrepairable DSBs caused by radiation exposure, we found ATM-dependent phosphorylation of the transcription factor CHD7. CHD7 is a transcription factor in early development, governing the morphogenesis of the heart and cranial sensory organs such as the eyes, mouth, nose and brain from neural crest cells. CHD7 gene haploinsufficiency induces fetal malformations and is known in humans as the causative gene of CHARGE Syndrome. Homozygous mutation causes embryonic death. CHD7 is strongly expressed during morphogenesis stage. We found that CHD7 was phosphorylated by radiation exposure, released from the native promoter binding, and relocated to DSBs in mouse embryos. Therefore, it was found that CHD7 has dual role; transcription factor for morphogenesis and DSB repair foci factor for stress response. Based on these results, we propose that a morphogenesis coupled DSB repair mechanism exists in early development of higher animals. For radiation-induced malformation, a possible mechanism is that a large amount of CHD7 protein is devoted to DSB repair during high-dose radiation exposure, resulting in incompleteness of morphogenesis.

Optogenetic manipulation of endogenous Rho signaling in the *Drosophila melanogaster* germband

A. D. Countryman[1], M. S. Puri[1], C. A. Doherty[2], S. Y. Shvartsman[2], K. E. Kasza[1]; [1]Columbia University, New York, NY, [2]Princeton University, Princeton, NJ

Despite significant insight into the physical mechanisms of animal development, the precise reconstitution of morphogenetic processes for science and engineering applications remains a challenge. Optogenetic manipulation of Rho signaling provides a promising avenue to achieve spatial,

temporal, and quantitative control over actomyosin-generated contractile forces and tissue folding processes in epithelia. Here, we use CRISPR/Cas9 gene editing in *Drosophila melanogaster* to generate a novel optogenetic tool via the endogenous tagging of RhoGEF2 with components of the iLID/SspB optogenetic system. This endogenous tagging approach is designed to produce flies that have normal levels and patterns of RhoGEF2 protein. Spatially localized blue light activation of the tool in the embryonic ectoderm recruits RhoGEF2 to the cell membrane and induces an invagination in the targeted area. Local activation of the tool in the converging and extending germband is sufficient to drive invagination in the intercalating tissue, demonstrating the ability to override the existing morphogenetic program and providing the opportunity to explore how out-of-plane deformations in a tissue interact with in-plane remodeling processes. In addition, we show that quantitative control of spatial light patterns influences the tissue invagination process, providing the opportunity to dissect how gradients in contractility affect tissue invagination. Notably, the observed tissue invaginations are accompanied by multiple distinct modes of cell shape changes, suggesting a spectrum of tissue mechanical responses that are capable of producing invaginations. Taken together, our findings lay a foundation for the use of calibrated optogenetic perturbations of contractility to reconstitute morphogenetic events and precisely fold tissues into a range of desired shapes and structures.

B668/P1645

Molecular analysis of Toll receptor function during the polarization of contractile and adhesive proteins during *Drosophila* embryogenesis

C. A. Kuebler, A. Paré; University of Arkansas, Fayetteville, AR

Elongation of the head-to-tail axis is a conserved process during animal development, and it occurs through remodeling of epithelial sheets via cell intercalation. The process of cell intercalation is driven by the polarization of contractile proteins (e.g., myosin) and adhesive proteins (e.g., Par-3) within the plane of the epithelium. An outstanding question is how planar polarity is established consistently across large groups of cells. In *Drosophila*, three Toll receptors--*Toll-2, Toll-6*, and *Toll-8*--are expressed in a complex pattern of vertical stripes, and planar polarity in triple mutants lacking these three receptors is severely disrupted. However, it is unclear how these three receptors function together to generate uniform polarity across the tissue. Preliminary data suggest that these three receptors can function independently, but it is still not known whether they play distinct roles in specific cells. All Toll family receptors (including vertebrate Toll-like receptors) contain extracellular leucine-rich repeats and a highly conserved intracellular TIR (Toll/Interleukin-1) domain. In addition, *Drosophila* Toll-2, Toll-6, and Toll-8 contain extended C-terminal regions--the functions of which are not well understood. To consistently quantify which receptor regions are required for polarity, we have created a genetic system in which endogenous planar polarity is absent and can be induced in response to an ectopic horizontal stripe of transgene expression. Currently we are performing structure-function analyses of the Toll-2 receptor using this system, and we are characterizing the ability of specific Toll-2 protein regions to induce planar polarity. Narrowing down the protein regions required for proper cell intercalation will help reveal the downstream interactions involved in tissue remodeling during *Drosophila* embryogenesis.

Secretome of differentiating trophoblast stem cells and urine proteomics identifies functional candidates for pregnancy detection in ruminants

C. R. Detrick, P. Koganti, K. E. Gingrich, K. M. Schalich, V. V. Pillai, B. T. Nguyen, V. Selvaraj; Cornell University, Ithaca, NY

Trophectoderm development is the first lineage-separation during early embryonic differentiation with a sole purpose of setting up the placental interface in mammals. Unlike most species, epitheliochorial attachments in ruminants are restricted to regions of uterine caruncles necessitating an extended 3-week period of embryo elongation prior to implantation. Therefore, early embryo-maternal communication and maternal recognition of pregnancy relies on embryo-secreted humoral factors released by trophoblast stem cells (TSCs). In this study we sought to profile unique factors secreted by the bovine preimplantation TSCs and in early stages of differentiation for a systems biology investigation of fetal-driven humoral communication using TSCs and differentiated trophoblasts transcriptomics data. Concurrently, we investigated the urine proteome of pregnant cows to identify, clone and develop trophoblast-secreted candidate biomarkers for pregnancy detection in ruminants. This was performed using tandem predictions using SignalP and TargetP for the classical secretory pathway and SecretomeP for the non-classical secretory pathway, followed by eliminating transmembrane domain containing proteins using Phobius. We identified 600 and 617 transcripts destined to be secreted in TSCs and differentiated trophoblasts respectively. Shotgun proteomics of urine samples from pregnant cows identified 2134 unique proteins, of which 671 proteins were identified as secreted. Analysis of overlap between the secretome of cells and urine resulted in 180 candidates. Unique to the trophoblast/placenta, pregnancy-associated glycoproteins (PAGs) were identified in both urine (PAG1) and in the transcriptome (PAG2, PAG8, PAG11 and PAG12). Levels of PAG2, PAG8 and PAG12 decreased with TSC differentiation, and PAG11 appeared only after differentiation. Although their functions remain unknown, the high abundance of PAG1 and PAG2 agree with the temporal expression patterns from early pregnancy to parturition in cows. In preparation to study the physiological effects of PAG1 and PAG2, we cloned and expressed these genes in HEK293T cells for purification and functional assessment in uterine and ovarian signaling. In summary, transcriptomics and proteomics analysis identify PAG1 and PAG2 as secreted biomarkers for functional analysis and testing in bovine reproductive function.

Host Anti-viral Responses

SARS-CoV-2 Spike Protein Induces Cell-Cell Fusion of Endothelial Cells

K. V. Tieu, D. E. Conway; Ohio State University, Columbus, OH.

SARS-CoV-2 Spike protein mediated cell fusion plays an important role in host cell infection. Cell-cell fusion is seen in several human viruses such as herpes simplex virus, human immunodeficiency virus, hantavirus, and in the previous severe acute respiratory coronavirus (SARS). The SARS and SARS-CoV-2 Spike protein are known to cause cell-cell fusion in epithelial cells, and is characteristic to infect epithelial cells. In addition, recent studies have shown SARS-CoV-2 can also infect endothelial cells, but how this affects endothelial cells, including syncytia formation is not well understood the replication process in endothelial cells is not fully understood. Thus, we sought to examine the effects of Spike protein expression in if cell-cell fusion also occurs in endothelial cells, including whether or not this

would result in syncytia formation. In this study, human umbilical vein endothelial cells (HUVEC) were transfected with SARS-CoV-2 D614G variant adenovirus. We observed that in HUVEC, Spike protein expression results in cell-cell fusion in HUVEC, including the formation of larger syncytia with >6 nuclei, as well as gaps forming between cells that suggest a compromised barrier. Syncytium size and frequently is similar to what we and others have observed in epithelial cells. Interestingly we observed that cells treated with arterial shear stress (12 dynes/cm^2) do not undergo syncytia formation when Spike protein is expressed, whereas cells exposed to lower levels of shear stress (characteristic of smaller blood vessels such as capillaries) still were able to form syncytia. We also observed gaps between cells near syncytia, suggesting that the formation of syncytia compromises the vascular endothelial barrier. These observations support the hypothesis that COVID-19 infection may affect the endothelium, with the possibility that endothelial cell-cell fusion may be an important factor in vascular dysfunction in severe COVID-19 infection.

Assessing SARS-CoV2 Neutralizing Antibody Activities in Sera with a Cell-Based ELISA

B. Saepoo[1], J. Hines[2], Z. Assar[3], J. Bickel[4], P. Good[5], **W. Ho**[5]; [1]Assay Service, Cayman Chemical, Ann Arbor, MI, [2]Protein Core, Cayman Chemical, Ann Arbor, MI, [3]Structural Biology Service, Cayman Chemical, Ann Arbor, MI, [4]Antibody R&D, Cayman Chemical, Ann Arbor, MI, [5]Cell & Molecular Biology, Cayman Chemical, Ann Arbor, MI.

Neutralizing antibodies produced after COVID-19 vaccination or infection interfere with the binding of SARS-CoV2 to the angiotensin-converting enzyme 2 (ACE2) on the cell surface. A cell-based ELISA has been developed using reverse transfection to produce a more native platform to monitor these protein-protein interactions. The receptor binding domain of the spike protein (S1-RBD) with a rabbit Fc-tag was used as a tracer for measuring its binding to the ACE2 receptor on the cell which can be detected with a HRP-conjugated anti-rabbit Fc antibody in a colorimetric read-out. By using a fixed concentration of S1-RBD at submaximal signal level, inhibitors for S1-RBD binding on ACE2 can be identified in the cell-based ELISA. The assay was first validated using a soluble fragment of ACE2 (sACE2) and human recombinant neutralizing antibodies as inhibitors. After pre-incubation with S1-RBD and then applied to the cells, these proteins displayed dose-dependent suppressions of S1-RBD binding up to 100% effectiveness. The assay protocol was further simplified to increase throughput by pre-mixing the HRP-conjugated anti-rabbit Fc antibody, the Fc-tagged S1-RBD, and test sample before adding to the cell. Including the 1 hour incubation on cell, plate washing, and incubation with HRP substrate, the whole assay can be completed within 2 hours. Using this assay protocol, sera collected from volunteers before and after vaccination were examined in parallel with a positive control neutralizing antibody. All volunteers received the vaccines from Pfizer or Moderna exhibited very strong neutralizing antibody activities within 2-3 weeks after the first injection. A lower but still significant inhibition of S1-RBD binding was also observed in the sample from a patient with COVID-19 diagnosed within a few months. To examine if these sera with neutralizing antibodies can inhibit the binding SARS-CoV2 variants, S1-RBD proteins containing N501Y (B.1.117) and K417N/E484K/N501Y (B.1.351) mutations were examined with these samples in the cell-based ELISA. The neutralizing antibodies were found to produce weaker inhibition in the binding of N501Y S1-RBD, and even more so with the triple mutant, than the original S1-RBD to the ACE2. This progressive reduction in the effectiveness of the neutralizing antibody binding among variants were confirmed in SPR studies.

TFEB and TFE3 contribute to the cellular response againts ß-coronavirus

P. Contreras, P. Tapia, E. Jeong, R. Puertollano; National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD.

IntroductionThe transcription factors EB and E3 (TFEB and TFE3) are master regulators of lysosomal biogenesis and autophagy. The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) belongs to the ß-coronaviruses family. Recently it was described that ß-coronaviruses use lysosomal trafficking for egress the cell. The aim of this work was to analyze if ß-coronavirus infection promotes TFEB/3 activation and to evaluate their impact on the cellular response to viral infection. **Methods**We used mouse hepatitis virus (MHV) as a model of ß-coronavirus. We infected Hela-mCC1a cells that stably overexpress the receptor for MHV virus and evaluated TFEB/TFE3 nuclear translocation by immunofluorescence. In addition, we used siRNAs to deplete TFEB/TFE3 and evaluated changes in gene expression upon viral infection by RNA-seq and q-PCR, and performed a Chip-seq analysis to assess TFE3 promoter occupancy in MHV-infected cells. We also evaluated the contribution of TFEB/3 to immune response and cellular death pathways induced by MHV infection using antibody arrays for human cytokines, western blots against PARP1 and Caspase-3, and flow cytometry measuring Annexin V and 7-ADD. Finally, we evaluated viral infectivity in control and TFEB/TFE3-depleted cells using crystal violet experiments. **Results**MHV infection caused a robust and persistent TFEB/TFE3 nuclear translocation. TFEB activation occurred in the absence of mTORC1 inactivation but required calcineurin. At later infection times, MHV induced TFEB and TFE3 degradation that was mediated by the E3 ubiquitin ligase subunit DCAF7. TFEB and TFE3 regulated expression of several immune genes under MHV infection. Concordantly, TFEB/TFE3 depletion significantly reduced the upregulation of immune and inflammatory genes induced by viral infection. Furthermore, TFEB/TFE3 depletion prevented MHV-induced cellular death and decreased MHV infectivity. **Discussion**Our data strongly suggest that MHV infection induces TFEB and TFE3 activation, which greatly contributes to the anti-viral inflammatory and immune host response, but may also result in increased cellular death. The degradation of TFEB/TFE3 induced by MHV virus seems to be part of a viral strategy to maintain a restricted immune response and favor cellular survival for its own benefit.

CP47, an Autophagy Inhibitor, Reduces the Replication of Feline Coronavirus *in vitro*

Y. Park[1], R. Park[2], Y. Park[1], S. Lee[1], J. So[1], C. Kim[1], J. Park[1]; [1]Yonsei University, Wonju, KOREA, REPUBLIC OF, [2]Yongin University, Yongin, KOREA, REPUBLIC OF.

Feline coronavirus(FCoV) is a common viral pathogen of domestic and wild cats. FCoV includes two subtypes, feline enteric coronavirus (FECV) and feline infectious peritonitis virus (FIPV). FIPV is known to cause fatal systemic diseases and considered as the virulent mutant form of FECV. However, the effective treatment is not available and effective treatments are required. Recent studies showed that autophagy is required for the efficient replication of coronavirus, and AMPK plays an important role in autophagy regulation. Here, we used Feline enteric coronavirus(FECV) to measure the feline coronavirus replication and reported treatment of CP47, an autophagy inhibitor, reduced the replication of FECV. Quantitative RT-PCR analysis and titration assay demonstrated that the viral titer of FECV was reduced by treatment of CP47. In addition, CP47 treatment decreased the cytotoxicity of FECV infection in a dose

dependent manner. These results suggest that CP47 is potentially useful to treat feline coronavirus disease.

COVID-19 pandemic has resulted in huge number of deaths from 2020 to 2022. Although a vaccine for SARS-CoV-2 is now available, herbal medicine can be very useful to treat and protect COVID-19. Many studies showed that natural compounds have therapeutic effect to treat COVID-19. Recently, We showed that EGCG treatment inhibits SARS-CoV-2 3CL-protease. However, the effect of EGCG on coronavirus replication remains unclear. Herein, we examined the inhibitory effect of EGCG on coronavirus replication. Human beta corona virus (HCoV-OC43) and human alpha corona virus (HCoV-229E) were used to examine the effect of EGCG on human coronavirus replication in vitro. EGCG treatment reduced the level of human coronavirus RNA level in infected cell media. EGCG treatment also decreased HCoV-OC43 induced cytotoxicity. Scanning electron microscopy analysis results showed that EGCG treatment reduced coronavirus protein and virion particle production. In addition, we verified the effect of EGCG on coronavirus replication using an animal model. Quantitative RT-PCR analysis showed that EGCG-fed mice exhibited reduced levels of coronavirus RNA in mouse lungs. These results demonstrate that EGCG, green tea polyphenol, treatment inhibits human coronavirus replication effectively in vitro and in vivo.

A Rare Case of Kaposi Sarcoma in an Immunocompetent Heterosexual Hispanic Male - A Potential Budding Clinical Subtype

A. Fijany[1], M. Chalman[1], K. Givechian[2]; [1]TCU School of Medicine, Fort Worth, TX, [2]Yale School of Medicine, New Haven, CT.

Purpose: Kaposi sarcoma (KS) is a malignancy associated with endothelial spindle cell proliferation. This vascular neoplasm is due to an infection by human herpesvirus 8 (HHV-8), which is also known as Kaposi sarcoma-associated herpesvirus (KSHV). At the cellular level, KS is composed of spindle cells derived from vascular endothelial cells along with a variable cocktail of inflammatory cells. Historically, four subtypes of KS have been described based on the clinical circumstances by which they develop: classic (Mediterranean descent), endemic (African origin), iatrogenic (immunosuppressive therapy-associated), and AIDS-associated. A fifth recently described variant includes men who have sex with men (MSM) without HIV infection. We present an unusual case of classic KS in an immunocompetent, heterosexual

Hispanic male lacking any of the risk factors found in the literature. Design: A literature review on PubMed was performed on May 12th, 2022, which searched for articles that included the terms "Kaposi sarcoma" AND "immunocompetent" or "HIV-negative" or "HIV negative". The literature was then surveyed for other relevant cases of Kaposi sarcoma in individuals lacking immunodeficiency to identify associated risk factors and confirm the paucity of this patient's KS subtype.
Findings: Here, we present the case of a middle-aged, heterosexual Hispanic male with a single violaceous, non-blanching patch on the plantar surface of his foot. The patient is immunocompetent, HIV-negative, and with no other identifiable risk factors of HHV-8 exposure or (re)activation. He has no significant medical history, steroid use, IV drug use, or prior blood transfusion. Biopsy was performed and histopathology findings were consistent with classic Kaposi Sarcoma. The patient was worked up and found to be negative for any potential immunodeficiency. The lesion's full-thickness excision was successful, and the patient has had no recurrence to date. Given this patient's lack of risk factors, clinical suspicion of KS prior to biopsy was extremely low. Few similar cases have been described; however, a potential unrecognized Hispanic KS variant has been proposed in recent literature. Here we overview the viral cell entry mechanism and propose a genetic susceptibility in this subgroup.
Summary: Hispanic males with biopsy-proven Kaposi sarcoma may represent an infrequently recognized subtype of KS. As such, clinicians should have a lower threshold when considering biopsy of suspicious violaceous lesions, even in the absence of other KS risk factors. The utilization of appropriate biopsies and histological analyses may lead to Kaposi sarcoma diagnoses in patients who do not fall into the currently accepted four clinical subtypes.

Generation of a Cas9-Expressing Macrophage Line to Facilitate Ebolavirus Research

T. McGee[1], J. A. Aguilar Briseño[2], J. Elliff[3], W. Maury[2]; [1]Hampden-Sydney College, Hampden Sydney, VA, [2]Department of Microbiology and Immunology, University of Iowa, Iowa City, IA, [3]University of Iowa, Iowa City, IA.

Ebolavirus (EBOV) is a highly virulent negative-stranded RNA virus endemic to Western and Central Africa, with mortality rates ranging between forty and ninety percent. There are limited effective antiviral treatments, and the efficacy of the FDA-approved vaccine using a recombinant Vesicular Stomatitis Virus expressing the EBOV glycoprotein protein has recently been called into question by evidence of breakthrough infections in the Democratic Republic of Congo among vaccinated individuals. Macrophages are important cell targets during early EBOV infections. Among the many contributions of macrophages to EBOV pathology are their capacity to serve as vehicles for viral dissemination and to produce pro-inflammatory mediators. However, mature macrophages cannot be easily genetically manipulated to characterize host genes responsible for these activities. Our previous research has identified Interferon gamma (IFN-γ) as highly protective against EBOV infection in macrophages but mechanistic means by which this protection is mediated remains unclear. To study antiviral host responses mediating the effects of IFN-γ, we identified a murine Kupffer cell line that recapitulates most characteristics of primary mature macrophages. The *Streptococcus pyogenes* Cas9 gene governed by an EF-1a promoter was introduced into murine Kupffer cells in preparation for Cas9/guide RNA knockout of genes to improve the mechanistic understanding of EBOV infection and the protection IFN-γ can provide. The lentivirus transfection and blasticidin selection protocol were successfully optimized to generate and subsequently select transduced cell populations. Bioinformatics tools were also employed to identify guide RNA sequences that are being used to edit genes relevant to IFN-γ protection during

EBOV infection of macrophage populations. Western blotting was used to confirm Cas9 Expression. We successfully developed this important cellular reagent for future studies to elucidate host genes in macrophages that control EBOV infection.

B678/P1654

Characterizing the infection dynamics of a novel nematode virus variant

S. Khan[1], C. Fujii[2], L. van Sluijs[3], D. Wang[4], J. Sowa[1]; [1]West Chester University of Pennsylvania, West Chester, PA, [2]Washington University in St. Louis, St. Loius, MO, [3]WAGENINGEN, Wageningen University, Wageningen, NETHERLANDS, [4]Washington University in St. Louis, St. Louis, MO.

The model organism *Caenorhabditis elegans* is a nematode that is commonly used to study the interactions between pathogens and host innate immunity. One branch of the *C. elegans* innate immune system is the Intracellular Pathogen Response (IPR). The IPR is a transcriptional response that is activated in response to intracellular pathogens, such as viruses, entering the cells. To date, there is only one virus that is known to naturally infect *C. elegans*, the Orsay virus. In an effort to identify novel viruses, wild nematode samples were collected from the Netherlands and screened for infections that could be transmitted to *C. elegans.* In this process, a putative virus (V2) was discovered. RNA sequencing revealed that V2 is likely a new variant of Orsay. In order to compare the infection dynamics of V2 to standard Orsay, a 72-hour infection time course was run by infecting N2 *C. elegans* with V2 and Orsay in parallel. The viral transcript and IPR activation levels from each time point were quantified using RNA extraction, cDNA synthesis, and qPCR. Future studies will investigate the tissue tropism of both viruses using FISH. Further studying these two viruses could lead to a better understanding of the genetic factors that influence infection dynamics.

B679/P1655

The effect of Orsay virus protein expression on *C. elegans* Intracellular pathogen response

N. Martinez, B. Chen, E. Cooper, J. N. Sowa; Biology, West Chester University of Pennsylvania, West Chester, PA.

C. elegans are a popular genetic model organism used by many fields to investigate fundamental questions of cell biology. *C. elegans* innate immune signaling shares many similarities with that of humans, making them a useful model system to study how viruses interact with innate immunity. There is one known virus capable of naturally infecting *C. elegans*, the Orsay virus, a positive sense ssRNA virus that infects the *C. elegans* intestine. Using a transcriptional reporter strain, we found that the *C. elegans* innate immune response is suppressed by Orsay virus infection. This is particularly interesting in light of the fact that the Orsay genome only encodes four proteins: capsid, delta, capsid-delta fusion, and RNA-dependent RNA polymerase. In order to find out which of these proteins mediates the suppression of *C. elegans* immunity, we created transgenic *C. elegans* strains expressing each of the four Orsay proteins individually. Our next steps are to test each of these single Orsay protein transgenic strains to see which (if any) show suppression of *C. elegans* innate immunity. If we are able to identify which one of the proteins is responsible for the suppression of *C. elegans* immunity, then future studies will focus on determining the mechanism of action of the immunosuppression. This could provide a new system for studies of the evolution and mechanisms of viral suppression of host immunity.

B680/P1656

Antiviral function and viral antagonism of the rapidly evolving dynein activating adapter NINL

D. Stevens[1], C. Beierschmitt[2], S. Mahesula[1,3], M. Corley[2], J. Salogiannis[4,1], B. Tsu[2], B. Cao[2], A. Ryan[2], S. Reck-Peterson[5,3,6], M. Daugherty[2]; [1]Department of Cellular and Molecular Medicine, University of California San Diego, San Diego, CA, [2]Department of Molecular Biology, University of California San Diego, San Diego, CA, [3]Howard Hughes Medical Institute, Chevy Chase, MD, [4]Department of Molecular Physiology and Biophysics, University of Vermont, Burlington, VT, [5]University of California San Diego, San Diego, CA, [6]Department of Cell and Developmental Biology, University of California San Diego, San Diego, CA.

Viruses interact with the intracellular transport machinery to promote viral replication. Such host-virus interactions can drive host gene adaptation, leaving signatures of pathogen-driven evolution in host genomes. Here we leverage these genetic signatures to identify the dynein activating adaptor, nineinlike (NINL), as a critical component in the antiviral innate immune response and as a target of viral antagonism. Unique among genes encoding components of active dynein complexes, NINL has evolved under recurrent positive (diversifying) selection, particularly in its carboxy-terminal cargo binding region. Consistent with a role for NINL in host immunity, we demonstrate that NINL knockout cells exhibit an impaired response to interferon, resulting in increased permissiveness to viral replication. Moreover, we show that proteases encoded by diverse picornaviruses and coronaviruses cleave and disrupt NINL function in a host- and virus-specific manner. Our work reveals the importance of NINL in the antiviral response and the utility of using signatures of host-virus conflicts to uncover new components of antiviral immunity and targets of viral antagonism.

B681/P1657

Discovery of new viral pathogens of *C. elegans* from wild nematode isolates

I. Cannon[1], S. Lancaster[1], N. Diarra[1], L. van Sluijs[2], J. N. Sowa[1]; [1]West Chester University, West Chester, PA, [2]Wageningen University, Wageningen, Netherlands

Caenorhabditis elegans are a popular model system for studying host-pathogen interactions because their short life cycles, optically transparent bodies, and ease of genetic screening make them powerful tools for discovery. To date, there are only three known viruses that naturally infect *Caenorhabditis* nematodes and of those, only the Orsay virus infects *C. elegans*. Through collaboration with colleagues in the Netherlands, wild nematode communities were collected from various sampling sites. We then tested these wild nematodes for the presence of intracellular infections that could be transmitted to *C. elegans* using a co-culture method. In this method, wild nematodes are co-cultured together with transgenic *C. elegans* engineered to express fluorescent reporters when infection-induced genes are activated. To prioritize potential viral infections specifically, co-cultures that showed reporter activation were homogenized and filtered through 0.22µm filters to size-exclude non-viral pathogens. These filtrates were then tested for their ability to transmit the infection. For infections that did transmit via the 0.22µm filtrates, samples of infected worms were taken and stained using Fluorescence in Situ Hybridization (FISH) probes for each of the known *Caenorhabditis* viruses. Through this process, at least one new viral isolate, has been identified: V2, which appears to be a novel variant of Orsay. The discovery of this and other novel virus variants will provide scientists with new research opportunities to explore mechanisms of host immunity and pathogen virulence.

CoV2PIM: Establishment of a Virus-Host and Virus-Virus Interaction Map of SARS-CoV-2

P. Tafelmeyer[1], F. Moisant[2], V. Collura[2], R. Benarous[2], K. Wijesiriwardana[3], P. Diamantis[4], L. Lane[3], J.-C. Rain[2]; [1]HYBRIGENICS Corp., Boston, MA, [2]HYBRIGENICS Services, Evry, France, [3]Faculty of Medicine, University of Geneva and SIB-Swiss Institute of Bioinformatics, Geneva, Switzerland, [4]current address : Hengrui Europe Biosciences AG, Zuerich, Switzerland

In the fight against the SARS-CoV-2 pandemic, huge progress has been made by the scientific and industrial community to bring to the market efficient vaccines and antiviral drugs. However, many details about the viral biology and the interaction of the virus with the human host remain unknown. The identification of protein interactions between the virus and the host is often crucial to understand the mechanisms of viral replication and transmission. Moreover, knowledge of the molecular details of these protein interactions can lead to the discovery of new therapeutic targets. We have therefore used our high-throughput platform that allows exhaustive and reproducible yeast two-hybrid (Y2H) screening to establish a protein interaction map (PIM) between 29 proteins or protein fragments of SARS-CoV-2 and proteins from a human lung cells library. Our PIM connects 780 CDS by 979 protein interactions, and also determines the sites of interactions. The validation of a subset of these interactions is in progress. The fundamental knowledge provided by a large-scale PIM aims to better understand SARS-CoV-2. Moreover, the convergence between virus and host cell-control makes these efforts useful for the understanding of infections with other (Corona)viruses. A detailed comprehension of the molecular levels of the host-virus interactions will help to pave the way for the identification of new targets of therapeutic interest and will contribute to better control similar events that will likely occur in the future.

B683/P1659

Identification of critical residues for palmitoylation of human cytomegalovirus tegument protein pp28 and their functions during viral infection

J. B. Lee, J. Y. Seo; Severance Biomedical Science Institute, Graduate School of Medical Science, Brain Korea 21 Project, Yonsei University College of Medicine, Seoul, KOREA, REPUBLIC OF.

Human cytomegalovirus (HCMV) tegument protein pp28 is crucial for the final envelopment during viral maturation. This protein contains covalently bound fatty acids including myristic acid, which affects the activity and subcellular targeting of proteins. The pp28 protein localizes to the viral assembly compartment (AC) late in infection and its localization depends on myristoylation. Defect in this modification of pp28 leads to failure in infectious progeny virus production. Meanwhile, plamitoylation of pp28 remains poorly understood. Here, we showed that pp28 is palmitoylated at cysteine residues (aa 6, 10, and 11). Inhibition of its palmitoylation by site-directed mutagenesis or palmitoylation inhibitor 2-bromopalmitate treatment disrupted the subcellular localization of pp28 and also decreased the stability of the protein *via* a proteasome-dependent pathway in transiently transfected cells. When the three cysteine residues were substituted individually or in combination with alanine residues, the level of palmitoylation was significantly reduced. The recombinant HCMVs producing pp28 mutants in which two or three cysteine residues are substituted with alanine residues, exhibited delayed viral growth kinetics and a decrease of infectious virus secretion. However, these recombinant HCMVs did not exhibit defects in cell entry. In addition, the number of intracellular viral particles produced from cells infected with the recombinant HCMVs was similar to that from wild type HCMV. Collectively, our

data indicate that palmitoylation at the N-terminal cysteine residues of pp28 plays an essential role in its subcellular localization and the release process of infectious virions during HCMV infection.

Protists and Parasites

B684/P1660

Investigating the molecular basis of learning by a single cell

D. Rajan, W. Marshall; University of California, San Francisco, San Francisco, CA.

Learning is usually associated with a complex nervous system, but there is increasing evidence that life at all levels, down to single cells, can display intelligent behaviors such as decision-making and learning. In both natural and artificial systems, learning is the adaptive updating of system parameters based on new information, and intelligence is a measure of the computational prowess that facilitates learning. *Stentor coeruleus* is a unicellular pond-dwelling organism that exhibits habituation, a form of learning in which a behavioral response decreases following a repeated stimulus. *Stentor* contract in response to mechanical stimulation, an apparent escape response from aquatic predators. However, repeated low-force perturbations induce habituation, demonstrated by a progressive reduction in contraction probability. Habituated *Stentor* still contract after receiving high-force mechanical stimulation or photic stimulation. These observations, which align with Thompson and Spencer's classic criteria for habituation, strongly suggest that the original contractile response decrement is due to learning rather than fatigue or ATP depletion. As a free-living cell, *Stentor* can be studied without much interference from surrounding cells as would be the case in a multicellular tissue. Several additional features make *Stentor* a tractable system for studying learning: its large size (1 mm), quantifiable habituation response, ease of injection and micromanipulation, a fully sequenced genome, and the availability of RNA interference (RNAi) tools. But how can a cell learn without a brain or nervous system?
Here, we explore potential molecular mechanisms of *Stentor* learning. We find that protein phosphorylation likely plays a role in habituation at short timescales (under 60 minutes). We also further characterize *Stentor* learning in response to different forces and frequencies of mechanical stimuli. Intriguingly, high frequency stimulation significantly increases the speed of habituation. Furthermore, *Stentor* can habituate to high-force stimuli after longer timescales of mechanical training (overnight), calling into question the decades-old idea that high-force stimuli preclude habituation in *Stentor*. By understanding habituation at the level of a single cell, we are beginning to uncover learning paradigms that are independent of complex circuitry.

B685/P1661

Cell cycle genes and oral regeneration in *Stentor coeruleus*

C. Yan, P. Sood, A. Lin, R. McGillivary, W. Marshall; University of California, San Francisco, San Francisco, CA.

Regeneration and wound healing are hallmarks of life and are fundamental for tissues and cells to regain their integrity and functionality after injury from external perturbations. While regeneration has been extensively studied at the level of tissues and organs, much less is known about how cells themselves are able to regenerate. The giant single cell ciliate *Stentor coeruleus* is a classical model system that has unique advantages for studying wound regeneration on a single cell level, including large size and effective wound healing. When the cell's oral apparatus is removed, the cell can regenerate a new oral

apparatus in a series of defined, visible morphological steps. This regeneration paradigm provides an opportunity to study regeneration of complex structures and how this process is initiated. It is known that different geometric perturbations of the cortex can trigger regeneration, but the molecular mechanisms underlying this process are unknown. A transcriptional analysis of regeneration and proteomics produced candidate genes which are differentially expressed during regeneration. One approach for identifying signals that trigger regeneration is to determine which genes are expressed early in the pathway, then move upstream to identify signals required to turn these genes on. Among early-expressed genes, the transcription factor E2F was identified as a potential regulator of oral regeneration based on the expression pattern of its predicted target genes. The Rb-E2F-DP1 module plays important roles in regulating cell cycle dependent processes in many organisms. Phosphorylation of Rb by CDK4 releases binding from E2F, allowing for transcription of E2F target genes. RNAi-mediated knockdown experiments show that E2F is involved in the completion of regeneration, specifically the formation of the oral primordium, the first step of oral regeneration. Similarly, the addition of a CDK4 inhibitor, Palbociclib, produces the same phenotype. It is possible that cell cycle machinery might help regulate the timing of regeneration, as the morphological steps of forming a new oral apparatus appear identical to morphological changes that occur during cell division. This highlights a question in the biology of regeneration of whether regeneration is a distinct process, or does it reflect a re-activation of development?

B686/P1662

The role of a robust cytoskeleton in wound resistance and healing in the ciliate *Stentor coeruleus*

A. V. Nadkarni[1,2], K. S. Zhang[1], W. F. Marshall[2], S. K. Y. Tang[1]; [1]Stanford University, Stanford, CA, [2]University of California San Francisco, San Francisco, CA

Wound healing is a fundamental property of living systems. It is especially important for free-living, single-celled organisms such as the freshwater ciliate, *Stentor coeruleus*. Wounds must be sealed promptly to prevent both the leakage of cytoplasm, and the influx of undesirable molecules. Concurrently, these cells must possess properties that allow them to resist wounding in the first place. *S. coeruleus* has a robust capacity to heal from large mechanical wounds within a single cell. It can seal bisection wounds within 100 -1000s and can regenerate a new cell from a fragment $1/27^{th}$ its original size. We hypothesize that the cytoskeleton of *Stentor coeruleus* plays an important role not only in wound healing but also in resisting wounds. However, since the molecular players and arrangement of the *Stentor* cytoskeleton is not fully elucidated, the mechanism by which the cytoskeleton influences wound healing in these cells remains an open question. By using microfluidic methods of cell wounding and cytoskeletal perturbation (using RNAi and small molecule inhibitors), we find that disruption of the microtubule cytoskeleton makes cells more susceptible to shear-induced wounds. Once wounded, disruption of cytoskeletal elements, such as microtubules and septin, alters the cell's wound response and the healing rate. Thus far, we have not observed actomyosin purse-string contraction in *S. coeruleus* wound healing. The significance of our work lies in the elucidation of the role of the cytoskeleton and the identification of novel wound resistance and healing biology in the non-model system *Stentor* as well as its general relevance for the study of free-living, giant cells. Our work also has potential to inform the engineering of a new function—wound resilience—in synthetic cell systems.

B687/P1663

Actin and Myosin contribute to cell wall integrity in the pennate diatom Phaeodactylum tricornutum

P. Avasthi, C. D. MacQuarrie, A. Radkov; Arcadia Science, Berkeley, CA.

Diatoms are well known for their unique and intricate shapes. The pennate diatom *Phaeodactylum tricornutum* exists in 3 main morphotypes: fusiform, triradiate, and ovular. Recent work has uncovered that the actin cytoskeleton localizes proximal to the cell wall in this species. Additionally, transcriptomic studies revealed altered expression of actin-binding proteins between cells of different morphotypes, suggesting the actin cytoskeleton could be contributing to cell morphology. Here, *Phaeodactylum tricornutum* cells were treated with a panel of cytoskeletal inhibitors to determine what role, if any, actin plays in diatom shape determination. Surprisingly, many of these treatments resulted in the formation of protoplast-like, naked round cells. The myosin II inhibitor (-)-blebbistatin and the Arp2/3 complex inhibitor CK-666 had the most drastic effect. Because *Phaeodactylum tricornutum* express 10 different myosin proteins, it was unclear which protein (-)-blebbitation was targeting. Predicted structures of the *Phaeodactylum* myosins were compared to the solved structure of (-)-blebbistatin bound *Dictyostellium* myosin II to determine that *Pt*MyoE, which is upregulated in fusiform and triradiate cells, is likely to be targeted and inhibited by (-)-blebbistatin. To determine if these round cells were protoplasts, we treated cells with the cell wall degrading enzyme Alcalase and observed similar round cells leaving their cell wall shell, forming a protoplast. Because disruption of actin regulators and motors results in a phenotype similar to direct cell wall degradation, we speculate that the actin cytoskeleton contributes to cell wall integrity through cell wall anchoring, polarized secretion of cell wall components, transcriptional regulation of cell wall biosynthetic enzymes, or through other uncharacterized mechanisms.

B688/P1664

Lipid organization protects GPI-anchored proteins from membrane perturbing agents in *Leishmania major* promastigotes

R. M. Keane, C. Haram, S. Moitra, E. Breslav, K. Zhang, P. Keyel; Biology, Texas Tech University, Lubbock, TX.

Leishmaniasis is the fourth-largest neglected tropical disease and is caused by the kinetoplast *Leishmania major*. The *L. major* plasma membrane is a key therapeutic target. It contains key virulence factors like lipophosphoglycan (LPG) and the GPI-anchored metalloproteinase gp63, yet the accessibility of membrane components to toxic extracellular substances is poorly understood. Prior work suggests that membrane components are modified relative to their mammalian counterparts to reduce toxin access. The GPI-anchor in *L. major*, gp63, has reportedly bound to the beta pore-forming toxin (PFT) aerolysin when expressed in mammalian cells, but not in *L. major*, due to differences in GPI anchor structure. However, our recent observations conclude that PFTs depend on the absence of sphingolipids for cytotoxicity, raising the possibility of other membrane components sheltering the GPI-anchor in *L. major*. We hypothesize that LPG prevents cytotoxicity by sheltering gp63 from aerolysin. We genetically removed or altered membrane components, including sphingolipids, sterols, gp63, or LPG, to test their susceptibility to aerolysin. Using flow cytometry, we found that trypsin-activated aerolysin and pro-aerolysin bound and killed wild type *L. major*. We tested the impact of sphingolipids in protecting *L. major* from aerolysin and found no change in cytotoxicity. Disruption of sterol synthesis had mixed

results on cytotoxicity. Deletion of sterol methyltransferase was less susceptible to aerolysin than deletion of c14-demethylase. We next examined aerolysin's ability to bind GPI-anchored proteins, including gp63, on *L. major*. Knockout of gp63 or LPG did not block binding of fluorescently-labeled pro-aerolysin, indicating aerolysin can bind to multiple determinants in *L. major*. Aerolysin killed LPG-/- *L. major* 75-fold more effectively than wild type, suggesting LPG protects *L. major* from aerolysin. While trypsin-activated aerolysin killed gp63-/- *L. major*, pro-aerolysin did not. This indicates that gp63 can cleave pro-aerolysin into aerolysin. We conclude that *L. major* uses LPG and ergosterol to reduce clustering of GPI-anchored proteins following aerolysin binding to prevent cytotoxicity. Thus, targeting virulence factors in combination with sterols may enhance the susceptibility of *L. major* promastigotes to therapeutic drugs.

The Characterization of Two Novel Calcium Signaling Proteins in Toxoplasma gondii

A. Delapenha[1], E. A. Sizemore[2], S. Agrawal[1]; [1]Biological Sciences, University of Mary Washington, Fredericksburg, VA, [2]Biological Sciences, University of Mary Washington, King George, VA.

Toxoplasma gondii is an opportunistic apicomplexan parasite infecting humans and livestock. Infection in immunocompromised individuals can cause neurological damage and infection during pregnancy can lead to fetal death. These parasites engage in a complex life cycle, involving repeated invasion of host cell and egress from the host cell. Calcium signaling is an important regulatory mechanism for many essential processes in the parasite including gliding motility (actomyosin-dependent mode of motion), invasion, and egress. Our work focused on two previously uncharacterized calcium regulator proteins. The proteins of interest were modified using the CRISPR-Cas 9 system to express the Auxin Degron system downstream of each gene. Our work demonstrates the localization of these proteins and the role of these proteins on parasite growth and fitness.

B690/P1666

Energetics dissection of the ultrafast microsporidian polar tube invasion machinery

R. Chang[1], A. Davydov[2], P. Jaroenlak[2], B. Budaitis[2], D. Ekiert[2], G. Bhabha[2], M. Prakash[1]; [1]Department of Bioengineering, Stanford University, Stanford, CA, [2]Department of Cell Biology, New York University School of Medicine, New York, NY.

Microsporidia is a group of eukaryotic obligate intracellular parasites which causes huge economic burden worldwide. Their infection process is characterized by the rapid ejection of polar tube (a 100-nm wide thin cylinder shooting at a speed of 300 um/sec, creating a shear rate of 3000 1/sec) and passage of sporoplasm and entire nucleus through a narrow long tube (~60 um long, 100nm wide) into the host cell. Considering the large resistance in extremely thin tube and the low Reynolds number nature of the process, it is not known how exactly can microsporidia achieve this ultrafast shooting event without a functional mitochondria. In this study, we propose a theoretical framework accounting for all topological possibilities and systematically dissect them for their energy requirement. These geometries are classified and compared against each other for required energy, power, and pressure requirement. We compared the prediction from our theoretical framework to polar tube ejection experiments in varying viscosity and high-resolution serial block-face scanning electron microscopy (SBF-SEM) data. Our study provided the first comprehensive biophysical analysis of the energetics and dissipation of the polar tube ejection process in microsporidia and can point out new directions for future experiments.

B691/P1667

Water is not sufficient to reanimate Colpoda steinii after desiccation and solutions to quantitate complex lifestyles of protists

G. Garcia, III, P. Avasthi; Arcadia Science, Berkeley, CA.

Global climate change and increasing human population strain fresh water resources. Many protists, including the ciliate Colpoda steinii, live in ephemeral bodies of water and can survive for extended periods without water. Active Colpoda swim in dew that forms on the surface of plants. As the dew evaporates, Colpoda encyst and become dormant to resist desiccation. Colpoda harbor evolutionary innovations that shield the organism from desiccation and other harsh environments.Three questions guide our research to uncover these protective innovations. What is the composition of the resting cyst wall and how is it built? Which stimuli reanimate cells from the resting cyst? What is the evolutionary history of the resistance of cysts to desiccation? To begin to answer these questions we first needed to determine culturing conditions and how to reproducibly induce resting encystment and reanimation. We find that rehydration in water is not sufficient for reanimation. Instead, we find that reanimation occurs upon exposure to bacterized hay medium. After reanimation, Colpoda steinii divides in reproductive cysts which are distinct from resting cysts. The complex life cycle of Colpoda steinii - with a motile state and at least two static states- poses a challenge to microscopy-based experiments. Cells move out of, or encyst out of, the field of view. To solve these challenges, we developed microchambers to visualize behavior over long time scales while maintaining cells within a field of view. Currently, we are sequencing the genome and transcriptomes of Colpoda steinii to aid in molecular analysis of the resting cyst and desiccation resistance. We are also developing assays to phenotype Colpoda steinii across its life cycle in the context of drug screening or other experimental perturbation to uncover mechanisms of encystment and reanimation. Evolution has solved the problem of living with limited access to fresh water, and understanding Colpoda encystment offers strategies for management of freshwater resources in the context of global climate change.

B692/P1668

Molecular characterisation of two species of Lecithocladium (Hemiurid trematode) from two marine fish species in India.

R. Singh, A. Saxena; zoology, University of Lucknow, Lucknow, INDIA.

Genomic sequencing and molecular data on PCR-based methods are new sources to explore the identification and discrimination among helminth parasites and are helpful in resolving taxonomic and hierarchical issues. The rDNA is particularly useful for molecular studies because it contains regions with varying rates of evolution, from highly conserved (18S, 5.8S, and 28S) to highly variable. The aim of the study was to evaluate the genetic relationship between two species of Lecithocladium, from two marine fish hosts, based on 18s nuclear DNA. Genomic DNA was extracted from individual worms using Qiagen'sDNeasy Tissue Kit (Qiagen Hilden, Germany), as specified by the manufacturer. DNA concentration and purity were determined spectrophotometrically by measuring their absorbance at 260 and 280 nm. PCR amplification, the 18S region was amplified with the universal primer (Forward): 5'AACCTGGTTGATCCTGCCAGT -3' and (Reverse): 5'TGATCCTTCTG CAGGTTCACCTA -3'. Sequences of both species of Lecithocladiumhave been submitted to NCBI. (GenBank accession numbers; OM838287,ON855066). Sequences are subjected to Mfold for the reconstruction of secondary RNA

structure which brings our knowledge one step ahead. Secondary RNA structures are based on minimum free energy. The minimum negative free energy (G) of each RNA secondary structure has been measured in Kcal/mol. The minimum negative free energy (dG) ofLecithocladium sp. 1 and Lecithocladium sp. 2 are -348.06, and-293.84 respectively. The evolutionary trend of Indian representatives of the genusLecithocladium parasitizing on the Intestine of two marine fish was inferred for the first time, based on molecular data set of the 18S rDNA region using MEGA 6. The amplicon size of the sequences of both species of Lecithocladium were long 1064 & 1214 bp and G+C content was 47% and 48% respectively. Conclusion of the study: The present molecular investigation revealed only 63% similarity between both species of Lecithocladiumshowing they are clearly distinct species differing at variable nucleotide positions. The phylogenetic tree shows that both Indian species are clearly distinct and formed a sister clade with L. excisum from the UK. These species are also different in terms of morphological aspects such as the shape and size of the body, the ratio of oral sucker, and the position of the genital pore. Both the Indian species also have different fish hosts, locality as well as sites of infection. These differences may be due to variant nucleotide bases, consequences in the lineage of mutations, especially base substitutions and additions of nucleotide basepairs.

Composition, Biogenesis, and Sensory Architecture of the *Podophrya collini* Feeding Tentacle: a Novel Microtubule-based Organelle with Ultrafast Prey Recognition

Z. Xu, S. Coyle; University of Wisconsin-Madison, Madison, WI.

Microtubules are conserved cytoskeletal filaments that assemble into higher-order biochemical machines to perform diverse cellular functions, from motile cilia to the mitotic spindle. However, our understanding of how these microtubule-based machines are built and function is largely derived from metazoan systems, which represent only a small fraction of the Eukaryotic design space. Here we investigate the composition, biogenesis, and sensory architecture of a microtubule-based feeding tentacle from *Podophrya collini*, a single-celled predatory ciliate. While juvenile *P. collini* are highly ciliated, mature cells replace their cilia with dozens of feeding tentacles that extend hundreds of microns out from their body into the environment. The tips of these tentacles react within milliseconds of contact with specific prey, triggering membrane fusion and transport of prey cytoplasm down the tentacle into the cell body. To understand the biogenesis of these structures, we developed a high-throughput tentacle severing and regeneration assay that enabled us to track the *de novo* assembly of these microtubule structures over time and the transcriptional programs supporting their construction. We found that tentacles first assemble in the cytoplasm before being delivered to the cell periphery and identified time-specific transcriptional patterns that correlate with these stages of biogenesis. Differential gene expression analysis revealed that many cilia-associated and cilia-specific proteins are upregulated during tentacle assembly, and immunostaining confirmed a novel distribution for many of these factors in the tentacle structure. This suggests that tentacles may be assembled in part through the alternative use of canonical ciliary proteins. To investigate the tentacle sensory activity, we sought a soluble protein factor that could trigger a feeding reaction in the absence of prey. We identified that lectins could potently induce *P. collini* tentacle contraction, grabbing behavior, and vesicle discharge. Fluorescent lectins strongly stained the tentacle tips, suggesting these effects are mediated by direct interaction with molecules involved in prey recognition. These lectins provide a tool for studying the quantitative behavior of the feeding reaction and can also serve as baits to identify receptors responsible for *P. collini* tentacle ultrafast prey recognition. Through understanding the novel

microtubule-based structure of the suctorian *P. collini* tentacles, our results provide new insights into the design principles of microtubule-based architectures and molecular machines.

Three-dimensional reconstructions of the microsporidian parasite niche in infected mammalian cells

C. Lam, N. Antao, C. Petzold, J. Sall, F.-X. Liang, G. Bhabha, D. Ekiert[1]; New York University School of Medicine, New York, NY

Microsporidia are single-celled, obligate intracellular parasites closely related to fungi, which can infect a wide range of animals and can cause fatal illnesses in immunocompromised patients. *Encephalitozoon intestinalis* is a human-infecting species of microsporidia that initiates infection in the small intestine, where it develops and replicates in parasitophorous vacuoles (PV). As obligate intracellular parasites, *E. intestinalis* have evolved a highly reduced genome, about 2.3 megabase pairs, and are dependent on host metabolites for successful development and replication. *E. intestinalis* lack many key metabolic pathways and eukaryotic organelles, including a functional mitochondria that can perform oxidative phosphorylation. There is limited research that shows how this pathogen exploits their intracellular niche in order to survive and propagate. To understand the physical basis for how the parasite occupies and manipulates the host cell, we used serial-block face scanning electron microscopy (SBF-SEM) to generate a three-dimensional reconstruction of the intracellular niche for *E. intestinalis* in infected host cells. This technique allows us to examine the interactions between the parasite and host cell organelles at nanometer resolution. The three-dimensional reconstructions give us insights into how *E. intestinalis* interacts with host organelles, including the host cell mitochondrial network. Coupled with optical microscopy, our data show that microsporidia impact mitochondrial fusion and fission dynamics. An analysis of the aspect ratio of mitochondria from our SBF-SEM data show that while uninfected control cells have elongated, interconnected mitochondrial networks, infected cells contain a high number of small, disconnected, and spherical mitochondria, providing higher resolution insights into the increased fission phenotype observed in optical microscopy experiments. Our SBF-SEM data shows findings on how microsporidia manipulate and remodel mitochondria and other host cell organelles.

B695/P1671

A novel Peroxin is involved in the maintenance of mitochondrial morphology

E. Knight, A. Gianos, L. Crowe, M. Morris; Clemson University, Clemson, SC

Kinetoplastid parasites have peroxisome like organelles called glycosomes that are unique in that they harbor many glycolytic enzymes that are cytosolic in other eukaryotes. Proteins known as peroxins (Pexs) coordinate peroxisome (and glycosome) biogenesis. Homologs for only 50% of the peroxins characterized in eukaryotes have been identified in kinetoplastids. We are interested in identifying and characterizing additional Pexs. We queried the trypanosome genome for open reading frames that contain peroxin functional domains with the reasoning that functional domains would be more conserved than overall protein sequences. We found a single ORF (Tb927.9.11350) containing a putative Pex19 binding domain (P19BD; SNKLEIWEDLKIISFTR). Pex19 is a soluble chaperone that delivers peroxisome membrane proteins, many of which are Pexs, to the peroxisome via interactions with the glycosome membrane protein Pex3. Silencing Tb927.9.11350 in the model kinetoplastid, *Trypanosoma brucei*, resulted in slower growth rates. We were surprised that Tb927.9.11350-deficient *T. brucei* had swollen mitochondria while gross glycosome morphology (size, number, and shape) was unchanged. We

named the protein encoded by Tb927.9.11350, PIMM (Peroxin Involved in Mitochondrial Morphology). Immunofluorescence assays with epitope-tagged PIMM are inconclusive. We are working to define the mechanism by which PIMM influences mitochondrial morphology. PIMM-deficient cells have increased reactive-oxygen species and are more susceptible to apoptotic stimuli. We are currently working on measuring the extent to which mitochondrial metabolism (as opposed to mitochondrial structure) is altered. Understanding the function of this protein may shed light on novel ways in which mitochondria and these specialized peroxisomes communicate. While mitochondria-peroxisome communication in other eukaryotes is an active field of study, little is known about how these organelles interact in Kinetoplastid parasites.

B696/P1672

Targeting *Plasmodium* protein synthesis—the relationship between translation inhibitor efficacy and reversibility during *P. berghei* liver stage schizogony.

J. L. McLellan, K. K. Hanson; University of Texas At San Antonio, San Antonio, TX

Protein synthesis is a critical cellular process that is regulated in response to changing external stimuli and causally linked to cell growth and proliferation. Given the essentiality of protein synthesis throughout the complex lifecycle of *Plasmodium* parasites, the causative agents of malaria, parasite-specific translation inhibitors are emerging amongst the leading candidates for next generation antimalarials— capable of targeting both the asymptomatic liver stage and the disease-causing blood stage of infection. The liver stage is the obligate first step in mammalian infection and amplifies the parasite population, with each invading sporozoite generating thousands of progeny that initiate infection of the erythrocytes. Though the reversible effects of novel antimalarial translation inhibitors, including an elongation factor 2 (eEF2) inhibitor and several tRNA synthetase inhibitors, have been characterized in blood stage parasite populations, we know little about the effects of acute translation inhibition during the much more rapid growth happening during liver stage schizogony, and whether or not these effects are reversible. We hypothesized that a compound's translation inhibition efficacy, regardless of potency or mechanism of action, would determine the extent of liver stage growth and downstream developmental success after compound removal. To investigate, we developed a single cell bioimaging assay to quantify translation in hepatic schizonts of the model parasite, *P. berghei*, as well as the HepG2 hepatoma host cells. We selected a panel of reversible translation inhibitors, each having a distinct mechanism of action, with both *Plasmodium*-specific and pan-eukaryotic inhibitors included. After determining the translation inhibition EC_{50} for each compound, infected cell monolayers were treated for 4 hours at 5x and 10x EC_{50} concentrations early in the rapid schizogonous growth phase. Even at equivalent effective concentrations, we detected differences in the in efficacy of translation inhibition between the compounds. Unexpectedly, compound efficacy did not appear to determine either the speed or extent of translation recovery after thorough compound washout, or subsequent parasite growth and differentiation, as quantified by parasite size, expression of late liver stage maturation markers, hepatic merozoite formation, or release of merozoite-filled merosomes. Individual parasites from most treatments were capable of completing liver stage development, but with altered kinetics and widely variable numbers. Treatment with the least efficacious translation inhibitor resulted in only partial translation recovery, which did not appear sufficient for most parasites to resume growth, let alone complete differentiation.

Toroidal cellular topology enables vertical migration of a non-motile plankton

A. Larson, R. Chajwa, H. Li, M. Prakash; Stanford University, Stanford, CA

The mass of our planet, and its daily rotation on its axis, set universal conditions that shape every cell in every organism on this planet. The impact of earth's motion on evolution and behavior is generally appreciated in the context of molecular clocks and the ubiquity of circadian processes. However, the influence of earths gravitational pull on cellular anatomy is lesser realized. It is understood that the size and shape of individual cells are defined by their environment. However, this is a dynamic process, and its understanding requires quantifying cellular behavior within a cell's native environment. Single-celled eukaryotic plankton, with a vast diversity of cellular geometry, evolved to navigate the gravitational and hydrodynamic pressures of a vertically stratified ocean and provide a unique platform for ecophysiological studies - including cellular levitation. Here we present how cellular topology can enable sinking and rising dynamics of seemingly non-motile cells in the open ocean. Since the downward gravitational pull has been a constant throughout the origin of life on our planet, the density of cellular components presented a fundamental limit on the growth of a cell living a planktonic lifestyle, allowing gravity to directly shape evolution. Several successful adaptations have enabled cells to survive under the gravitational pull; including environmental sensing, osmoregulation, and size control- mechanisms ubiquitous in higher life. How these systems determined optimal parameters however, is unknown. For Pyrocystis integrating these adaptations is crucial. By measuring the rising and sinking dynamics of the non-motile dinoflagellate Pyrocystis noctiluca throughout its life cycle with a vertical tracking microscope, we uncover a unique role of a toroidal cellular topology in regulating buoyancy via a rapid volume increase. Combining field and lab measurements with system modeling, we present a general framework for how non-motile planktonic cells escape the gravitational sedimentation trap, and how precise regulation of cell size becomes crucial to survival. We believe our model is broadly applicable to a large class of organisms. As daily planktonic migrations constituting the `biological pump' fix from 40-60% of earth's carbon emissions, understanding of this process and our anthropogenic impact will only become more important.

Adipocytes, Metabolism, and Metabolic Disorders

Development of standard in vitro models of human white and brown adipose tissue.

C. Cero[1], W. Shu[2], A. Reese[3], A. R. Zhu[1], J. M. Katz[1], A. E. Pierce[1], D. Douglas[2], F. Tian[2], J. Jacobs[3], A. M. Cypess[1]; [1]NIH/NIDDK, Bethesda, MD, [2]ATCC, Biological Content, Gaithersburg, MD, [3]ATCC, Sequencing and Bioinformatics Center, Gaithersburg, MD.

The presence of bona fide thermogenic brown adipose tissue (BAT) in adult humans makes it an attractive therapeutic organ to treat metabolic diseases. However, limited access to patient-derived BAT or validated brown adipocytes (BA) cell lines hampers research of human BAT physiology. To overcome these limitations, we have established immortalized, clonal, brown (hTERT-hBA) and white pre-adipocytes (hTERT-hWA) cell lines derived from the peri-renal and subcutaneous abdominal regions, respectively, from a single donor. Differentiated BA have a higher gene (RNA-sequencing and RT-PCR) and protein (western blotting and immunohistochemistry) expression of BA-specific, thermogenic (*UCP1*, *PPARGC1A*) and mitochondrial markers (*TFAM*, *MT-CO2*). In contrast, differentiated WA express

established white adipocyte markers, including *HOXC8* and *TCF21*. Consistent with the molecular data, compared to WA, the BA have a higher metabolic rate as measured by cellular respiration. Since glucose and fatty acids are used to fuel UCP-mediated thermogenesis in brown adipocytes, we demonstrated that BA displayed higher glucose oxidation, glycolysis, and endogenous fatty acid oxidation compared to WA. Lipolysis measured by phosphorylation of hormone sensitive lipase and glycerol release was similar in differentiated WA and BA. Despite similar lipolysis, the released fatty acids produced an immediate increase in maximal respiration in BA compared to WA, indicating a higher respiratory capacity that is consistent with greater expression of transmembrane ion channels. This respiration was repressed by GDP, an inhibitor of UCP1, suggesting that the higher metabolic rate in BA is UCP1-mediated. RNA-seq transcriptomic studies revealed the β3-adrenregic receptor as clustering closest to UCP1, supporting a functional connection between the two. In summary, we have generated a well-characterized pair of WA and BA that are functional and scalable and can be used as standard models to study human adipocyte biology and physiology.

Ameliorating effects of processed Curcumae longae rhizome on high-fat diet induced obese mouse model

T. Gil[1], H. Kim[1], H. Kim[1], H. An[2], Y. Cha[3]; [1]Department of Pharmacology, Sang Ji University, Wonju-si, KOREA, REPUBLIC OF, [2]Department of Oriental Pharmaceutical Science, Kyung Hee university, Seoul, KOREA, REPUBLIC OF, [3]Department of Rehabilitation Medicine of Korean Medicine and Neuropsychiatry, Sang Ji University, Wonju-si, KOREA, REPUBLIC OF.

Continuing obesity pandemic leads to constant request for preventative and therapeutic agents against the manifestation or its accompanied diseases. As a popular herbal medicine, the rhizomes of *Curcuma longa* L. (PCLR) has been used for various therapeutic applications in inflammatory disorders, wound healing, or kidney injury. This rhizome is known for promoting weight loss and reducing the possibility of obesity-related diseases. Based on the property, PCLR enhancing drug delivery was evaluated its effect on high-fat diet induced obese mouse model. C57BL/6 mice were fed 45% high-fat diet for 11 weeks. To compare the effects of processed rhizome and non-processed one, we administrated them orally and used orlistat as a positive control. At the end of the experiment, the weight of total body and different adipose tissues weight were evaluated showing slightly decreased body weight. Subcutaneous and epididymal white adipose tissues are significantly enlarged in high-fat diet group and reduced in PCLR group. Interscapular brown adipose tissues showed similar tendency of size reduction in PCLR treated group. Not only the differences of the naked eyes, the histological images of adipose tissues were different using hematoxylin and eosin staining. Bigger adipocytes were presented in the high-fat diet group and the adipocytes were dwindled in the PCLR treated ones. At the same time, the adipogenesis markers were detected in subcutaneous white adipose tissue as protein expression using western blotting assay. PCLR treatment showed decreased protein expressions on peroxisome proliferator-activated receptor γ, CCAAT/enhancer-binding protein α, and sterol regulatory element-binding protein 1 which are comparable differences with high-fat diet induced obesity group. These results suggested that PCLR could be a potential therapeutic agent for obesity.

A Study on the Anti-Obesity Effects of Lythri Herba Water Extracts *In Vivo and In Vitro*

Y. Park[1], H. Kim[1], Y. Cha[2], H. An[3]; [1]Pharmacology, Sangji University, Wonju, KOREA, REPUBLIC OF, [2]Rehabilitative Medicine of Korean Medicine and Neuropsychiatry, Sangji University, Wonju, KOREA, REPUBLIC OF, [3]Oriental Pharmaceutical Science, Kyung Hee University, Seoul, KOREA, REPUBLIC OF.

Although several studies have been reported that Lythri herba has anti-inflammatory, anti-oxidative, anti-nociceptive, anti-microbial, and haemostatic activity, there are no evidences on the effects of Lythri herba in obesity. Therefore, in this study, we aimed to investigate the anti-obesity effects of Lythri herba on high-fat diet (HFD)-induced obese mice and differentiated 3T3-L1 cells. Male C57BL/6 mice were fed either a regular chow diet or 45% HFD. The HFD-fed mice were administered with distilled water, orlistat (20 mg/kg), garcinia cambogia extracts (375 mg/kg), or Lythri herba (50, 100 or 200 mg/kg) for 8 weeks. The body weight and weight gain were significantly decreased in the 100 or 200 mg/kg Lythri herba-administered mice; however, there were no differences in food intake among HFD-fed groups. Lythri herba administration significantly reduced the concentration of serum leptin in HFD-fed obese mice. In addition, Lythri herba administration showed decrease of the mass and adipocyte size in epididymal white adipose tissue of HFD-fed obese mice. Furthermore, Lythri herba treatment markedly inhibited lipid droplets in the differentiated 3T3-L1 adipocytes. Our results demonstrate that Lythri herba could be used as a potential natural agent to treat obesity.

The Regulatory Role of MAO-B Pathway in Obesity-associated Diseases

Y. SUNG[1], J. Kim[1], E. Kim[1], M. Lee[1], D. Yoon[1], H. Min[1], Y. Hwang[1], E. Park[2], S. Kim[2], E. Chang[1]; [1]University of Ulsan College of Medicine, Seoul, KOREA, REPUBLIC OF, [2]NeuroBiogen., Co. LTD, Seoul, KOREA, REPUBLIC OF.

Monoamine Oxidase-B (MAO-B) is a regulator of neurotransmitter which MAO-B inhibitors are known as treatment in various neurological disorders such as depression, Alzheimer's disease, and Parkinson's disease. Recent studies found that MAO-B inhibitors had correlation with metabolic syndromes, but little is yet known about the underlying therapeutic mechanism in obesity. Here we discovered the effect of newly developed reversible MAO-B inhibitor, KDS2010, on obesity *in vivo* and *in vitro*. We corroborated the effect on weight loss by oral administration(20mg/kg) of KDS2010 in diet induced obesity (DIO) mouse, while there was no significant difference in food intake between DW and KDS2010 treatment. Accordingly, we analyzed mouse activity by comprehensive lab animal monitoring system (CLAMS) whether KDS2010 supervises mouse mobility. However, mobility rate of KDS2010 treatment group was comparable with that of DW treatment group. Adipogenic differentiation of adipose tissue derived stem cell (ASC) from epididymal white adipose tissue cultured with KDS2010 showed augmented expression of brown fat related genes which is known to increase energy expenditure. These findings provide evidence for the possible role of MAO-B pathway in ameliorating obesity-associated diseases.

Local fat content determines global and local stiffness in fatty livers

D. Li[1,2], P. A. Janmey[2,3,4,5], R. G. Wells[1,2,3]; [1]Division of Gastroenterology and Hepatology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, [2]NSF Science and Technology Center for Engineering MechanoBiology, University of Pennsylvania, Philadelphia, PA, [3]Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, [4]Institute for Medicine and Engineering, Philadelphia, PA, [5]Department of Physiology, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA.

Nonalcoholic fatty liver disease (NAFLD) is the most common form of liver disease globally, and refers to a spectrum of pathology characterized by steatosis and other changes to the liver not associated with heavy alcohol use. The contribution of mechanical changes resulting from fat accumulation to NAFLD progression is unclear and the effects of steatosis on the mechanical properties of the liver has yet to be defined. Specifically, although histology indicates a preferential accumulation of fat near the central veins of the liver, it is unknown whether this fat accumulation is associated with local variations in stiffness. Indeed, the study of any effects of tissue microarchitecture and histological features on local tissue stiffness is hampered by the inability to correlate visualized microarchitecture with measured mechanical properties in sub-millimeter regions of tissue. We studied the livers of ob/ob and wild-type littermate mice using parallel plate rheometry as well as a sub-millimeter scale microindentation technique to define the stiffness of steatotic livers at both the whole organ and meso-scale. The microindentation technique was adapted to enable determination of local fat content and identification of other local features in the indented region. We found that steatotic livers and steatotic regions of fatty livers were softer than non-steatotic livers/regions. Higher lipid content in a region significantly correlated with decreased stiffness. The finding that steatosis is associated with both global and local liver softening has significant implications for understanding the progression of early stage NAFLD, given that stiffening is a mechanical stimulus for the development of fibrosis. The ability to correlate submillimeter-scale stiffness measurements with histological features can also be used to study other pathological states, such as steatohepatitis and fibrosis, and to investigate development and disease in other tissues and organ systems.

Multiomics Analysis for Characterization of the Contribution of High Fructose Corn Syrup to Non-Alcoholic Fatty Liver Disease in Obesity

G. Papadopoulos[1], A. Legaki[1], P. Vorkas[2], G. Stamatakis[3], I. Moustakas[1], H. Gika[4], M. Samiotaki[3], **A. Chatzigeorgiou**[1]; [1]Medical School, Department of Physiology, National and Kapodistrian University of Athens, Athens, GREECE, [2]Institute of Applied Biosciences, Centre for Research and Technology, Thessaloniki, GREECE, [3]Institute for Bio-innovation, Biomedical Sciences Research Center "Alexander Fleming", Athens, GREECE, [4]Department of Medicine, Aristotle University of Thessaloniki, Thessaloniki, GREECE.

Objective: High Fructose Corn Syrup (HFCS), a sweetener rich in glucose and fructose, is nowadays widely used in beverages and processed foods; its consumption has been correlated to the emergence and progression of Non-Alcoholic Fatty Liver Disease (NAFLD). Nevertheless, the exact molecular mechanisms by which HFCS impacts hepatic metabolism remain scarce, especially in the context of obesity. In contrast, the majority of current studies focus either on the detrimental role of fructose in

hepatic steatosis or compare separately the additive impact of fructose versus glucose in high fat diet-induced NAFLD. Additionally, studies investigating the role of fructose in NAFLD utilize molecular fructose, rather than HFCS, thus not simulating properly the role of HFCS on human NAFLD. By engaging combined omics approaches, herein we aimed to characterize the role of HFCS in obesity-associated NAFLD and reveal molecular processes, which mediate the exaggeration of steatosis under these conditions. Methods: C57BL/6 mice were fed a normal-fat-diet (ND), a high-fat-diet (HFD) or a HFD supplemented with HFCS (HFD-HFCS) and upon examination of their metabolic and NAFLD phenotype, proteomic and lipidomic analyses were conducted to identify HFCS-related molecular alterations of the hepatic metabolic landscape. These results were further evaluated with enzymatic assays, which focused on specific mitochondrial functions. Results: HFD and HFD-HFCS mice displayed comparable obesity; nevertheless HFD-HFCS mice showed aggravation of hepatic steatosis, while their hepatic proteome was characterized by an upregulation of the enzymes implicated in de novo lipogenesis (DNL). Besides, palmitic and stearic acid-containing diglycerides were significantly increased in the HFD-HFCS hepatic lipidome, as compared to the HFD group. Integrated analysis of the omics datasets suggested that TCA cycle overactivation is likely contributing towards the intensification of steatosis during HFD-HFCS-induced NAFLD. Conclusion: Overall, our results imply that HFCS may significantly contribute to steatosis aggravation during obesity-related NAFLD, with its fructose-rich properties being the main suspect.

A Rapid NASH Model and its Application in Candidate Drug Screening for Metabolic Syndrome and Hepatic Steatosis

C. Ju[1], Z. Chen[1], A. Zong[1], J. Zhao[1], X. Gao[1], **Z. Li**[2], M. Gao[3], X. Zhao[3]; [1]GemPharmatech Co. Ltd., Nanjing, CHINA, [2]GemPharmatech, Wilmington, DE, [3]GemPharmatech, Nanjing, CHINA.

<META NAME="author" CONTENT="陈中">

Non-alcoholic steatohepatitis (NASH) is the more aggressive form of non-alcoholic fatty liver disease (NAFLD) that may progress to cirrhosis and hepatocellular carcinoma (HCC), and so far, there is no FDA approved therapies for NASH. For therapeutic development, animal models of NAFLD/NASH are crucial for preclinical evaluation of efficacy and safety. Given the rapidly growing recognition that NAFLD/NASH is the hepatic manifestation of metabolic syndrome, scientists are paying a lot more attention to the metabolic characteristics of NASH animal models they choose to work with. Among most classical NASH animal models, the long duration of diet treatment or the lack of metabolic phenotypes limits their application in candidate drug screening. To fill the gap, GemPharmatech developed a rapid NASH model based on Alms1 mutant mice (B6-Alms1-del mice). B6-Alms1-del mice develop a plethora of early onset metabolic phenotypes on chow diet, such as obesity, hyperglycemia, hyperlipidemia and fatty liver. To accelerate the NASH progression, B6-Alms1-del mice were fed with western diet (high fat, high fructose and high cholesterol), which exacerbated obesity, hypercholesterolemia and liver injury within 6 weeks. Furthermore, major clinical features of NASH patients were observed in western diet fed B6-Alms1-del mice, including hepatic steatosis, inflammation, ballooning, mild fibrosis as well as significantly increased NAFLD activity score. To verify the applicability of this Alms1 NASH model in preclinical research, two promising preclinical drugs MGL-3196 and Semaglutide were used to treat Alms1 NASH mice. Our results indicate that both drugs lead to benefit on NASH, including body weight control, improvement in hyperlipidemia, liver injury, hepatic steatosis and fibrosis. In conclusion, we have

established a rapid mouse model for NASH. This model exhibits clinically relevant metabolic phenotypes and responds to candidate drugs that have recently showed promising phase II clinical results. This rapid NASH model provides a much needed preclinical capability to assess the efficacy of novel NASH therapeutics in a timely manner.

Axon guidance molecule Slit3 is essential for cold-induced remodeling of BAT neurovasculature and thermogenesis

T. Duarte Afonso Serdan[1], H. Cervantes[1], F. Mousovich Neto[1], Y.-H. Tseng[2], **F. Shamsi**[1]; [1]New York University, New York, NY, [2]Joslin Diabetes Center, Harvard Medical School, Boston, MA

Brown adipocytes are embedded in a dense network of blood vessels and sympathetic nerves that supports their thermogenic activity. Cold acclimation enhances brown adipose tissue (BAT) thermogenesis through the coordinated induction of brown adipogenesis, angiogenesis, and sympathetic innervation. Increasing the density of blood vessels and sympathetic innervation is essential for enhanced thermogenesis in cold. However, how these distinct processes are spatiotemporally coordinated remains unclear. We have recently used single-cell RNA-sequencing (scRNA-seq) to build a network of ligand-receptor interactions involved in the cold-induced remodeling of BAT. We identified Slit guidance ligand 3 (Slit3) as a new adipokine that mediates the crosstalk among adipocyte progenitors, endothelial cells, and sympathetic nerves. Slit3 is a member of the Slit family of secreted axon guidance molecules. Using a combination of in vivo gain and loss of function studies, we showed that Slit3 is essential for BAT thermogenesis. Mice lacking Slit3 exhibited severe cold intolerance and decreased energy expenditure concomitant with abnormal BAT morphology and reduced expression of thermogenetic and mitochondrial genes. Conversely, the overexpression of Slit3 enhanced BAT thermogenesis. Analysis of BAT vasculature using imaging and molecular analyses revealed that loss of Slit3 expression significantly impaired cold-induced angiogenesis in BAT, indicated by the lower density of vasculature and reduced expression of endothelial-specific transcripts. Additionally, BAT-specific loss of Slit3 led to a drastic reduction in the density of Tyrosine Hydroxylase (TH) expressing sympathetic neurites in BAT. Our mechanistic studies identified the key regulatory events that control Slit3 signaling in vascular endothelial cells and sympathetic nerves. Collectively, these findings established the essential role of Slit3 signaling in the regulation of BAT angiogenesis, sympathetic innervation, and thermogenic function and introduced Slit3 as a new niche factor that promotes adipose tissue health. This work introduced a potential node of intervention for improving systemic metabolisms by stimulating the healthy expansion of thermogenic fat.

Gonadotropin insensitivity mediates obesity-associated hypotestosteronism in mouse Leydig cells

C. Chuang, M. Hsu, C. Chiu; National Taiwan University - Taipei, Taipei city, TAIWAN.

Obesity is a public health issue in the current society and threatens the humanbody in multiple ways. One of obesity-linked reproductive disorders ishypotestosteronism which shows the lower testosterone levels in the male patient.Since how the obesity causes hypotestosteronism is still unclear, this study aims toidentify the factors that result in steroidogenic impairment in both mouse model andcultured cell study. To test the gonadotropin sensitivity in the obese mice, the controldiet (CD) or high fat diet (HFD)-fed C57BL/6 mice were injected with humanchorionic gonadotropin (hCG) to stimulate

testosterone production before sampling.The results shown that the plasma testosterone level in the HDF mice wassignificantly lower than CD group after hCG stimulation. In the cell experiments, tomimic the high level of free fatty acid in the blood in the HFD-fed mice, we treatedthe mouse Leydig cell line MA-10 with high concentration BSA-conjugated fattyacids. The results shown that the steroidogenic ability was significantly decreased inthe fatty acid-treated cells. We further examined the activity of steroidogenic enzymesby supplying the cells with different steroid intermediates. The progesteroneproduction was significantly lower in the fatty acid-tread cells when the cells given22R-OHC but not pregnenolone, which suggests that CYP11A1 was impaired underthe fatty acid-overloading condition. Moreover, both mRNA and protein levels ofCYP11A1 is significantly decreased after the fatty acid treatment. To summarize,obesity-induced hypotestosteronism may be caused by the gonadotropin insensitivityin the Leydig cells. The excessive level of free fatty acids plays an important role inimpairing steroidogenic enzyme expression; however, the transcriptional regulationinfluenced by fatty acid overloading needs more studies to elucidate.

Optimizing Immunostaining for Adipose Tissue in Adult Drosophila Melanogaster

R. K. Ott, A. R. Armstrong; University of South Carolina, Columbia, SC

Obesity prevalence and increased risk for several comorbidities, such as diabetes mellitus, coronary artery disease, and several cancers, highlight the importance of multisystem-based research aimed at addressing complex health problems. The Armstrong laboratory uses Drosophila melanogaster, commonly known as the fruit fly, to investigate how adipose tissue communicates dietary input to peripheral organs, such as the ovary. While it is clear that adipocytes in adult Drosophila females use nutrient-sensing pathways like mTOR to dynamically influence the ovarian germline stem cell lineage, we know relatively little about how nutrition and signaling pathway activity impact the adipose tissue. One crucial step toward filling this knowledge gap is establishing a protocol to robustly and reproducibly assess changes in the adipose tissue at the cellular level. By modifying various steps of routine whole mount immunofluorescence labeling, we report a contemporary process for obtaining optimal cellular imaging of adult Drosophila adipose tissue, or the fat body. Specifically, I find that carrying out fixation, washes, and antibody incubations on splayed and pinned abdominal carcasses enhances endogenous fluorescence reporters and immunoreactivity. We are currently altering additional steps to optimize the immunostaining protocol - fixative type (e.g. paraformaldehyde versus glutaraldehyde) and concentration, primary antibody concentration, and detergent type (Triton X-100 versus Tween 20) and concentration. This optimized whole mount immunofluorescence protocol will be employed in future studies investigating the dietary response of Drosophila adipose tissue.

Defining Therapeutic Targets and New Therapeutics- For Neurological Diseases

B713/P1684

Discovery of a novel dual-action small molecule that improves multiple Alzheimer's disease pathologies

H. Jin[1], M. Park[2], K. Park[2], B. Choi[1], H. Yoon[2], H. Jung[2], J. Bae[2]; [1]College of Veterinary Medicine, Kyungpook Natl Unive, Daegu, KOREA, REPUBLIC OF, [2]Department of Physiology, School of Medicine, Kyungpook Natl Unive, Daegu, KOREA, REPUBLIC OF.

Alzheimer's disease (AD) is characterized by complex, multifactorial neuropathology, suggesting that small molecules targeting multiple neuropathological factors are likely required to successfully impact clinical progression. Acid sphingomyelinase (ASM) activation has been recognized as an important contributor to these neuropathological features in AD, leading to the concept of using ASM inhibitors for the treatment of this disorder. Here we report the identification of KARI 201, a direct ASM inhibitor evaluated for AD treatment. KARI 201 exhibits highly selective inhibition effects on ASM, with excellent pharmacokinetic properties, especially with regard to brain distribution. Unexpectedly, we found another role of KARI 201 as a ghrelin receptor agonist, which also has therapeutic potential for AD treatment. This dual role of KARI 201 in neurons efficiently rescued neuropathological features in AD mice, including amyloid beta deposition, autophagy dysfunction, neuroinflammation, synaptic loss, and decreased hippocampal neurogenesis and synaptic plasticity, leading to an improvement in memory function. Our data highlight the possibility of potential clinical application of KARI 201 as an innovative and multifaceted drug for AD treatment

Generation of CRISPR- and AID-based reagents to assess the neuroprotective effects of HUM-2 and SPAS-1 loss in *C. elegans*

J. Feduccia, **F. Akoachere**, E. S. Luth PhD; Simmons University, Boston, MA.

Parkinson's disease (PD) is associated with excessive alpha-Synuclein (αS) buildup, which induces the death of dopaminergic neurons. There's no cure for PD, and identification of new therapeutic targets would be impactful. Preliminary data suggests that pharmacologic inhibition of cytoskeleton-associated proteins myosin-V and spastin in cell culture reduced αS aggregations and improved neuroblastoma cell growth. Additional preliminary evidence indicates that genetic disruption of protein homologs in *C. elegans*, HUM-2 and SPAS-1, promotes dopaminergic neuron survival in a model with αS-induced neuronal loss. However, lifelong knockout of myosin-V and spastin in humans is not a viable therapeutic strategy. To assess whether myosin-V/HUM-2 and spastin/SPAS-1 are truly viable therapeutic targets, we must determine whether reduction of protein activity in adults is sufficient to confer neuroprotection. To test this cleanly, we designed a strategy that uses the auxin-inducible degron (AID) system that allows for spatial and temporal control of protein degradation in the presence of auxin and the enzyme TIR1. We generated a set of CRISPR- and AID-based reagents that will allow us to insert an AID tag to endogenous HUM-2 and SPAS-1 proteins, and disrupt their expression in adult *C. elegans* neurons. This includes guide RNA to direct the CRISPR-Cas9 machinery to the *hum-2* or *spas-1* locus and specific donor repair DNA to be inserted into the cut site. To generate single guide RNAs, we used templateless PCR to combine the DNA for locus-specific crRNA with a universal tracrRNA DNA sequence, followed by in vitro transcription. To create linear DNA repair templates, we performed PCR using

primers with homology surrounding the HUM-2 or SPAS-1 translational start sites to amplify, from a plasmid, DNA containing an AID sequence and fluorescent tag. We then used magnetic bead purification to remove excess primer. Overall, we have generated and purified the reagents necessary to use the AID system and combined our products with purified Cas9 protein for injection into worms that express TIR1. Upon confirmation of successful CRISPR editing, we will introduce auxin to adult worms to assess the degree of neuroprotection at this late stage. This work will support the evaluation of myosin-V and spastin as potential drug targets to treat aSyn-induced dopaminergic neuron death in PD.

Eclipse, an automated CRISPR platform for the large scale generation of cell models for the iPSC Neurodegenerative Initiative (iNDI)

P. Deng, A. King, M. Morell, A. Chair, D. Sailor, A. G. Sommer, K. Holden; Synthego, Redwood City, CA.

The National Institutes of Health led iPSC Neurodegenerative Disease Initiative (iNDI) is the largest iPSC genome engineering project attempted with the goal of generating a widely available and standardized set of diseased cell models for over 100 single nucleotide variants (SNV) mutations associated with Alzheimer's disease and related dementias (ADRD) in isogenic IPSC lines. The standardization of cell models is of vital importance for the generation of reproducible and actionable data in therapeutic development. As part of a multi-institution collaboration, Synthego was selected for the generation of 25 SNVs in the candidate KOLF2.1 iPSC line. Toward these goals, we describe the use of our automated, high throughput CRISPR editing platform, ECLIPSE, for the rapid generation of knock-in iPSC models of ADRD. We leveraged our state-of-the-art knock-in methods and automated pipelines for the design, experimental optimization, and clonal isolation of 23 of the candidate target mutations in iPSCs. For each SNV target, at least 3 clonal homozygous and 6 clonal heterozygous mutation lines were generated for a total of 264 clonal cell lines over a 6-month period. The utilization of automated systems such as our ECLIPSE platform are critical catalysts for the rapid development of relevant cell models in large scale disease initiatives such as iNDI.

B716/P1687

Vitamin B5 rescues TANGO2 deficiency-associated defects in flies and human cells

M. Sacher[1], P. Asadi[1], M. Milev[1], D. Saint-Dic[1], C. Gamberi[2]; [1]Concordia University, Montreal, QC, CANADA, [2]Coastal Carolina University, Conway, SC.

Mutations in Transport and Golgi Organization 2 (TANGO2) are associated with intellectual deficit, neurodevelopmental delay and crisis-induced phenotypes including rhabdomyolysis and cardiac arrhythmias, the latter of which are potentially lethal. These phenotypes contribute to the morbidity and mortality rate in affected individuals and preventing a metabolic crisis would reduce the mortality rate. The function of TANGO2 remains unknown but is suspected to be involved in some aspect of lipid metabolism. Here, we employ insect and human cells to examine the effects of vitamin B5, a Coenzyme A (CoA) precursor, on alleviating the cellular and organismal defects associated with TANGO2 deficiency. We demonstrate that this vitamin specifically positively affects multiple behavioural aspects of TANGO2 deficiency in *Drosophila melanogaster* and rescues membrane trafficking defects in human cells. We also observed a rescue of some of the fly defects by vitamin B3, though not to the same extent or level as vitamin B5. Our data suggest that a B complex supplement containing at least vitamin B5 may have therapeutic effects in individuals with TANGO2-associated disease.

B717/P1688

Identification of β-III-spectrin actin binding modulators for treatment of spinocerebellar ataxia

P. Guhathakurta[1], S. A. Denha[2], A. R. Keller[2], A. L. Carter[1], A. E. Atang[2], R. T. Rebbeck[1], B. Svensson[1], D. D. Thomas[1], T. S. Hays[1], **A. W. Avery**[2]; [1]University of Minnesota, Minneapolis, MN, [2]Oakland University, Rochester, MI.

β-III-spectrin is a key cytoskeletal protein that localizes to the soma and dendrites of cerebellar Purkinje cells, and is required for dendritic arborization and signaling. Mutations in the *SPTBN2* gene encoding β-III-spectrin cause the neurodegenerative disorder spinocerebellar ataxia type 5 (SCA5). Currently, there is not cure or therapy for SCA5. Numerous SCA5 mutations localize to the β-III-spectrin N-terminal actin-binding domain (ABD). We previously showed that an ABD-localized L253P mutation causes a 1000-fold increase in actin-binding affinity. Here we report the molecular characterization of ten additional ABD-localized mutations, and our progress towards developing a SCA5 therapeutic. Significantly, we found that increased actin binding is a shared molecular consequence of all tested SCA5 mutations. Further we developed a novel fluorescence-based high throughput screening platform that uses purified L253P β-III-spectrin ABD protein and F-actin. To validate the assay, we screened a 3,000-compound library of FDA approved drugs. Significantly, numerous compounds were identified that decreased FRET between fluorescently labeled L253P ABD and actin. The activity of multiple Hit compounds was confirmed in orthologous co-sedimentation actin-binding assays. The activity of a subset of compounds results from compound-induced aggregation of the mutant L253P ABD, but not wild-type ABD. Our results suggest that a small molecule that reduces actin binding of mutant β-III-spectrin may be broadly effective as a SCA5 therapeutic. Future medicinal chemistry to optimize our current Hit compounds may lead to a SCA5-specific therapeutic.

Evaluation of Blood-Based, Extracellular Vesicles as Biomarkers for Aging-Related TDP-43 pathology

C. N. Winston-Gray[1], S. Sukreet[1], V. M. Lee[2], D. M. Wilcock[3], P. T. Nelson[3], R. A. Rissman[1,4]; [1]Neurosciences, UC San Diego, LA Jolla, CA, [2]University of Pennsylvania, Philadelphia, PA, [3]University of Kentucky, Lexington, KY, [4]VA San Diego Healthcare System, La Jolla, CA.

ABSTRACT

INTRODUCTION: Limbic predominant age related TDP-43 encephalopathy neuropathological change (LATE-NC) is a recently characterized brain disease that mimics Alzheimer's disease (AD) clinically. To date, LATE-NC is difficult to diagnose antemortem using clinical information or biomarkers. Recent studies suggest concentrations of extracellular vesicle (EVs) protein cargo derived from neuronal and glial cells may serve as useful diagnostic biomarkers for AD and other neurodegenerative diseases. **METHODS**: TDP-43 was evaluated in neuronal (NDEVs), astrocyte (ADEVs), and microglial derived extracellular vesicles (MDEVs). EV preparations were isolated from the plasma of research subjects with autopsy-confirmed diagnoses, including many with LATE (n = 22). Quantified TDP-43 concentrations were compared to cohort that included healthy controls, mild cognitively impairment (MCI), and AD dementia with diagnoses other than LATE-NC (n = 42). **RESULTS**: TDP-43 was significantly elevated in plasma ADEVs derived from autopsy confirmed LATE-NC subjects, with or without comorbid AD pathology. Measurable levels of TDP-43 were also detected in EV depleted plasma; however, TDP-43 levels were not significantly different between persons with and without eventual autopsy confirmed

LATE-NC. No correlation was observed between EV TDP-43 levels with cognition-based variables, sex, and APOE carrier status. **DISCUSSION**: Blood-based EVs, specifically measuring TDP-43 accumulation in ADEVs, may serve as a potential diagnostic tool to rapidly identify subjects who are currently living with LATE-NC.

Genipin rescues sensory neuron defects in the peripheral nervous system

K. Saito-Diaz[1], P. Dietrich[2], A. Patel[1], C. G. Wzientek[1], A. R. Prudden[1], G. Boons[1], S. Chen[3], L. Studer[4], I. Dragatsis[2], N. Zeltner[1]; [1]University of Georgia, Athens, GA, [2]The University of Tennessee, Memphis, TN, [3]Weill Cornell Medical College, New York, NY, [4]Sloan Kettering Institute, New York, NY.

The peripheral nervous system (PNS) allows us to sense temperature, pain, regulate blood pressure, detect the position of our body, and is essential for proper body function. Diseases of the PNS are inflicted by various causes, including injury, infection, toxins, and mutations. Currently, there are no treatments for peripheral neuropathies. Familial Dysautonomia (FD) is an extremely devastating, genetically defined childhood disorder that specifically affects the PNS, and serves as a model disorder to study PNS dysfunction. FD currently has no available cure. It is caused by a homozygous point mutation in the *ELP1* gene leading to developmental and degenerative defects in the sensory and autonomic lineages, which are associated with loss of pain perception, heart-rate instability, and dysautonomic crisis, a severe dysregulation of the autonomic nervous system. Current FD treatments are only supportive and do not address the disease mechanism. We previously employed human pluripotent stem cells to show that peripheral sensory neurons (SNs) are not generated efficiently and degenerate over time in FD. Here, we conducted a chemical screen to identify compounds able to rescue this SN differentiation inefficiency. We discovered genipin, a compound that is prescribed in the form of a Traditional Chinese Medicine for neurodegenerative disorders. We describe genipin's neurogenic and neuroprotective properties. Genipin restores neural crest and SN development in FD, both in the hPSC model as well as in the FD mouse model. Importantly, genipin was able to cross the placenta, exert its restorative action and showed no toxicity to mother or pups. It further protects against neurodegeneration in FD, an important finding since prevention of degeneration is a treatment that could be offered to FD patients and possibly other patients suffering from PNS neurodegenerative disorders. We found that genipin's mode of action is exerted via crosslinking of the extracellular matrix. Finally, we show genipin's potential to enhance PNS regeneration in an *in vitro* axotomy model. Our results suggest genipin as a promising drug candidate for treatment of FD neurodegeneration. They further suggest that genipin may be further developed to enhance regeneration of PNS neurons.

CRISPR/Cas9 mediated generation and characterization of a zebrafish epilepsy model with mutant *slc25a22a*

S. H. Lee[1], M. K. Kim[2], S. Y. Choi[1]; [1]Biomedical Sciences, Chonnam National University Medical School, Hwasun 58128, KOREA, REPUBLIC OF, [2]Neurology, Chonnam National University Medical School, Gwangju 501759, KOREA, REPUBLIC OF.

Epilepsy is a group of neurological disorders characterized by abnormal neuronal activity in the central nervous system (CNS). Approximately 3% of the population is affected by epilepsy in the world. The etiology of epilepsy remains elusive, yet epilepsy has been reported to have a strong genetic

component. Nevertheless, genetic abnormalities that may cause epilepsy remains mostly unknown. To identify epilepsy-related genes, we analyzed genome sequences of 400 Korean epilepsy patients by Whole Exome Sequencing (WES) and identified 171 candidate genes linked to epilepsy. Among them, the role of 17 candidate genes in epilepsy remains elusive. Whole-mount in situ hybridization revealed that all the 17 candidate genes are expressed in the zebrafish brain. Among them, only the *slc25a22a* morphants displayed epileptic-like hyperexcitability phenotype. Slc25a22a, a mitochondrial glutamate carrier 1 (GC1), was localized to the zebrafish forebrain's mitochondria. Further, to explore a role for *slc25a22a* in epilepsy, *slc25a22a* zebrafish mutant was generated using the CRISPR/Cas9 system. The *slc25a22a*$^{-/-}$ embryos recapitulated the morphant phenotype and showed hyperactive and convulsive behavior. In addition, the GABAergic/glutamatergic balance and excitatory/inhibitory post-synaptic balance were disrupted in *slc25a22a*$^{-/-}$. Interestingly, the *slc25a22a*$^{-/-}$embryos showed excess lipid accumulation similar to the human *SLC25A22* mutant epilepsy patients. Further, we intend to perform electrophysiological recordings and real-time neuronal activity to uncover the precise molecular mechanisms leading to the onset of epilepsy in *slc25a22a*$^{-/-}$. Taken together, our *slc25a22a*$^{-/-}$ line can be used for extensive epilepsy-related studies and to identify novel small molecules for therapeutic intervention in epilepsy.

B721/P1692

ARID1B plays a role in the development of social attachment behavior after early life adversity in mice

T. L. Ford, B. Jeon, W.-Y. Kim; Kent State University, Kent, OH

Adverse living environments can disrupt maternal behavior, leading to early life stress for infants. However, the molecular and cellular mechanism underlying adversity-induced behavioral changes in infants are unclear. AT-Rich Interactive Domain 1B (ARID1B) is a chromatin modifying protein and is involved in early cell development. Although ARID1B haploinsufficiency is known to cause autism spectrum disorder, nothing is known about whether ARID1B haploinsufficiency contributes to behavioral alteration after early life adversity. Using Arid1b heterozygous mice as a model of ARID1B haploinsufficiency, we created an early scarcity-adverse (S-A) environment for pups for a few days by reducing wood chip bedding and nesting materials by 80% in the cage. Then we assessed social bonding behavior of the pups by a battery of behavioral tests including the rodent strange situation paradigm (rSSP). Results showed that the wild type pups that underwent the S-A condition displayed decreased social attachment to their mother compared to wild type non-S-A pups. Importantly, the Arid1b haploinsufficient S-A pups showed a moderate increase in attachment behavior compared to the non-S-A Arid1b group. We further examined adolescent mouse behavior after weaning. The open field and three-chamber tests revealed a decrease in social exploration and an increase in anxiety-like behavior in the wild type S-A group compared to non-S-A wild type mice. However, both Arid1b haploinsufficient non-S-A and S-A groups showed decreased anxiety, which was not reflective of adult Arid1b mutant behavior, suggesting a potential phenotypic change throughout development. Together, our data reveals an impact of early adverse environment on pup social bonding and further suggests ARID1B as a mechanistic factor for the development of early social behavior.

B722/P1693

Inhibition of Notch signaling in endothelial cells preserves cognitive function in a model of familial Alzheimer's disease

S. R. Villa-Niemczyk, L. A. Naiche, J. I. Arowolo, J. K. Kitajewski; University of Illinois At Chicago, Chicago, IL

Alzheimer's disease (AD) afflicts over 6 million people in the United States and is expected to grow to 13 million by 2050. The development of effective therapeutics is hampered not only by an incomplete understanding of AD pathogenesis, but also the challenges of identifying disease-modifying therapies that can penetrate the blood-brain barrier (BBB). Increasing evidence implicates cerebrovascular dysfunction in the pathogenesis of AD. Brain endothelial cells act simultaneously as a barrier and signal transducer between the brain and peripheral environment and contribute to the regulation of neurogenesis and neuroinflammation via expression of angiocrine signaling factors. Notch proteins play critical roles in vascular development and function. Dysregulation of brain endothelial Notch (EC-Notch) signaling leads to dysregulation of neurogenesis and BBB integrity, and AD-associated alterations in γ-secretase activity have been shown to affect Notch signaling. Here, we investigate changes in EC-Notch signaling during normal aging and AD and test the effect of EC-Notch inhibition on AD onset and progression. We found that EC-Notch signaling in the brain changes with age, is disrupted in AD, and inhibition of EC-Notch signaling is protective against AD-induced cognitive impairment. Although Notch is a well-described regulator of angiogenesis, we did not find overt changes in vascular morphology or density in response to Notch inhibition, suggesting that preservation of cognitive function may result from altered angiocrine signaling in the brain. These data suggest that precision targeting of EC-Notch could be therapeutically beneficial without requiring BBB penetration.

B723/P1694

Dopamine-beta-hydroxylase Short Interfering Nucleic Acid Overcomes the Short-term Efficacy of Timolol and Bimatoprost in Noradrenergic Overactivated Glaucomatous Eye

C. Carneiro[1], L. Carvalho[2], M. Moutinho[2], S. Bessa[1], P. Kennedy[1], P. Correia-de-Sá[2,3], **P. Soares-da-Silva**[4,5,6]; [1]Phyzat Biopharmaceuticals, PORTO, PORTUGAL, [2]Laboratório de Farmacologia e Neurobiologia, Instituto de Ciências Biomédicas Abel Salazar - Universidade do Porto (ICBAS-UP), PORTO, PORTUGAL, [3]MedInUP – Center for Drug Discovery and Innovative Medicines, University of Porto, Porto, PORTUGAL, [4]MedInUP – Center for Drug Discovery and Innovative Medicines, University of Porto, PORTO, PORTUGAL, [5]University Porto / Faculty Medicine, Porto, PORTUGAL, [6]Phyzat Biopharmaceuticals, Porto, PORTUGAL.

We report a novel anti-glaucoma short interference Nucleic Acid Therapy (GLAUsiNAT) targeting dopamine-β-hydroxylase (DBH) to specifically and selectively attenuate sympathetic noradrenergic overactivity in the glaucomatous eye. Human neuroblastoma SK-N-SH cells were transfected with 0.1-10 nM of anti-DBH double-stranded nucleic acid (dsNA) complexed with a commercial liposomal transfection agent. DBH gene and protein expression were analysed by RT-qPCR and Western blot, respectively. DBH activity was quantified as the conversion of dopamine to noradrenaline by HPLC-EC. The effects of anti-DBH dsNA, timolol and bimatoprost eyedrops were evaluated in a rat model of intraocular hypertension induced by topical application of tyramine 0.1% (all experiments involving animals were approved by DGAV and the ICBAS-UP Animal Ethics Committee; decision 316/2019/ORBEA). The intraocular pressure (IOP) was measured hourly for 6 hours in rats using a

rebound tonometer (TonoLab). Human and rat dsNA sequences were selected from human (NM_000787.4) and rat (NM_013158.3) DNA target sequences. In SK-N-SH cells, human dsNA sequences decreased DBH mRNA expression (IC_{50}=1.3 nM) causing an 80% knockdown of DBH protein expression, associated with significant reductions (49.1±4.1%) in DBH activity and noradrenaline content. Tyramine eyedrops raised the IOP by 40-30% above baseline. Increases in IOP were prevented by timolol eyedrops (0.5%, 30 min before) and by reserpine IP (1 mg/kg, 24h before). Eyedrops containing the anti-DBH rat dsNA or the vehicle (PBS) were applied twice (12 h apart) in the day before the first tyramine test to right and left eyes. The topical application of anti-DBH rat dsNA (0.004-4.0µg/10µL) prevented tyramine-induced IOP increases in a dose-dependent and sustained manner up to 7 days. This contrasts with the limited efficacy of timolol (0.5%) and bimatoprost (0.1%) commercial eyedrops, which drastically declined 24h after topical application using the same experimental procedure. Data show that anti-DBH GLAUsiNAT produces a long-lasting decrease in DBH expression and activity and restrained noradrenaline availability, which allow it to overcome the short-term efficacy of timolol and bimatoprost in the noradrenergic overactivated glaucomatous eye. *Work partially supported by SIRNAGLAU project (#39743), co-funded by NORTE2020, PT2020 and the European Union.*

B724/P1695

Exploring the Effect of Aurora Kinase Inhibitors on Growth Suppression in a Yeast ALS Model

G. Cruz[1], M. Kozlov[1], R. Segal[1], S. Cobos[1,2], M. P. Torrente[1,2]; [1]CUNY Brooklyn College, Brooklyn, NY, [2]CUNY Graduate Center, New York City, NY.

Amyotrophic Lateral Sclerosis (ALS), or Lou Gehrig's Disease, is a fatal neurodegenerative disease characterized by the degeneration of motor neurons. Neuronal death results in muscle atrophy, loss of motor control in the limbs, and paralysis. Currently, ALS has no cure and FDA-approved treatments fail to control symptoms.

ALS is associated with various genes, most notably chromosome 9 open reading frame 72, or *C9orf72*. Hexanucleotide repeat expansions in the *C9orf72* gene are the most common cause of ALS. These hexanucleotide expansions result in dipeptide repeat proteins, which aggregate into inclusions in the motor neurons of ALS patients.

Exploiting a yeast ALS model overexpressing the dipeptide repeat protein PR_{50}, comprising 50 repeats of the dipeptide Proline-Arginine under a galactose-inducible promoter, we have previously discovered that overexpression of PR50 is associated with an increase in the phosphorylation level of Histone H3 on Serine 10 (H3S10ph). Furthermore, we previously found that knockdown of Ipl1, the yeast homolog of Aurora B Kinase responsible for H3S10ph in yeast, leads to a decrease in the levels of H3S10ph and growth rescue in yeast overexpressing PR_{50}.

Histone modifications are highly accessible targets for pharmaceutical intervention. Therefore, with the aim of preventing H3S10 phosphorylation increases and ameliorating PR_{50} toxicity without the need for genetic manipulation, we investigated the effects of chemical inhibition of Aurora Kinase in cell survival in the context of PR_{50} overexpression. We performed serial dilution growth assays on PR_{50} yeast in the presence of two Aurora B Kinase inhibitor drugs, Jadomycin B or Barasertib, at varying concentrations. However, we found that there was minimal rescue from growth suppression. Moving forward, we will test out other drugs that may be more specific for Ipl1 inhibition and able to penetrate yeast. We will also carry out virtual screening to uncover more potent inhibitors of Ipl1/Aurora B kinase. After successful inhibition of Ipl1 and growth rescue of PR_{50} yeast, we will establish the significance of epigenetic drugs in the treatment of neurodegenerative disease.

Scholarship of Diversity

B1/P1696

Increasing Diversity and Re-engaging Undergraduates in Course-Based Research Experiences (CURE) in a COVID-19 World

L. Schramm; Department of Biological Sciences, St. John's University, Queens, NY.

Undergraduate research is a high-impact learning practice. COVID-19 has severely debilitated participation in undergraduate research for many undergraduate students. Further, higher education experienced a significant change in the full-time faculty available to mentor undergraduate independent research. This project aims to combine the technical skills of undergraduate students and faculty to re-engage students in research projects in various STEM disciplines based on student interests and faculty expertise while increasing diversity and inclusion. Using publicly available datasets and an open-source web-based scientific analysis platform, we created an online independent research experience for undergraduates tailored to students' interests. For example, we had students interested in the opioid crisis in the United States, pesticides in fish, and the biological effects of xenoestrogens. All students, with one faculty member, completed a mini-research project with data to present at a research conference. The methodology has the advantage of scaling up to a larger venue such as a major elective for credit and provides real-time assessment data. Of greater significance, our method provides a means to discuss diversity and inclusion in the public datasets (old versus newer datasets) while creating a research space conducive to best diversity and inclusion practices in the student researchers participating in our customizable research experience.

B2/P1697

A transatlantic perspective on LGBTQ+ retention in STEM

C. Chinowsky[1], S. Coffield[2], K. Clark[3], A. Dye[4], J. O'Connor[5], R. Prawer[6]; [1]Salk Institute for Biological Studies, La Jolla, CA, [2]University of California Irvine, Irvine, CA, [3]Washington University at St Louis, St Louis, MO, [4]North Carolina State University, Raleigh, NC, [5]California Council on Science and Technology, Sacramento, CA, [6]United Kingdom Science and Innovation Network, Boston, MA.

Increasing LGBTQ+ retention is vital to improving the diversity of perspectives and experiences necessary to drive high-quality scientific innovation. The issue of LGBTQ+ attrition has become more apparent in recent years, with some studies estimating that LGBTQ+ people across STEM professions are 17-21% less represented, drop STEM majors at high rates, and face clear limitations and harassment. However, the issue has received very little attention, resources, and policy interventions, partly due to a lack of widespread demographic data on sexual orientation and gender identities. Our group of early-career scientists in the US partnered with the UK Science and Innovation Network via the National Science Policy Network's (NSPN) Science Diplomacy Exchange and Learning (SciDEAL) program. We took a multifaceted approach to understanding and addressing the data on LGBTQ+ attrition. This included a comprehensive literature review, interviews, and roundtables with stakeholders across universities, governments, and non-profit organizations from the US and UK. We present a set of policy recommendations on how to improve data collection, combat toxic professional environments, and

support LGBTQ+ scientists in various settings. This synthesis will help provide clear actions universities, funding agencies, and professional societies can take to better understand and address LGBTQ+ attrition.

B3/P1698

Reverse Mentoring in STEM: Changing Perspectives to Foster Dialogue

Y. R. Seger, **F. Banda**; Federation of American Societies for Experimental Biology (FASEB), Rockville, MD.

By pairing a senior-level mentee with a junior-level mentor, reverse mentoring provides organizations with key insights into the personal and professional needs and preferences of staff members from a variety of backgrounds and experiences. Although successfully utilized by the corporate world for over a decade to help employees gain appreciation of colleagues' lived experiences, reverse mentoring has not been adopted in academic research settings. Given the well-documented barriers to participation and attrition of individuals from historically excluded groups from the professoriate, we established a reverse mentoring program for scientists and staff of scientific societies to assess the ability of this strategy to foster a greater understanding and appreciation of differences between individuals at different career stages and lived experiences. Our presentation will summarize key findings from our pilot cohort of six reverse mentoring pairs, including applicant statistics, reverse mentoring curriculum, and preliminary participant feedback, demonstrating the utility of reverse mentoring in dismantling traditional hierarchies in academic research environments.

Growing the Pipeline of Men of Color in Medicine

M. C. Pickron-Davis, Administra, J. Gerhart, Researcher, M. Martin, Student; Office of Diversity and Community Relations, Philadelphia College of Osteopathic Medicine, Philadelphia, PA.

Healthcare professions suffer from an imbalance in the number of culturally and ethnically diverse providers and the populations they serve. This poster presentation illustrates our commitment to mitigating the dearth of underrepresented men in medicine. Currently, African Americans make up 13% of the U.S. population, but only 4% of U.S. doctors and less than 7% of U.S. medical students. (Of active U.S. doctors in 2013, 48.9% were white, 11.7% were Asian, 4.4% were Hispanic or Latinx, and 0.4% were American Indian or Alaska Native.) (HBR, August 10, 2018). In 1986, 57% of black medical school graduates were men — but by 2015 that number had declined to just 35%, even as the total number of black graduates in all fields had increased. Although Latinos are the fastest growing ethnic group in the nation, the rate of Latino doctors as compared to the population has steadily declined in recent years. In 1980, there were 135 Latino physicians for every 100,000 Latinos, but by 2010 the number had dropped to 105 for every 100,000, a 22% decline. (nbcnews, February 11, 2015). Since minority health professionals are more likely than Whites to practice in minority and medically underserved areas, a more diverse health workforce could help to improve access to healthcare. (KFF, October 2008).
In summer 2019, the Office of Diversity and Community Relations and Division of Research and Science at the Philadelphia College of Osteopathic Medicine (PCOM) partnered with Cabrini University, an emerging Hispanic-Serving Institution, to pilot the inaugural African American and Hispanic Male Undergraduate Research initiative. Studies show that African American and Hispanic males are under-represented in science, technology, engineering and mathematics (STEM) educational programs and careers. Existing research has suggested that a lack of access to advanced science courses and

professional environments could be one reason for the disparity. Addressing this crises and challenge requires intentionality, innovation, resources, and partnerships. Our program aims to offer opportunities for African American and Hispanic male undergraduate science majors at Cabrini University to engage in research at PCOM and to expose them to the intricacies of working in a professional laboratory. Since launching this initiative, we have paired six Cabrini interns with PCOM faculty mentors. One of our graduates is currently employed as a Lab Assistant at PCOM and another is pursuing a graduate degree in Pharmaceutical Chemistry. The other interns are completing their senior year in Biology at Cabrini University and plan to pursue careers in medicine. We will share lessons learned about the power of partnerships in leading this social change work.

B5/P1700

Pathways to academic success of underrepresented student groups- access to undergraduate research

P. Callahan, J. Sanjeevi, B. Porter, **J. Fernandes**; Miami University, Oxford, OH.

A National Science Foundation award made possible through the Undergraduate Research and Mentoring [URM] program, was used to mentor approximately 50 students in the biological sciences, with a goal of improving retention outcomes of underrepresented student groups. The award lasted from 2008-2014, and involved four departments, Botany, Chemistry and Biochemistry, Microbiology and Zoology. Students were accepted into the program having successfully completed their first year in the major, and were provided with scholarships for up to 3 years of their college education. The research mentoring program involved enrichment such as monthly meetings, one-on-one advising, peer mentoring, outreach activities and a number of skills based workshops such as literature searches, grant writing and opportunities for on-campus as well as conference presentations. 67% of the cohort graduated in 4 years, which was a significantly higher [4 year] degree completion rates and final GPA when compared with matched controls. Ethnic under-representation was a risk factor for degree completion, only when additional factors were present, such as pell eligibility, high financial need and first generation to college. Qualitative data obtained from student interviews revealed that the cohort experience and access to mentors and professional development, raised their awareness of research based career opportunities, and that the enrichment activities offered by the program prepared them to be confident about careers after college. Based on the success of this program, a first year research experience program has been developed to provide early access to research experiences, and to raise awareness about research opportunities across disciplines. The undergraduate research office has collaborated with institutional programs aimed at retention to provide pathways for engagement in research and scholarly activities.

BioImaging North America: supporting bioimaging scientists through professional development and educational opportunities.

N. Bialy[1], V. L. Orr[1], K. W. Eliceiri[2], C. M. Brown[3]; [1]BioImaging North America, Morgridge Institute for Research, Madison, WI, [2]Departments of Biomedical Engineering and Medical Physics, University of Wisconsin at Madison, Madison, WI, [3]Department of Physiology and Advanced BioImaging Facility, McGill University, Montreal, QC, CANADA.

BioImaging North America (BINA) is a network of optical imaging scientists across Canada, Mexico and the United States, dedicated to supporting and strengthening light microscopy-based bioimaging, while

partnering and contributing to global bioimaging efforts. BINA is a non-profit association founded in 2018, with active, volunteer-based working groups focusing on communications, corporate partnership, diversity, equity and inclusion, image informatics, quality control and data management, and training and education (https://www.bioimagingnorthamerica.org/). BINA has supported the professional development of more than 70 imaging scientists in the past 18 months, 47% of whom self-identified as belonging to an underrepresented group. Imaging scientists that were trained came from the USA (75%), Canada (20%) and Mexico (4%). The list of supported 2022 training courses and those which BINA members can apply for support to attend in 2023 are found at https://tinyurl.com/BINA-PD. BINA membership is required to receive financial support or participate in any of BINA's programs, but membership is free - https://www.bioimagingnorthamerica.org/join/. Members receive a monthly newsletter where we highlight opportunities that are available. The BINA Training and Education working group hosts a monthly virtual Exchange of Experience meeting (EoE, https://tinyurl.com/BINA-Virtual-Group-EoE) where imaging scientists share their experience and expertise. In-person EoEs will kick off in late 2022, so imaging scientists interested in learning about facility management, a new instrument or technique or image analytics can visit the facility of a BINA member to acquire the new skills/knowledge. BINA has also coordinated an international effort to develop a community-driven, global database for training and education materials in light-microscopy, that can be searched easily to retrieve pertinent resources through a user-friendly web interface. MicroscopyDB launched in June of 2022 and researchers and microscopy organizations interested in sharing their resources or displaying content from the database on their organization's website should visit https://microscopydb.io/ to learn more and get involved.
This project has been made possible in part by a grant from the Chan Zuckerberg Initiative DAF, an advised fund of Silicon Valley Community Foundation.

B7/P1702

An analysis of Course-based Undergraduate Research Experience (CURE) efficacy at community colleges

M. J. Wolyniak[1], J. Zhang[2], S. DeChenne-Peters[3], D. A. Hecht[4], M. L. Kuhn[5], C. Koletar[6], N. Galport[6], R. Eddy[6], J. J. Provost[7], J. K. Bell[7], J. E. Bell[7]; [1]Hampden-Sydney College, Hampden-Sydney, VA, [2]University of Nebraska, Lincoln, NE, [3]Georgia Southern University, Savannah, GA, [4]Southwestern College, Chula Vista, CA, [5]San Francisco State University, San Francisco, CA, [6]Cobblestone Applied Research and Evaluation, Inc., La Verne, CA, [7]University of San Diego, San Diego, CA.

Course-based Undergraduate Research Experiences (CUREs) have emerged as a well-supported high-impact practice for improving both retention of students in science, technology, engineering, and mathematics (STEM) disciplines and overall achievement of students in STEM coursework. While considerable scholarship has been performed on the overall efficacy of CUREs as a teaching approach, comparatively little work has been done to uncover the more nuanced data on how CUREs serve students at two-year institutions, especially students in minoritized groups (MGs). In this study, we leveraged the Malate Dehydrogenase CURE Community, a CURE network focused on bringing research experiences in protein biochemistry to undergraduates, to collect data on student achievement at two-year institutions. Using the Test of Scientific Literacy Skills (TOSLS), a validated assessment instrument, we considered how the CURE experience effected the overall scientific literacy of students enrolled in the CURE at two-year institutions when compared to students enrolled in control classes with traditional labs. Our data revealed that the CURE approach to instruction was especially effective with respect to

MG student scientific literacy relative to control students. Importantly, we noted that two-year college students exposed to a CURE experience were 24% more likely to be retained in the STEM disciplines relative to their peers. Taken together, the data suggest that CUREs may present an effective means for the providing of equitable opportunity for scientific literacy and retention for students at two-year colleges. The outcomes of this research will hopefully enable these institutions to provide biochemistry-focused high-impact educational experiences for their undergraduates tailored to enable them to join a well-equipped next generation of life scientists.

B8/P1703

Linking biological and sociological reflections to cultivate STEM research experiences.

M. Juarez; DNA Learning Center, Cold Spring Harbor Lab, Brooklyn, NY.

DNA Learning Center NYC offers a series of 9 week-longsummer camps for students entering 6th grade thru 12thgrade. The goal of these summer camps is to promote Biology laboratoryexperiences for the New York City public school community of over 1,000,000students. The recent demographic data for the region reports that 90% of thestudent population are science PEERs (persons excluded because of theirethnicity or race). The impact of intentional efforts to increase retention forDNALC NYC camp participants can provide a case study on effective strategies tofoster early development of a diverse community of future STEM scholars. Theprevious assessments of summer camp participants focused on a pre- andpost-test of students' basic knowledge about grade-level matched Biologyconcepts. As an extension of the evaluation on learning gains, the goal of thecurrent study is to determine how the summer camp students rank their attitudesand awareness with careers in Biology and STEM. Through a collaboration withCUNY City Tech and College Now, two high school summer research internsinitiated a research project to explore survey methodology to determinestudents' perspectives on their summer camp experiences. The summer internsobserved four different weeks of summer camps. Concurrent with learning thebiological concepts and lab techniques, the summer interns conducted aliterature survey to identify questions that may determine summer campstudents' attitudes toward STEM. Preliminary data was collected from 68 summercamp respondents using an online Google form. Overall, the summer camp studentsreported high interest in Biology but rated lower confidence in pursuing a STEMcareers. Complementing this initial study with the perspectives of the summerresearch interns, as both summer camp participants and survey designers,provided unique insights into the data analysis. Comparing the survey data ofcamp participants and the weekly reflections written by the summer internshighlighted what specific activities can develop student self-efficacy andconfidence with a potential career in STEM. The future goal of this project isto adapt our teaching methods to better support a broader range of studentbackgrounds and focus on instructional activities that promote scienceidentity.

B9/P1704

A model for diversity, equity and inclusion workshops in STEM: Designed for science culture, by scientists

L. Dahlberg[1], R. Barber[1], B. Coleman[2], K. Christiani[1], R. Kodner[1]; [1]Western Washington University, Bellingham, WA, [2]Clark University, Worcester, MA

Increasing the diversity of Science, Technology, Engineering, and Math (STEM) fields has become a priority at many colleges and universities. However, efforts to build inclusive institutions can be

hampered by a lack of understanding of how current structures reinforce inequity. We describe a series of workshops designed “by scientists, for scientists” to discuss race, racism, and inclusion in scientific cultures and communities. We outline the four-part workshop curriculum and activities, which were presented as interconnected workshops to STEM faculty and staff at a predominantly white, mid-sized regional state university. We used quantitative and qualitative methods to assess the impact of the workshops on participants. Surveys of participants prior to and following workshops showed that participants increased their knowledge and understanding of topics that were the explicit focus on the workshop, for example: intersectionality, microaggressions, and bias. A qualitative evaluation to assess focus group interviews of participants in the workshops defined five themes, which point to the complex layering of scientific “objectivity” with an increasing emotional and social awareness in the mostly white participants. While participants were open to learning more about racism and how science culture intersects with systemic racism, many also remained largely unaware of their own conflicting views and tendencies to center whiteness in their narratives. These findings are reflected in the scientific community, at large, and are part of the deepening conversation on access, diversity, equity, and inclusion in STEM cultures and communities.

B10/P1705

Leveraging, Enhancing and Developing Biology (LED-BIO) Scientific Societies Shedding Light on Persistent Cultural Challenges: A Research Coordination Network

V. A. Segarra; Goucher College, Baltimore, MD

Each field in the sciences has historically been represented by its own scientific society, bringing together individual researchers for regular meetings where they can network, share discoveries, and collaborate. While it is rare for multiple distinct scientific societies to interact, they often perform similar functions, such as promoting the professional development of their members and promoting diversity among the next generation of researchers in their respective fields. We have established a collaborative network of experts to identify evidence-based inclusion strategies to accomplish the following: (1) collect consistent demographic data of society memberships, (2) better integrate scientists in transitional career stages into scientific society activities, and (3) diversify the ranks of scientific society leaders. By fulfilling these goals, this project aims to overcome persistent challenges that frequently undermine diversity efforts within independent communities of scientists and to broadly share this information for the benefit of all scientific communities. This project is an extension of the work of the Alliance to Catalyze Change for STEM Success (ACCESS), and its member societies in the life sciences (the American Society for Biochemistry and Molecular Biology, the American Society for Cell Biology, the American Society for Pharmaceutical and Experimental Therapeutics, the Endocrine Society, and the Biophysical Society), joined by the Quality Education for Minorities Network, the Marine Biological Laboratories in Woods Hole, and the NSF INCLUDES Aspire Alliance. We share the progress made during the first year of the three-year grant.

B11/P1706

ASCB and ACCESS+: A cohort-based program for STEM professional societies to advance diversity, equity, and inclusion

V. Segarra; Goucher College, Baltimore, MD

The Amplifying the Alliance to Catalyze Change for STEM Success (ACCESS+) is an ADVANCE-funded initiative working with STEM professional societies to create intersectional gender equity throughout their organizations. ASCB is part of the first cohort that participated in this program, joining a Community of Practice of societies and evaluating its diversity and equity efforts using the a comprehensive assessment of different society functions. In this poster we share ASCB's progress through the ACCESS+ program.

B12/P1707

The gene editing research lab — a classroom-based research experience at UC Merced

G. Ligunas, S. Materna, **S. Woo**; University of of California, Merced, Merced, CA

The University of California Merced is a designated Hispanic- and Minority-Serving Institution (HSI and MSI, respectively). Our undergraduate student population is majority nonwhite (54.3% Hispanic, 20.6% Asian/Pacific Islander, 9.5% White, 4.2% African American/Black, <1% Native American, and 3.3% Multiracial), and over 70% of our students are the first in their family to attend college. Especially for underrepresented minority (URM) and first-generation students, authentic research experiences are an effective way to improve retention and learning outcomes in the sciences. We have developed a Course-based Undergraduate Research Experience (CURE) that introduces students to discovery-based research through hands-on experience with CRISPR/Cas-based gene editing techniques, which have quickly become standard in biology and biomedical research. Our first pilot cohort consisted of 6 students who all identified as URM and/or first-generation. Each student was assigned one gene and designed and executed a CRISPR-based knock-in strategy for each gene. Course activities were a combination of lectures, structured training demonstrations, and self-paced lab work. Throughout the semester, students were surveyed on their perceptions and attitudes towards scientific research. In terms of scientific outcomes, we are currently in the process of identifying germline transmission for 4 of the initially targeted 6 genes. In terms of educational outcomes, all students have presented their work at departmental, campus-wide, and national conferences. Two students have since matriculated into Master's degree biology programs and another two students are currently working as research lab technicians. We are currently running a second cohort of an additional 6 students.

B13/P1708

Diversifying academia: Understanding and implementing equitable and inclusive hiring practices through faculty learning communities

E. Arevalo[1], E. Fuentes-Lopez[1], M. Wilton[2], **S. M. Lo**[1]; [1]University of California San Diego, La Jolla, CA, [2]University of California Santa Barbara, Santa Barbara, CA

Academia has historically been a space where majoritized individuals have been represented. More recently, student demographics are becoming more diverse; however, faculty demographics have not followed suit at the same rate. This presents a critical issue as the lack of representation within faculty limits not only the success of students from diverse communities but also the diversity of ideas in

academia. To address this issue, we utilize the context of search committees to examine how equitable and inclusive hiring practices are understood and implemented by faculty in science, technology, engineering, and mathematics (STEM) disciplines at four research-intensive institutions. Using an iterative design-based research approach, a total of about 10 faculty on search committees from the four campuses each year engage in faculty learning communities, peer-led structured groups that support collaborative discussion and reflections. Specifically, for the first two years of the project, we examined research literature on how to write the job advertisement and discussed the potential barriers and support in different departmental contexts for implementation. We identified four dimensions relating to equity and inclusion in the advertisement: use of language to describe the ideal candidate; description and placement of the institutional commitment to diversity, equity, and inclusion (DEI); biases and assumptions built into the evaluation criteria; and promotion and dissemination of the advertisement. In terms of barriers and support for implementation, we found that the job advertisement can be constrained by institutional structures on what is allowed to be included. However, the values and visions of a department are symbols that can be reflected in the language choice, placement and description of a DEI statement, and the inclusivity of how requirements of the position are evaluated. Individuals on a search committee are people with goals, agency, needs, and identities that may be embedded into the advertisement, and they also have strategies for distributing the advertisement that are reflective of their professional networks. We also found that the writing of the advertisement is influenced by power, i.e. the status, positioning, and political coalitions of members of the committee, department, and institution. While structures can be represented in the form of policies and symbols can guide how the structures are spoken about, power ultimately determines how specific implementations are enforced. Through this work, we are able to make key recommendations for all aspects of the hiring process that could support the diversification, inclusion, and belonging of minority faculty from minioritized communities across STEM disciplines at different institutions.

B14/P1709

Fostering An Appreciation for Research: The Meharry-Stanford Program Initiative As A Strategy for Eliminating Barriers To Career Transitions

T. Clemons; Meharry Medical College, Nashville, TN

Introduction/Statement of Problem/Background/Question: The Meharry-Stanford Program Initiative began in 2017 in an effort to partner Meharry students with scientists at Stanford who would mentor the students through a hypothesis-driven project. Since its inception in 2017, the program has evolved into a stronger program and the question we will continue to ask is how can we make the initiative even stronger than the year prior in order to help eliminate barriers to career transitions. **Goals/Objectives of the Project or Intervention**: The objective of the initiative is to allow medical students to engage in research at Stanford in an effort to foster long-lasting mentor-mentee relationships and to provide students with an opportunity to strengthen their application for their future endeavors. **Methods/Description of Project/Intervention**: The initiative has been followed since 2017 with certain critical questions being asked of the Meharry students after they have completed the program. Based on the student's responses, the goal is to improve the program each year. **Findings to Date/Evaluation to Date**: The findings to date will be shared on the poster and include valuable responses, such as do students think that their research experience at Stanford contributed to them submitting a successful application to any specific programs or positions. The data suggests that

students have found conducting research at Stanford to be a worthwhile endeavor that has aided them in their future success. **Questions still unanswered**: Although there are several questions that need further exploring, one major question that has yet to be captured in the responses is do students believe that their time at Stanford contributes to their critical thinking abilities in their medical school pre-clerkship and clerkship work.

B15/P1710

Use of community listening sessions to disseminate research findings to past participants and communities

J. Erves, E. Stewart, J. Duke, L. Alexander, **J. Davis**, D. Wilus, K. Wythe-Etheridge, S. Miller-Hughes; Meharry Medical College, Nashville, TN

The purpose of this sequential, explanatory mixed methods study is to determine changes in attitudes towards research, trust in medical researchers and the process, and willingness to participate in research among African Americans immediately after receiving past study findings in a community listening session (CLS). We developed and implemented four CLSs with a total of 57 African Americans who were either past research participants or members of the community-at-large. In the quantitative (dominant) phase, 32 participants completed pre-post surveys and 10 of those participants completed the follow-up semi-structured interviews. Paired samples t-tests and McNemar's test determined bivariate differences between pre- and post-surveys. Thematic analyses determined emerging themes to further understand these differences. There was a significant increase in: (1) perceived advantages of clinical trials pretest ($M = 26.63$, $SD = 5.43$) and post-test ($M = 28.53$, $SD = 4.24$, $p < .01$); and (2) in trust in medical researchers from pre to post ($M = 36.16$, $SD = 10.40$ vs. $M = 27.53$, $SD = 9.37$, $p < 0.001$). There was no significant difference in pre- and post-tests as it relates to perceived disadvantages of clinical trials and willingness to participate. Qualitative analysis yielded the following themes: (1) sharing research results and the impact on attitudes towards research; (2) community listening sessions: a trust building strategy; and (3) satisfaction with the community listening session. Community listening sessions hold promise as a method that researchers can use to simultaneously disseminate research findings and positively impact research perceptions and potentially participation among racial and ethnic minorities.

B16/P1711

Striving for inclusive excellence through critical reflection of teaching practices

L. R. Vega, C. J. Hegartner, B. Schoffstall, P. V. Banaji, S. M. Bingham, H. Del Rio, R. Jimenez, M. Painter, M. P. Robinson, Z. Zajickova; Barry University, Miami Shores, FL

Barry University is a mission-driven institution founded by Adrian Dominican Sisters in 1945 that now operates as a private non-profit institution with a Catholic tradition for social justice. It is recognized as a Hispanic-Serving Institution and most of its undergraduate student body originates from cultural, ethnic, or racially underrepresented minorities that are often at socioeconomic disadvantage. In 2020-2021, over 70% of our undergraduates were eligible for means-tested financial tuition assistance (IPEDs). Inclusivity, collaborative service, and social justice are key components of Barry University's mission that are infused into courses and co-curricular activities. Moreover, community engagement and collaboration are also important components of the continuing contract and promotion process for faculty. The College of Arts & Sciences at Barry University is home to our undergraduate STEM programs

(Biology, Computer Sciences, Chemistry, Physics, Psychology, and Mathematics) with full-time faculty teaching the majority of lectures and labs. STEM faculty hold advanced degrees from research-intensive intuitions and records of scholarship, but these do not necessarily guarantee that they will be effective educators for our undergraduate body. Like research, effective teaching requires experimentation and continual reflection for growth. Striving for excellence in teaching and inclusive practices is vital for institutions who focus on the undergraduate education of a diverse student body. Here, we describe how a group of faculty volunteers across STEM disciplines and beyond utilized an iterative process of study/learning, practice, and reflection to address this goal. Our fundamental premise was that broadening participation and retention within the sciences should start with careful examination of how our educational practices might unintentionally include or exclude Barry STEM students. To support STEM student persistence and success, and to improve the pedagogical practices to support student learning and inclusivity, the Barry Faculty Discussion Group was formed in 2019. We describe how our group of diverse and committed faculty, mostly in STEM, examined, discussed, and explored inclusive excellence through the framework of Paolo Freire's critical pedagogy. Faculty whose identities aligned or did not align with traditional Persons Excluded because of Ethnicity or Race (PEER) both realized how they fell back on a “banking model” of instruction because of learned practices and ease. In this poster, we also describe some critical reflections on our own teaching philosophies and practices and discuss our attempts to support and empower our students as co-investigators in their professional development in our classrooms.

B17/P1712

Cultivating Ensembles: Inclusive Interdisciplinary Community at the Intersection of Science, Theater and the Humanities.

S. Borinskaya[1], A. K. Lancaster[2], C. Sealfon[3], N. Gross[4], R. M. Holmes[5], B. J. Natalizio[6], J. E. Martinez[7]; [1]Saint Elizabeth University, Morristown, NJ, [2]Ronin Institute, Boston, MA, [3]University of Toronto & Ronin Institute, Toronto, ON, Canada, [4]Boston University, Boston, MA, [5]improvscience, Cotati, CA, [6]University of Massachusetts Chan Medical School, Worcester, MA, [7]New York Institute of Technology, New York, NY

What CE is about -> Cultivating Ensembles (CE) is an interdisciplinary and inclusive community where we co-create playful, interactive, collaborative spaces for practitioners and scholars to explore, demonstrate, and share how they build and advance science and research. Each bi-annual CE conference is a unique professional development opportunity, produced by a combination of previous organizers, recent attendees and new associates. The format is highly collaborative and participatory with a variety of different components, such as interactive, hands-on sessions; intensive workshops; lightning talks; and share fair presentations. We are educators, researchers, performers, artists, students, activists, advocates and entrepreneurs from diverse areas - academia, the arts, community organizations, business, industry, and nonprofits. We are bringing people together (ensembles) to transform the human/cultural experience of professional and social identities in STEMM (science, technology, engineering, mathematics, medicine).

History -> Historically, the CE conference is a 2 to 3-day experience of sharing research, education, and science communication practices in the sciences, arts, and humanities. We’ve hosted four conferences with more than 200 attendees from 2012 to 2019 and are currently planning the CE 2022 conference. These gatherings inspired new work and collaborations within and beyond the life sciences that have led to publications, conference presentations, and performance based workshops that inform our cultures

and advance collaboration skills. Past conferences also offered us opportunities to grow as a community of practice that cultivate ensembles across disciplines, cultures and identities.
Recent Events (Coffee Chats, CE 2022) **->** In response to the pandemic, we pivoted to a new interactive performatory form - Coffee Chat Series, a free and informal bi-monthly gathering where the Cultivating Ensembles community meets online to hear from innovative practitioners at the intersection of science and the arts and discuss topics that elevate inclusive and collaborative STEMM cultures. In our poster we will share highlights from our Coffee Chat Series, as well as the upcoming CE 2022 Conference (Nov 10-11, 2022; hosted in collaboration with the Lloyd International Honors College at the University of North Carolina-Greensboro). We will discuss how these events are part of creating inclusive and equitable ensembles where connection, play, and building relationships redefine and enrich established STEMM environments.

B18/P1713
BlackMatters: Anti-black racism in science, a film project
K. Maar[1], V. King[1], B. Yadegari[2], R. Heald[1]; [1]University of California, Berkeley, Berkeley, CA, [2]Science Communication Labs, Berkeley, CA

Black hands built the buildings of many of the most prestigious academic institutions in USA. Despite a great interest in science, Black students leave STEM fields at high rates and only a small percentage receive PhDs compared to other groups. Black people were experimented on, mutilated, and used without their consent to produce some of the most important research of our time. Black people still experience extreme racism and prejudice in the very institutions that pride themselves on being forward thinking and having inclusive cultures; they are pushed out of the science academy under the pressure of white supremacy. In this film, two Black Women graduate students, Valeria King and Khansaa Maar, provide a mirror through which science in USA has an opportunity to observe itself. Having faced racial aggressions that made them feel unwelcome, it is time to look at these BlackMatters under the microscope of social justice and expose the inequities that permeate our scientific research culture. Through interviews with Black scientists and trainees in academia and industry, we explore the effects of anti-Black racism in science in the USA. Our film production has started with the first trailer in post-production, and we are now reaching out to the larger community of Black scientists and allies for support. This is a two-year commitment with UC Berkeley's MCB program and the help of group of talented, strong Black scientists as advisory board to address all aspects of anti-Black racism in science. We need your help spreading the word and providing support for our documentary film project that directly tackles this important issue, which continues to hinder scientific progress and the well-being of our Black colleagues.

B19/P1714
Using the largest diverse human dataset to increase underrepresented biomedical researchers in research careers
D. Murray, S. Ferbach, L. Rosales, B. Lee; Baylor College of Medicine, Houston, TX

Introduction: According to the U.S. Department of Education, in Fall 2018, full-time faculty in degree-granting postsecondary institutions were 3% each Black males, Black females, Hispanic males, and Hispanic females.[1] Under-representation is one of the barriers to success for African American and Hispanic faculty. Barriers to women's career advancement from underrepresented groups in academic

medicine, science, and engineering and obtaining external research funding support for African American faculty do not occur in a vacuum and co-exist with barriers to research productivity overall.[2] This data establishes the necessity of increasing representation, creating more accessible research opportunities, building networks, mentoring relationships in STEM-related fields, obtaining a diverse scientific workforce, and ensuring the success of all underrepresented biomedical researcher (UBR) trainees and early career faculty. The *All of Us Evenings with Genetics* Research Program developed the *All of Us* UBR Faculty Summit to train early career faculty and senior postdoctoral trainees on the *All of Us* data platform. The AoUEwG Research Program aims to increase research productivity among UBR early career faculty and support their promotion to the next career level. **Results**: The *All of Us Evenings with Genetics* (AoUEwG) Research Program recruited *All of Us* UBR Scholars to the *All of Us* UBR Faculty Summit. There were 34 participants with the following demographics: 26 female, 7 male, 1 gender non-conforming, and 14 African American, 2 Asian, 13 Hispanic, 9 White, and 9 Other. The Scholars represented a variety of Carnegie Classified Institutions ranging from Doctoral/Very High (8) to Special Focus Research Institution (6), to Master's/Larger Programs (2). Six multidisciplinary research teams were formed, and these teams will develop research projects using the *All of Us* data. **Conclusion**: This researcher engagement program provides research opportunities available through the *All of Us* research hub. The research teams form a community that works toward a common goal that fosters collaboration beyond the summit's focus. Several Scholars were interested in incorporating the *All of Us* researcher workbench into their teaching curriculum. This experience will be translated to their students through didactic courses where this platform is introduced and in the Scholar's research labs.

Science Education: Primarily Undergraduate 1

B21/P1715

Analyzing student performance and problem-solving barriers in open-ended genetic problems

M. Ellefson; Molecular and Cellular Biology, University of California, Davis, Davis, CA.

The need to build problem solving skills in STEM undergraduates has been widely reported. This study seeks to better understand undergraduates' STEM problem solving performance to develop a model that will guide instructional support of students' problem-solving skill development. Specifically, the project is investigating the role of student knowledge structure, knowledge retention, and barriers in solving open-ended genetic problems. Study participants were enrolled in an upper-division genetics course that covers transmission, molecular, and applied genetics. This four-unit course consists of two 110 minute lectures and an optional 50 minute discussion session each week of a 10-week quarter. 95% of the 293 enrolled students were majoring in STEM and required to take the course. To gather a baseline of students' genetics knowledge, a Genetics Diagnostic Test (GDT) was administered to students in the first and last week of class. Students answered open ended genetic problems on an in-class summative assessment, from which ten high performing and ten low performing students were identified and invited to participate in one hour think aloud interviews (TAInt). The TAInt were conducted during weeks 7 and 8 of the quarter and entailed participants speaking through their thought processes while solving several open ended genetic linkage problems. To assess levels of knowledge retention, participants completed a follow up TAInt 8-9 weeks after the end of course during which they solved the same open-ended problems. Several developed instruments were used to analyze participant responses on the open-ended genetic problems from the in-class assessment and transcribed TAInt. Specifically, the COSINE (Coding System for Investigating Sub-problems and the Network) method is an

in-depth analysis of the difficulties students have during the problem-solving process. To apply the COSINE method, sub-problems that correlate with specific steps of genetic linkage problems are assigned a code based on student performance on a particular task. Quantitative analysis of the results uncovered that low-performing students not only spend less time on higher-level cognitive tasks but also attempt less tasks, indicating the lack of awareness of steps in the problem-solving process. Together, these results provide specific knowledge to inform important areas to model and develop improved problem-solving skills across STEM classrooms.

B22/P1716

Project CUREOS: Characterizing Undergraduate Research Experiences and Outcomes in STEM

A. L. Goodman[1], A. F. Somoza-Norton[2], D. G. Bachrach[3]; [1]California Polytechnic State University, San Luis Obispo, CA, [2]School of Education, California Polytechnic State University, San Luis Obispo, CA, [3]The Culverhouse College of Business, The University of Alabama, Tuscaloosa, AL.

Undergraduate research experiences (UREs) are among the most impactful practices promoting student persistence, self-efficacy, and science identity in science, technology, engineering, and mathematics (STEM) careers. Social factors, like mentoring, can drive positive student outcomes from UREs. But, the role played by the structure of the work, or the way that students' activities are designed, in undergraduate research has not been characterized. We use Job Characteristics Theory (JCT) as a theoretical framework to characterize how the work design of UREs generates positive student outcomes in STEM fields. Based on JCT, core job characteristics (e.g., skill variety, task identity, task significance, autonomy, and feedback) affect work-related outcomes, including motivation, satisfaction and performance (Hackman, J. R. & Oldham, G. R., 1975). In this early stage of the project, we are adapting existing survey items from the literature used to measure job characteristics to the undergraduate research context. We are using cognitive interviews to validate adapted survey items and to identify related outcomes of students' research experiences. For survey item validation (or revision), we use coding provided by multiple raters using three criteria, which Karabenick et al. (2007) defined as item interpretation congruency, coherent elaboration congruency, and answer choice congruency. Transcripts are also analyzed for emerging themes related to outcomes and benefits, as well as challenges of undergraduate research in different work contexts (e.g, fieldwork, lab work, computational work). We focus on characterizing the work design and implementation of UREs during the academic year at undergraduate-focused institutions. UREs during the academic year pose unique challenges for students, including balancing the demands of research with coursework, employment, student clubs, sports, and family obligations. URE work design structure intentionally addressing these challenges has the potential to improve student outcomes. Based on the first round of interviews, we present emerging models for different work structures in the UREs. In the future, we will explore the relationships between structural facets of URE design and key student outcomes. One of our goals is to provide recommendations for improving the design of UREs, including course-based undergraduate research experiences, ultimately improving the experiences of students in pursuit of STEM degrees, for all students, and increasing the diversity of the STEM workforce. This work was supported by NSF IUSE #2142404.

Harvard Systems & Quantitative Biology REU: Fostering Student Engagement and Learning in Virtual and In-person Formats

A. Jambhekar[1], B. N. Queenan[2]; [1]Systems Biology, Harvard Medical School, Boston, MA, [2]Quantitative & Synthetic Biology, Harvard University, Cambridge, MA.

To remain competitive in science and technology, the US must recruit and retain an intellectually diverse scientific workforce. Research experiences for undergraduates (REUs) are a critical component of these recruitment and retention efforts, increasing the odds of earning a Bachelor's degree in a STEM field and acceptance to graduate school.
The Harvard Systems & Quantitative Biology REU has been running as a cross-campus program between Harvard College (Cambridge, MA) and Harvard Medical School (Boston, MA) for the past three summers, the first two virtually and the last in-person. Measures were developed and implemented during the virtual phase to promote student engagement, facilitate interactions within the REU cohort, and reduce structural barriers to participation; these have been successfully transitioned to the in-person program. The REU includes research and didactic components. The research activities foster skills in hypothesis-generation, creation of a research plan, rigorous data analysis, and understanding fundamental concepts in the research field. Interns are selected based on their motivation for research and coursework in math and biology, with the goal of providing interns unique opportunities to participate in cutting-edge systems biology research. Every intern is assigned to a laboratory and works with a dedicated mentor on a research project, with increasing autonomy and project ownership as the summer progresses. Interns develop technical skills in coding and/ or wet-lab approaches. The goals of the didactic component are to foster rigorous scientific thinking and communication skills and to build a network of peers and senior researchers. Didactics include highly-structured cohort activities such as writing workshops and journal clubs, which feature individualized feedback from peers and faculty. The training is enhanced by guest talks, departmental seminars, and social hours. To reduce barriers to participation, students receive funds and necessary computer supplies in time to arrange for travel, living expenses, and conducting program activities. Interns find the REU a transformative experience, citing the exposure to diverse research topics, structured didactics, and networking opportunities as unique elements. Alumni have gone on to receive competitive science fellowships and attend graduate programs in science and medicine.

B24/P1718

Effective multimodal science communication in a cancer biology seminar course

K. Johnson; UNH Manchester, Manchester, NH.

Science literacy and effective communication skills are remarkably important. Yet, it has been aptly stated that the language, structure, and conventions of most scientific publications might almost have been created to obscure information, using words that the general public will have never heard or used. Undergraduate students are often trained in scientific writing skills, communicating their research through a variety of scientific papers in traditional text formats. Yet, there exists a gap in scientific training with exposure to a variety of communication styles that enables both accessibility and inclusivity. Thus, it is imperative that we facilitate opportunities for students to practice making science more accessible. This is directly addressed in an advanced cancer biology seminar course in which students are given assignments that require them to step back from published scientific work and create

a variety of accessible visualizations, including graphical abstracts and video abstracts. Positive outcomes indicate students can process complex scientific concepts and translate them into simple graphical outputs accessible to a wider audience.

B25/P1719

Developing a multi-institutional, cross-disciplinary parasitology CURE (Course Undergraduate Research Experience

S. Agrawal; University of Mary Washington, Fredericksburg, VA.

Course based undergraduate (CUREs) courses provide an opportunity to develop essential research skills for undergraduates especially in primarily undergraduate institutions. Over the last two years, University of Mary Washington, Georgia State University and Albright University students and faculty have collaborated in a Molecular parasitology CURE. This collaboration across three institutions with different expertise, resources and student populations is unique among other multi-institutional CUREs in that students, not just PIs - from all three institutions interact to collaboratively work on original research problems involving the Kinetoplastid parasite *Crithidia fasciculata*. Highlights of the courses included diverse speakers on molecular parasitology, direct interaction of PI's with students at other institutions, shared project reports and joint conference presentations. Our model for collaborative CURE research can be helpful to other faculty and provide ideas to productively overcome challenges of asynchronous engagement, accelerate research process, and engage a larger number of undergraduates in the research community.

B26/P1720

Lessons Learned for Post-COVID Application from a Pandemic-resilient, Computer-based, Nationwide Genomics CURE

D. Lopatto[1], **C. S. Silver Key**[2], M. Van Stry[3], J. Siders[4], A. L. Goodman[5], W. Leung[6], M. S. Santisteban[7], K. M. Sandlin[8], C. P. Rele[9], L. K. Reed[9]; [1]Grinnell College, Grinnell, IA, [2]North Carolina Central University, Durham, NC, [3]Lane College, Jackson, TN, [4]Ohio Northern University, Ada, OH, [5]California Polytechnic State U, San Luis Obispo, CA, [6]Washington University in St. Louis, St. Louis, MO, [7]University of North Carolina at Pembroke, Pembroke, NC, [8]The University of Alabama, Tuscaloosa, AL, [9]University of Alabama, Tuscaloosa, AL.

The objective of this study is to identify the lessons learned from implementing a nationwide Course-based Undergraduate Research Experience (CURE) during the COVID-19 pandemic that can be applied post-pandemic. Established in 2006, the Genomics Education Partnership (GEP; https://thegep.org/) is a computer-based CURE in which students experience "hands-on" how to use web-based genome browsers, bioinformatics tools, and databases to investigate eukaryotic genes and genomes. The student CURE research project involves analyzing multiple sources of evidence (e.g., sequence similarity, computational gene predictions, RNA-Seq data) to construct a probable gene model in one or more Drosophila species. The efficacy of the program was assessed using student pre-/post-surveys and quizzes. In Spring 2020, the COVID-19 pandemic forced many courses to change their modality from in-person to virtual, and the courses in subsequent semesters were usually delivered in a hybrid format. During this period, GEP membership grew from pre-pandemic levels of approximately 100 faculty members to more than 260. Despite the shift from in-person to fully-virtual or hybrid delivery, the hands-on GEP student research experience persisted. Additionally, the number of annotation projects

submitted by GEP students has remained high. Furthermore, when comparing pre-COVID assessment results and more recent results, we find similar learning and attitudinal gains. We believe that the following lessons contributed to the robustness of the GEP CURE: 1) synchronous live sessions with the use of screen-sharing enhanced communication with students on genome annotation; 2) pre-recorded classes and help sessions allow more instructional time than the traditional "one-and-done" approach; 3) an increase in "flipped classroom" teaching enabled students to engage in problem-solving during the synchronous sessions; and 4) hybrid delivery of help sessions featuring both in-person and virtual teaching assistants facilitated student success. Continued application of these lessons to computer-based CUREs may provide increased access to science research for underrepresented minorities and non-traditional students as called for by Vision and Change — leading to the democratization of access to STEM careers. Supported by NSF IUSE-1915544 and NIH IPERT-R25GM130517.

B27/P1721

No Major, No Problem: Developing a Life Sciences Curriculum from Scratch at a Small Liberal Arts College

S. Walsh; Soka University of America, Aliso Viejo, CA.

Most 4-year colleges have a system of majors that includes both foundational and advanced courses where enrollment is restricted by multiple prerequisites. However, our small liberal arts college offers concentrations where students graduate with a minimum of 5 courses in an area to complement their liberal arts degree. Together with my colleagues, we developed a streamlined Life Sciences concentration that enables students to meet the prerequisites for health professions and graduate school or to explore a broad variety of topics within Life Sciences. Because of this flexibility, our curricular emphasis shifted from content mastery to authentic research experiences, experimental design, and scientific and science communication. For example, we designed an introductory, co-taught course to integrate both biology and chemistry concepts using the hallmarks of cancer as a theme, and we require at least 1 semester-long, 3-credit laboratory course-based undergraduate research experience (CURE) where students explore a faculty member's research. Rather than an independent weekly laboratory period, content-based courses have embedded laboratories where active learning is sometimes exchanged for related hands-on experience. In contrast to a traditional physics laboratory, our physics courses teach Python to investigate biological problems through coding. As part of general education (GE), students are also required to take 2 science courses so students interested in maximizing their upper level science courses can immediately engage in GE courses designed to fulfill prerequisites for upper level Life Sciences courses or instead explore other topics, such as Astronomy or Nutrition. The GE program requires all students to take cross-concentration courses so some upper level courses, such as Evolution, minimize prerequisites, allowing interested students focused on other disciplines to learn a specific scientific topic in-depth. All students across the college complete a capstone thesis, and Life Sciences thesis projects range from wet or dry laboratory projects with Soka faculty or external mentors to social sciences surveys interrogating health professionals to literature-based analysis of a specific scientific problem. The Life Sciences concentration officially launched in fall 2020, and we continue to revise the curriculum to both meet student demand and align with Vision and Change.

The CRISPR IN THE CLASSROOM NETWORK: A SUPPORT SYSTEM FOR INSTRUCTORS TO BRING GENE EDITING TECHNOLOGY TO THE UNDERGRADUATE CLASSROOM

M. J. Wolyniak[1], D. L. Pattison[2], T. Hoage[3], S. K. Olson[4], J. N. Pieczynski[5], M. S. Santisteban[6], L. Hammonds-Odie[7], D. Carter[8], N. J. Ruppell[9], A. K. Challa[10]; [1]Hampden-Sydney College, Hampden-Sydney, VA, [2]University of Houston, Houston, TX, [3]University of Wisconsin-Stout, Menomonie, WI, [4]Pomona College, Claremont, CA, [5]Rollins College, Winter Park, FL, [6]University of North Carolina at Pembroke, Pembroke, NC, [7]Georgia Gwinnett College, Lawrenceville, GA, [8]Rochester Institute of Technology, Rochester, NY, [9]Randolph-Macon College, Ashland, VA, [10]University of Alabama at Birmingham, Birmingham, AL.

CRISPR-Cas9 technology represents a once-in-a-generation advance that allows precise gene editing and has become a mainstream technique in research. However, most undergraduate instructors do not have the training or support to integrate CRISPR-Cas9 into their courses. To remedy this, we formed the "CRISPR in the Classroom" Network and are facilitating workshops and mentoring activities designed to provide instructors with the skills, support, and confidence needed to introduce and implement CRISPR-Cas9 technology in undergraduate classrooms (NSF RCN-UBE #2120417). Our summer workshops provide participants with a flexible, easily-adapted curriculum and start-up kits to overcome the hurdles associated with implementing a new technology. Assessment data from previous workshops show that over 80% of attendees indicated that the design and organization of the workshop facilitated their understanding of CRISPR and that two-thirds of attendees had implementation plans for CRISPR-based activities for their courses within one year of the workshop. The CRISPR in the Classroom Network represents a dynamic community of practice for integrating CRISPR-Cas9 into courses and across model systems.

B29/P1723

Implementation and evaluation of a CURE in which students use CRISPR in budding yeast cells

K. B. Shannon; Biological Sciences, Missouri S&T, Rolla, MO.

Course-based Undergraduate Research Experiences (CUREs) are designed so that students in a class can research a question or problem for which the outcome is unknown. The opportunity for students to conduct original research is important for developing their critical thinking skills and identity as scientists. In the redesign of a Molecular Genetics lab, I used the Yeast ORFan project as a jumping off point for students to choose a gene of interest. Students then design an experiment to modify their chosen gene using CRISPR and perform an in vitro assay before attempting to modify yeast cells. Students make predictions and design assays to test their hypotheses. Student course evaluations and the Measure of College Student Persistence in the Sciences (PITS) survey were used to evaluate the effectiveness of this lab experience on student outcomes. Preliminary results show that students thought incorporating CRISPR made the lab more interesting and relevant and was useful to prepare them for careers at the bench. Students expressed feelings of ownership of the project and enjoyed working towards a self-determined goal.

B30/P1724

Harnessing MARC professional development concepts to close the gap in STEMM graduate program preparedness between Underrepresented non-MARC and MARC students.

E. Spencer, A. Hinton, Z. Vue, T. Barongan, K. Neikirk, S. Murray, H. Beasley, A. Marshall, E. Garza-Lopez; Vanderbilt University, Nashville, TN.

Providing persons excluded because of their ethnicity or race (PEERs) with professional development opportunities to help them smoothly transition into science, technology, engineering, and mathematics (STEM) fields can be incredibly powerful for institutions to implement. Programs such as Maximizing Access to Research Careers (MARC) aid in creating pipelines and preparing undergraduate PEERs to obtain foundational skills in research. It also aids PEERs to navigate the challenges of applying to graduate school and cultivate networking and mentoring relationships in STEM. To improve the graduate school preparedness of PEERs, we provided non-MARC students (i.e., non-MARC-affiliated students with no background in the subjects that MARC programs educate students on) with workshops based on professional development provided to MARC students at Winston-Salem State University. These workshops included topics on graduate school and professional programs, the application process, and the tools for graduate school success. We assessed the efficacy of these workshops by pre- and post- surveys of both non-MARC and MARC cohorts. Upon completion of these workshops, the non-MARC cohort increased their understanding of professional programs, the application process, scientific tools, and soft skills needed to thrive in STEM. Furthermore, the workshops significantly closed the gap in understanding of the same subjects between the non-MARC and MARC students. These results suggest that, given the high financial needs to implement the MARC program, institutions can consider using these workshops to meet student graduate preparedness goals more economically.

B31/P1725

Improving students' understanding of the scientific process through a complimentary multi-approach molecular genetics lab

R. L. Adams; Biology, Belmont University, NASHVILLE, TN.

Undergraduate labs serve many purposes for students: to improve their laboratory skills, to expose them to experimental techniques, to improve their scientific communication, and ideally, to help them gain an understanding of the scientific process. However, many traditional undergraduate labs often fall shy of achieving all of these goals. For example, when all students in a classroom perform the same experiment to test a hypothesis, they can struggle to understand the distinction between a scientific hypothesis from an experimental prediction. Additionally, scientific communication is challenging when all students perform the same experiment as they struggle to be motivated to explain their approach clearly. Instead, it is often the instructor who first explains the method and theory of an experimental approach for the entire class. To provide a more realistic scientific experience that would better achieve all goals, I developed a multi-week experiment for a sophomore-level Genetics course. Students initially perform a bacterial conjugation experiment to develop a hypothesis regarding antibiotic resistance genes on a plasmid. Following this, students then choose one of three different molecular approaches (PCR, restriction enzyme digest, or bacterial transformation) to test their hypothesis, forming a prediction of experimental outcome based on their own research of the approach. After the lab work, the students develop a group oral presentation that focuses on the theory of the approach to explain anticipated and actual outcomes in regard to their hypothesis. Because students do their own research

to explore the technique and they are tasked with teaching the approach to the class (i.e. each group presents a different approach they took), students are motivated to develop strong, explanatory presentations, which enhances their ownership and understanding of their lab work. Qualitative assessment of a piloted lab has indicated that having various experimental options available improves student understanding of the scientific process and communication skills. A pre- and post-survey will be conducted on an expanded group this fall to quantitatively assess the outcomes of this lab. Overall, this lab provides an inexpensive method to both improve understanding of the scientific process and allow students to compare several complimentary experimental approaches.

B32/P1726

Computer-based "virtual" labs and attainment of learning objectives and attitudes in introductory cell biology at a large, public university

L. D. Hutson, S. Kapoor; University At Buffalo, Buffalo, NY

Over the course of several years prior to the pandemic we overhauled our introductory cell biology lab program, which serves approximately 1100 Biological Sciences and related majors per year, doubling the number of labs from six to twelve and increasing the biology content of the labs. As these increases did not come with added staff, space, or equipment, we contracted with an educational software company to develop computer-based simulations of all of the labs. The computer-based labs were designed to serve students in majors that do not require much in the way of hands-on lab experiences, while the parallel traditional lab program served students in majors that are more likely to lead to research or technical careers. Because there have been limited, if any, well-controlled studies comparing the effectiveness of an entirely computer-based lab program as compared to an entirely hands-on lab program, we assessed the learning outcomes of students enrolled in each type of program over the course of two consecutive years. We found that there were some predictable and some unexpected differences between groups in both scientific and technical learning objectives of the labs. These differences, however, were relatively small, and neither group consistently attained learning objectives at a higher rate than the other. On the other hand, there were considerable differences in attitudes toward the labs between the two groups, even with respect to the activities that were identical between the two groups. The differences in attitudes that we observed have implications for all students, but it may impact minoritized groups and first-generation college students disproportionately. We have since leveraged our limited resources to minimize the reliance on computer-based labs for all students.

B33/P1727

Learning biological physics via modeling and simulation: A course for undergraduates

P. Nelson; University of Pennsylvania, philadelphia, PA

Undergraduate physical-science curricula are heavily mathematicized, despite research showing that learning should begin with qualitative phenomena of broad current interest. Meanwhile, undergraduate life-science curricula are often rooted in descriptive approaches, despite the fact that much current research involves quantitative modeling. I'll describe an alternative, an intermediate-level course now embodied in the 2022 edition of the textbook Physical Models of Living Systems. The course is the foundation of Penn's biophysics undergraduate major, as well as a response to rapidly growing interest among students in a broad range of science and engineering majors. Students acquire several research skills that are often not addressed in traditional undergraduate courses. The combination of

experimental data, modeling, and physical reasoning used in this course represents a new mode of "how to learn" for many of our students. These basic skills are presented in the context of case studies from cell biology, including: •Virus dynamics in single patients, and in populations; •Bacterial genetics and evolution of drug resistance; •Statistical inference, with applications to superresolution microscopy and cryo-EM; •Mechanobiology, for example catch bonding in immune cell receptors; •Cellular control circuits. Outcomes include student reports of improved ability to gain research positions as undergraduates, and greater effectiveness in such positions, as well as students enrolling in more challenging later courses than they would otherwise have chosen. [NSF EF-0928048; CMMI-1548571; PHY-1607611.]

B34/P1728

A CURE for the Teaching Blues: A Collectivist Framework to Move a Research Project from Conception to Manuscript in a Single Semester of an Undergraduate Laboratory Course

S. K. Olson; Molecular Biology, Pomona College, Claremont, CA.

Investigative course-based undergraduate research experiences (CUREs) are known to promote the engagement and retention of students in STEM disciplines. They are also more exciting for instructors to teach than traditional cookbook labs that do not expose students to the authentic nature of science. In the Fall semester of 2021, we challenged students in my Advanced Cell Biology class to engage collectively with the full cycle of scientific inquiry in a single semester - to start with a new project idea, generate preliminary data, propose a mechanistic model, refine the model through iterative rounds of experimentation, and draft a full-length manuscript. We chose the project based on an exciting observation made by a previous Advanced Cell lab group - that a subset of proteins required for *C. elegans* eggshell formation appears to be secreted *independently* of the conventional COPII-dependent ER-to-Golgi trafficking pathway. This year's students began by repeating the original experiments, which reinforced the importance of reproducibility in science, and allowed them to learn the standard cell biological techniques typically taught in the course. The students then shared their preliminary data and collectively developed a model to explain their findings, outlining a potential storyline for a manuscript. Next, they designed experiments to test possible explanations for the unexpected findings and to fill any gaps in knowledge that would allow them to complete the storyline, and spent the remainder of the semester conducting those experiments. At the end of the semester, students shared their findings in formal oral presentations and posters, and convened to discuss how to put the manuscript together and divide the work equitably among the lab groups. While we originally sought to complete a full manuscript in a single semester, we fell a bit shy of this ambitious goal. However, the paper is ~2/3 complete, and one student from the course joined our lab to complete the remaining experiments over the summer. Exit surveys showed the students were highly engaged with the lab, felt ownership over their project, became more confident in their ability to carry out scientific research, and came to value the collaborative and collective nature of research. This pedagogical experiment shows that significant progress toward a full-length publication can be made by undergraduates in a single semester. This model could help instructors at primarily undergraduate institutions (PUIs) improve research productivity during the busy academic year, and increase publication rates and student authorships.

Proteomics and Genomic Methods

B36/P1729

Perturb-seq analysis reveals key mediators of TNFα-induced transcriptional response

D. Tedesco[1], T. Liu[2], D. Hu[2], N. Isachenko[2], D. Deng[2], **P. Diehl**[2], A. Chenchik[2]; [1]Cellecta, Inc., Mountain View, CA, [2]Cellecta, Inc., MOUNTAIN VIEW, CA.

To identify genes involved in TNFα induced transcriptional response, a 10X single-cell Perturb-Seq screen was run on HEK293-Cas9 cells with a 88-sgRNA pooled library. As a benchmark, a parallel screen was run with cells transduced in arrayed format with a subset of the sgRNAs of the pooled library. The 10X Perturb-Seq screen was carried out in triplicate with increasing amounts of cells/10X reaction, in order to determine: a. the minimum number of cells/sgRNA required to cover the full complexity of the pooled library, and b. the maximum number of cells that can be loaded in the 10X reaction without losing single-cell resolution due to encapsulation of cell doublets. Transcriptional profiling identified TNFRSF1A, IKBKG, RELA, and CHUK as key mediators of TNFα transcriptional response in both the arrayed and pooled library screens. Increasing the number of cells per 10X reaction had a positive effect on the sgRNA library coverage, without adversely affecting the magnitude of the observed effect of TNFRSF1A, IKBKG, RELA, and CHUK knockout (KO) on TNFα mediated transcriptional response. Perturb-seq is a promising technology for the efficient and scalable interrogation of many individual genes in one single experiment, enabling the identification of transcriptional profiles linked to specific gene knockouts.

Total-sync ultra-content microscopic opto-biotinylation enables high-sensitivity hypothesis-free in situ subcellular protein discovery

C. Chang[1], Y. Chen[1], C. H. Y. Cheung[1], C. Chung[1], H. Chang[1], Y. Sie[1], Y. Liu[1], Y. Lin[1], H. Kai[1], W. Chong[1], **J. Liao**[1], H. Wu[2]; [1]Syncell Inc, Taipei, TAIWAN, [2]National Taiwan University, Taipei, TAIWAN.

Localizing proteins at specific subcellular regions without using target-specific antibodies or fluorescent proteins is challenging. Laser capture microdissection is able to achieve hypothesis-free in-situ protein discovery, but the resolution cannot reach a subcellular level limited by the laser beam size, and the sensitivity is limited by the sensitivity of mass spectrometry, where only high copy-number proteins at a specific dissected region can be identified. Mass spec imaging with localized ionization can achieve a subcellular resolution, but the sensitivity is also highly limited. A major obstacle of in situ proteomic studies versus in situ transcriptomic studies is that proteins lack a PCR-equivalent amplification method to boost sensitivity. Here, in order to achieve hypothesis-free in situ subcellular protein discovery with high sensitivity and high specificity, we integrated methods of microscopy, artificial intelligence, photochemistry, and automation control to perform microscopy-guided targeted opto-biotinylation. Total-sync ultra-content biotinylation of proteins in thousands of fields of view (FOV) with similar morphological features was achieved by FPGA-based mechatronics. Convolutional neural networks-based deep learning is applied to the image to determine the regions of interest (ROIs) in real time. Multifunctional molecules that contain a photochemical warhead (such as $Ru(bpy)_3^{2+}$ or benzophenone) and a tagging molecule (such as biotin) were used for protein labeling. The three-step process of imaging-image processing-opto-biotinylation was repeated for thousands of FOVs automatically to enrich biotinylated proteins in similar ROIs enough for avidin bead purification and successive mass

spectrometry analysis, effectively beating the limit of protein amplification. With this platform, we were able to validate the technology by showing a >90% specificity and a sensitivity of >1000 species for nuclear proteins. We were also able to identify novel protein players for specific biological problems, including EIF3CL, DDX17, PPIA, RPSA, and RPLP0 for stress granules positively validated by antibody staining. Together, our total-sync ultra-content microscopic opto-biotinylation method can be applicable to widely diverse cell biology problems to identify novel protein players in the ROIs, enabling hypothesis-free subcellular protein discovery with high sensitivity and specificity.

B38/P1731

Directed evolution of new enzymes for proximity labeling in living cells

S. Lee, J. Cheah, H. Roh, A. Ting; Stanford University, Stanford, CA.

Proximity labeling (PL) catalyzed by genetically-encoded promiscuous enzymes has enabled high-resolution proteomic mapping of organelles and interactomes in living cells. The two major classes of PL enzymes are peroxidases (such as APEX2) and biotin ligases (such as BioID and TurboID). Each class has advantages but also notable limitations: peroxidases require H_2O_2 which is toxic to living organisms, while biotin ligases exhibit background leak. Both enzyme classes have spatial specificity limited by existing genetic targeting schemes. To address these limitations, we used structure guided protein engineering and directed evolution to generate two new PL enzymes: Laccase and LOV-Turbo. Laccase generates biotin-phenoxyl radicals, like APEX2, but uses non-toxic O_2 rather than H_2O_2, making it far more compatible with living organisms. LOV-Turbo is a single-chain variant of TurboID that can be reversibly turned on and off with visible light. We demonstrate multiple applications for each enzyme: PL in various organelles and cell types, pulse-chase labeling to map proteome trafficking, and electron microscopy. These new PL enzymes expand the toolkit of PL methods and enable novel applications in cell and organismal biology. <!--EndFragment-->

B39/P1732

Mapping proteome trafficking in living cells via tandem proximity labeling

J. Cheah, W. Qin, S. Lee, A. Ting; Stanford University, Stanford, CA.

Proximity labeling has been a cornerstone technique for mapping organelle proteomes and interactomes at single timepoints in living cells. However, proteins are highly dynamic, and their locations within a cell will vary through their lifetimes. To capture such changes, we developed a tandem proximity labeling platform to track protein movements through multiplexing the orthogonal promiscuous enzymes TurboID and APEX2. We apply our technique to map the trafficking proteome between membraneless organelles, stress granules and nucleolus, during stress induction and recovery. We discovered that during cellular stress, a subpopulation of the transcription factor JUN relocalizes to stress granules, and that this helps to protect JUN from aggregation and degradation to promote rapid recovery from stress. Our tandem proximity labeling platform is widely applicable to studies of proteome trafficking in intracellular and intercellular signaling.

B40/P1733

An Optically Activated Proximity Labeling Method for Spatially and Temporally Resolved Proteomics

C. M. O. Davis, O. Shafraz, S. Sivasankar; Biomedical Engineering, University of California, Davis, Davis, CA.

Membrane protein interactions are essential for cell proliferation, differentiation, and survival as well as for maintaining tissue homeostasis. However, due to the lack of appropriate technologies, the interactomes of membrane proteins, especially at distinct spatial locations within the cell and at different stages of the cell cycle, are poorly understood. Here, we have developed a light-activated proximity labeling method for high precision mapping of membrane protein interactions with high spatial and temporal resolution. Our method combines a split version of the proximity biotinylation enzyme TurboID with the optically activated protein dimerization pair CRY2 and CIB1. As a proof of principle, we engineered cells expressing CIB1 and an inactive TurboID fragment on the cell membrane along with the complementary TurboID fused to CRY2 in the cytoplasm. Using immunofluorescence imaging and mass spectrometry, we demonstrate that the split-TurboID fragments assemble, become functional, and biotinylate proteins on the cell surface only upon exposure to light. Next, we tagged E-cadherin, an essential cell-cell adhesion protein, with our optically activated proximity labeling system in order to validate our tool by comparing the measured interactome upon light exposure with known E-cadherin binding partners. Our results demonstrate that light-triggered proximity labeling can map protein interactomes with high precision. We anticipate that our optically activated technique will serve as a revolutionary tool to map junctional protein interactions within cells with high fidelity, in a previously unprecedented spatially and temporally resolved fashion.

B41/P1734

Development of LipoID: an orthogonal proximity labeling enzyme with substrate promiscuity

P. E. Cavanagh[1], W. Qin[2], A. Y. Ting[3]; [1]Stanford University, Stanford, CA, [2]Genetics, Stanford University, Stanford, CA, [3]Biology, Genetics, and by courtesy, Chemistry, Stanford University, Stanford, CA.

Enzyme-catalyzed proximity labeling (PL) has enabled the characterization of unpurifiable organelles, identification of transient protein-protein interactions, and profiling of protein translocation *in vivo*. However, all *in vivo*-compatible PL enzymes use biotin as a chemical handle, limiting the range of applications and allowing background from endogenously biotinylated proteins. Development of PL enzymes utilizing orthogonal substrates could enable proteome tagging with other functional groups such as degrons, multiplexing for studies of proteome trafficking, and background reduction. To meet this need, we are developing LipoID, an engineered promiscuous variant of *E. coli* Lipoate-protein ligase A (LplA). LipoID is engineered via a combination of structure-guided mutagenesis, machine learning, and directed evolution. We have shown that first-generation LipoID has activity with a range of substrates, including a clickable azide handle. We are characterizing LipoID for spatially specific proteomic profiling in living cells across a range of organelles.

B42/P1735

Cyto R1 Platform Enriches Samples' Viability for Single Cell Sequencing and Downstream Assays

D. Thomass, K. E. Degen, R. Barua, D. Keck, A. R. Hyler; CytoRecovery, Inc., Blacksburg, VA.

Maintaining stable sample heterogeneity with sample co-cultures during dead cell removal and sample enrichment assays is an important process for DNA and RNA sequencing, protein analyses, and phenotypic studies. These single-cell level studies require an input sample with a high rate of viability. If too many dead cells are present in the input, degraded proteins and ambient DNA or RNA can increase background noise that may lead to missing identification of crucial targets. Since the cost for single-cell sequencing experiments remains high, it is critical to ensure the input sample is optimized for high viability to ensure cost-effective and reproducible data. Current bead assays or other sample viability enrichment techniques used in preparation for single-cell analyses typically result in a significant sample loss and bias of sample heterogeneity. These beads or kits can be biased and change the cell population, subject cells to unwanted stresses, and diminish sample integrity with the time needed for preparations. Here, we investigate sample cell viability enrichment on the Cyto R1 Platform, a label-free, cell enrichment, sorting, and recovery platform. At the core, the Cyto R1 uses Cyto Chips, microfluidic technologies utilizing contactless dielectrophoresis (cDEP), to phenotypically enrich and sort various cells based upon unique physical structures and subcellular features. Thus, the Cyto R1 ensures native cell recovery without any unwanted cell tagging to maximize sample integrity. Initial experiments characterized the change in concentration for several co-cultures undergoing batch processing at a voltage of 600 Vpp and frequency of 300 kHz on the Cyto R1 Platform. Co-cultures included combinations of EL4, stem cell population, slow-developing ovarian cancer, fibroblasts, THP-1 monocytes, highly aggressive ovarian cancer, and K562 cells. For all cell types listed the change in concentration of a single species in the co-culture was less than 5%. Notably the change in concentration was less than 2% for THP-1 cells, FFLs, and K562 natural killer cells in their respective co-culture. In parallel studies comparing the EL4 cells batched on the Cyto R1 platform to the current industry standard, magnetic bead assays, the magnetic bead assays altered the heterogeneity of the sample by an average of 20% more when compared to the Cyto R1 Platform. Advancements are being made to characterize the change in concentration of heterogenous cultures for different batch voltages and frequencies to ensure that the sample heterogeneity and viability are maintained.

Long-read sequencing methods for studying centromere organization, evolution, and function

N. Altemose; Molecular & Cell Biology, UC Berkeley, Berkeley, CA.

Reference genome assemblies have historically excluded repetitive satellite DNA sequences found within and near centromeres, limiting the ability to study these regions using modern genomic and epigenomic tools. Recently, long-read sequencing and assembly methods have enabled reconstruction of complete centromeric and pericentromeric sequences, providing an unprecedented opportunity to study their organization, evolution, and function. In order to fully leverage these complete assemblies, we have created and applied new sequence analysis tools to reveal the organization and evolutionary relationships of human satellite DNA sequences. We also developed DiMeLo-seq, a long-read, single-molecule method for mapping protein-DNA interactions, and we applied it to measure the density of CENP-A containing nucleosomes across human centromeres. These efforts revealed strong associations between low CpG methylation, high CENP-A density, and the very recent expansion of underlying

satellite repeats, raising important questions about the molecular and evolutionary mechanisms responsible for these associations.

A Rapid and Noninvasive Method That Extracts Polymerase Chain Reaction-Ready Genomic DNA from Adult Zebrafish

J. Y. Jang[1], T. Liang[1], M. K. Kim[2], K. W. Kang[2], B. Lee[3], S. Y. Choi[1]; [1]Biomedical Sciences, Chonnam National University Medical School, Hwasun 58128, KOREA, REPUBLIC OF, [2]Neurology, Chonnam National University Medical School, Gwangju 61469, KOREA, REPUBLIC OF, [3]Biochemistry, Chonnam National University Medical School, Hwasun 58128, KOREA, REPUBLIC OF.

Genotyping usually entails analysis of the products of polymerase chain reaction (PCR) carried out with genomic DNA (gDNA) as template, and is employed for validation of mutant or transgenic organisms. For genotyping of adult zebrafish, gDNA is often extracted from clipped caudal fin or skin mucus through either alkaline lysis using NaOH or proteinase K (PK) treatment. Further purification of the gDNA using ethanol precipitation was optional. To develop a rapid and noninvasive method that extracts PCRready gDNA from adult zebrafish, we combined skin swabbing with PK treatment and demonstrated its efficiency. This method could be applied to a wide range of fish.

Evaluating RNA Isolation Methods for Spheroids and Organoids

J. Bhandari, A. Gupta, E. Quandt, L. Chapman; ThermoFisher Scientific, Austin, TX.

Three-dimensional (3D) cultures such as spheroids and organoids have recently gained the attention of the scientific community because they have been found to more closely model *in vivo* natural systems. However, due to their inherent 3D structure, these culture types present unique challenges to existing nucleic acid extraction methodologies that were primarily developed for 2D cultures. In this study, we evaluated the efficacy of several commonly used extraction methods such as phenol/chloroform-based extraction, solid-phase-based extraction using spin columns or magnetic beads, as well as a direct-to-PCR lysate-based method. Extraction performance was evaluated by performing RT-qPCR with the isolated RNA to measure and compare gene expression levels in spheroids and organoids. Our results showed efficient RNA recovery from spheroids and organoids could be achieved with all four methods. Hence, the selection of an appropriate extraction method depends on end-user requirements. For instance, direct cell lysate would be ideal for high-throughput users who need to process individual spheroid and organoid samples for large-scale gene expression studies. The spin column-based extraction may be most suitable for users who process <24 samples at once. The magnetic bead-based method is desirable for processing a large number of samples with minimal hands-on time. Organic solvent-based extraction may be suitable for processing a pool of spheroids and organoids.

A CNN-Based Computer Vision approach for CRISPR Genomic Edit Detection

T. Patterson, H. Farris, K. Rosfjord, E. Mace, P. Hinson; MITRE, McLean, VA.

Clustered regularly interspaced short palindromic repeat (CRISPR) technology provides an inexpensive method for making genomic modifications within organisms. The field is rapidly expanding, creating

tools with increased efficiency and precision in performing these genomic edits. Editing the genome with CRISPR introduces regions of abnormally increased methylation around the edit location. These variances in normal methylation patterns can be leveraged to identify edited locations within a genome. In this project, provide a computer vision-based method of identifying CRISPR edits in mouse genomes, through visual representations of methylation variance data between edited and unedited mice. We describe an image-generation algorithm to create usable images for training a convolutional neural network (CNN), using bisulfite whole genome-sequenced mouse epigenomes. Our method implements a Convolutional Neural Network model that was trained on generated images of epigenome methylation calls of CRISPR-edited and unedited mice, to identify methylation patterns in the epigenome that are indicative of CRISPR edit locations. The application of CRISPR technology has potential repercussions, such as altering gene regulation through methylation changes, that are passed to offspring. The faster and unsupervised method for identifying CRISPR edits presented in this paper provides a path towards the rapid detection of CRISPR edits and their effects on biological processes. This is necessary to mitigate unintended consequences of CRISPR in the epigenome that may persist over generations.

High-throughput genetics and essential gene discovery in the human fungal pathogen*Cryptococcus neoformans*

R. Billmyre, C. Craig, M. Eickbush, S. Zanders; Stowers Institute for Medical Research, Kansas City, MO.

Advances in sequencing technologies have revealed dramatic variation in gene content and sequence between different species and even between different isolates within individual species. However, our ability to understand the functional consequences of these changes has lagged behind significantly. The *Cryptococcus* genus is an ideal model fungal system to explore these questions. There are at least seven species within this genus amenable to lab experimentation that diverged around the same time as humans and birds. In addition, *Cryptococcus* species are pathogens of humans, causing nearly 200,000 deaths annually. We have developed a high-throughput quantitative genetics approach in the human fungal pathogen *Cryptococcus neoformans* by using massively parallel insertional mutagenesis coupled with targeted sequencing and machine learning to determine the set of genes important for growth under a given condition. Using this method, we have identified the set of essential genes in *C. neoformans*. This set includes dozens of genes that are nonessential in other fungi but required in *C. neoformans* and vice versa. These differentially essential genes include genes important for establishing cell polarity and nuclear organization in other fungi, but which are unstudied and essential in *Cryptococcus*. In addition, we have used this same approach to map genome-wide resistance to existing antifungal agents. Taken together, this work will produce a global understanding of drug resistance and a map of essential genome function to guide future drug development in *C. neoformans*. In addition, this project will establish an experimental tool and framework that can be used to analyze other non-model fungal pathogens and help bridge the gap between sequence and function.

Single-cell transcriptomic network combined with imaging unveils the heterogeneity of the clonal macrophage cells during phagocytosis

S. Janewanthanakul[1], H. Ikeda[2], K. Kurimoto[2], T. Nishimura[1], K. Yakura[1], F. Garcia[3], P. Sri-iesaranusorn[3], K. Ikeda[3], S. Suetsugu[1]; [1]Molecular Medicine and Cell Biology laboratory, School of Biological Science, Nara Institute of Science and Technology, Nara, JAPAN, [2]Department of Embryology, Nara Medical University, Nara, JAPAN, [3]Mathematical Informatics laboratory, School of Information Science, Nara Institute of Science and Technology, Nara, JAPAN.

High content imaging and single-cell sequencing are the two most high throughput technology for studying gene functions related to cellular morphology and behavior. Investigating how single-cell transcriptomic profiles affect cell behavior has been a great challenge in cell biology to understand cellular heterogeneity in behaviors. Phagocytosis is a process of membrane deformation and cytoskeleton rearrangement for engulfing a foreign particle. Even by using the clonal cell lines, each macrophage cell does not undergo phagocytosis. Single-cell macrophage behaviors were recorded under a confocal microscope while adding zymosan, and then each single cell transcriptome was analyzed after recording. Out of ~10,000 genes, several hundred genes were identified to be significantly differentially expressed depending on the ability of the phagocytosis. The interactome data among these genes showed the genes that are well connected to each other. The weight gene co-express network analysis (WGCNA) analysis showed the 4 modules of correlated genes (correlation > 0.55) to phagocytosis, which are the genes encoding the toll-like receptor signaling proteins, pattern recognition receptor, SH3-domain-binding proteins, and PDZ-domain-binding proteins. These genes in each module that were retrieved from the transcriptomic profile will be further identified and studied for the regulation of phagocytosis. The finding of this study provides new insight into complex regulations in the phagocytosis process while suggesting candidate genes that can be involved in phagocytosis mechanism.

Unfolding the whole transcriptome of the American Type Culture Collection Cell Line Land for its application as a molecular reference standard in the next-generation biomedicine research

A. P. Singh, A. L. Reese, C. Tabron, J. Duncan, R. Marlow, J. Kirkland, S. King, A. Fernandes, J. Bagnoli, B. Benton, J. L. Jacobs; ATCC, Manassas, VA

In the cell biology research space, the use of unauthenticated biological reference materials, irregularities in crucial related metadata and frequent gaps in data provenance often raise questions as to the credibility and reproducibility of the experimental data. To address this problem, we have begun efforts to characterize whole transcriptomes of all cell lines and primary cells held within ATCC's (American Type Culture Collection) cell biology collection to develop an authenticated application data resource to be used as a molecular reference standard. Here we present our initial analysis of authenticated whole transcriptome (RNAseq) datasets produced from 62 human kidney cell lines including primary cells found in ATCC's biorepository. These diverse datasets, represented by the ATCC Cell Line Land, include the first comprehensive collection of reference transcriptomes for use by kidney biology researchers and is available through QIAGEN's OmicSoft platform. Multiple biological replicates for each cell line are included to help establish a baseline for a wide range of cell lines under typical cell culture conditions. The ATCC Cell Line Land includes transcript and gene expression count data, RNAseq variant calls, raw sequencing data, and detailed metadata on laboratory methods employed, such as the

total cell counts, RNA extraction methods, RIN scores, number of replicates, tissue/cell-type information, disease association, passage number, catalog number, lot number, growth media, culture conditions, and cryopreservation conditions. Furthermore, all biological replicate data included in this resource is produced using a common, standardized RNA extraction, library prep, sequencing, and bioinformatics workflow - thereby enabling comparative transcriptomics of these data at scale. The ATCC Cell Line Land is a first-of-its-kind joint venture between ATCC and QIAGEN Digital Insights aimed at providing reference-grade whole transcriptome data that is authenticated, standardized and traceable to physical source materials available in ATCC's biorepository.

Quantifying cellular and cytosolic levels of actin binding proteins in *S. cerevisiae*

S. Gonzalez Rodriguez, A. C. E. Wirshing, B. L. Goode; Brandeis University, Waltham, MA

Animal and fungal cells express a conserved set of 15-20 actin binding proteins (ABPs), which together orchestrate the assembly, disassembly, and reconfiguration of the actin cytoskeleton. Understanding how these proteins work in concert in living systems requires quantitative information about their cellular abundance, physical interactions with actin and each other, and specific effects on actin. We are addressing this problem in the budding yeast *S. cerevisiae*, where the activities and interactions among these ABPs are now well established, but their cellular levels have remained undefined. To close this gap, we measured both the total cellular levels and cytosolic (freely available) concentrations of 15 conserved ABPs. To measure cellular levels, we used quantitative western blotting with antibodies specific to each ABP. To measure levels in the cytosol versus bound to F-actin structures, we performed two-color live imaging on strains co-expressing GFP-tagged ABPs and RFP-tagged cortical actin patches (Arc15) or linear actin cables (Lifeact). Total cellular concentrations of ABPs ranged from 0.4-11 µM, and the percentage of each that was in the cytosol ranged from 60-90%. Remarkably, these levels remained relatively constant throughout the cell cycle, despite dramatic changes in F-actin reorganization and cell size. Together, these results show that yeast maintain high concentrations of free ABPs in their cytosol, which may be important for keeping them in a 'primed state,' responsive to internal and external signals and able to rapidly reorganize their F-actin structures. Further, they provide the necessary information required to build more accurate and complete quantitative models of how ABPs control cellular actin organization and dynamics.

The Molecular Basis for Cell Migration in 3D

N. R. Martin[1], M.-H. Tang[2], W.-J. Rappel[2], O. D. Weiner[1]; [1]University of California, San Francisco, San Francisco, CA, [2]University of California, San Diego, La Jolla, CA

Immune function relies on cells that crawl through our tissues to neutralize threats. However, the overaccumulation of immune cells at damaged tissues and tumors can drive inflammation and cancer progression. Therefore, understanding the fundamental process of cell migration will provide us with strategies to bolster immune function, and to reduce damage from excessive immune cell migration. The canonical model for cell migration centers on a force-generating molecular clutch that depends on surface adhesion, but immune cells do not require adhesion to migrate *in vivo*. Thus, our current

understanding of how immune cells reach their target is incomplete. One reason may be that most studies of migration are done on 2D surfaces that fail to capture the complex 3D geometry of tissues. The Wiskott-Aldrich syndrome protein (WASP) is dispensable for migration on 2D surfaces but WASP mutations cause severe migration defects *in vivo* suggesting that WASP plays a critical role in 3D migration. Recently, we discovered that the actin nucleator WASP is curvature sensitive and integrates topographical information into the polarity program that steers cell migration. I will leverage this insight to uncover how cells engage with surface geometry to generate forces and steer their migration. To understand how substrate geometry influences migratory force generation, we are using model 3D substrates to measure WASP-dependent traction forces. We find that WASP localization and actin nucleating activity are correlated with force generation supporting the hypothesis that WASP plays a role in migratory force generation. To dissect the role of WASP in orienting migratory forces we will use optogenetics to spatially control WASP activity and measure the effects on cell polarity signals. Together, this work will uncover how and expand the model of cell migration to include geometry-guided migration in 3D.

Length regulation of stereocilia by the formin inhibitor SMIFH2

C.-y. Tung, X. Liao, B. Perrin; Indiana University Purdue University Indianapolis, Indianapolis, IN

Stereocilia are actin-based protrusions at the apical surface of auditory sensory hair cells. Several stereocilia of precisely regulated length and width form a bundle with a staircase-like structure that is required for detecting sound. Stereocilia are formed around a core of parallel, unbranched actin filaments. We speculated that formin proteins may contribute to elongating these filaments. To test this idea, we studied the effect of the formin inhibitor SMIFH2 on stereocilia length. Cochlear explants from mice at postnatal day 4 were cultured with SMIFH2. If formins elongate the F-actin in the core, then inhibition would result in shorter stereocilia. Instead, we observed a rapid and dose-dependent increase in the length of stereocilia in the shorter rows of the bundle. Actin incorporated at stereocilia tips, suggesting that F-actin in the stereocilia core elongated from their barbed ends. FMN1 and DAAM1 are the most highly expressed members of the formin family in auditory hair cells according to publicly available RNAseq data. Immunostaining revealed that FMN1 and DAAM1 localize just above the base of stereocilia and that each is mislocalized with SMIFH2 treatment. We also observed that actin binding proteins that normally localize to stereocilia tips were reduced as formins were inhibited. Together, these data suggest that formins can decrease actin polymerization and indirectly regulate the protein composition of stereocilia tips.

Activity and mechanism of the pan-formin inhibitor SMIFH2

C. Vizcarra; Barnard College, New York, NY

The small-molecule drug SMIFH2 was discovered in a biochemical screen for inhibitors of formin-stimulated actin polymerization (Rizvi, et al. 2009). While the *in vitro* screen was carried out against the mouse formin mDia1, SMIFH2 was also found to be a cell permeable inhibitor that targeted both yeast and mammalian formins. Since the original report, at least 340 published papers have reported experiments in which SMIFH2 was used to investigate formin function. Our research group is interested in the molecular basis of formin inhibition, specifically the potential for isoform-specific inhibition and

the effect of SMIFH2 on the myriad biochemical functions that formins carry out. In this study, we found that SMIFH2 inhibits actin assembly stimulated by formins from six of the seven families of mammalian formins. To explore the relationship between chemical structure and biological activity, we synthesized and assayed 17 analogs of SMIFH2 against a panel of five human formins (DIAPH1, DIAPH2, FMNL3, FMN2, and INF2). While some modifications improved inhibitory potency, none imparted specificity, indicating that the alkylidene thiobarbiturate core of SMIFH2 may not be an ideal platform for distinguishing among highly conserved FH2 domains. Computational studies point to reactivity instead of molecular geometry as a determinant of inhibitory potency. We are currently exploring the effect of SMIFH2 on the FH2 domain's structure and interactions with microtubules.
Rizvi, S. A., Neidt, E.M., Cui, J., Feiger, Z., Skau, C.T., Gardel, M.L. Kozmin, S.A., Kovar D.R., Chemistry & Biology 2009, 16: 1158-1168.

B55/P1747

Universal Length Fluctuations of Actin Fibers

A. Rosario, S. G. McInally, B. L. Goode, J. Kondev; Brandeis University, Waltham, MA

Actin is one of the most important and abundant cytoskeletal proteins in most eukaryotic cells. The central property of actin is its ability to polymerize into helical filaments and bundling into higher order structures *in vivo* to form parallel actin bundles which is influential in various cellular functions such as motility, signaling, and cell division. Cells tightly control the sizes of these bundles as their size is closely associated with their function even though individual filaments within these bundles are dynamic. Balance point model where two competing rates, the length dependent assembly and/or disassembly can match to produce a single, stable fixed point has been proposed as possible mechanism of length control in the context of both actin and microtubule filaments. Using a master equation approach, we find that length fluctuations, small deviations in length produced by stochastic addition and removal of monomers/fragments during filament assembly and disassembly, are Gaussian independent of the nature of feedback. The variance of this distribution is given by the product of the steady state filament length and the size of the fragments added or removed. Comparing our calculations to experimentally measured length perturbations of stereocilia and microvilli, we find that the variance scales with the square of the mean length. We propose an alternate model of length control for parallel actin bundles where individual filaments in a bundle are polymerized and can be removed at specific rates and the length of the bundle is set by the longest filament in the bundle. This leads to a peaked distribution of bundle length even though individual filaments are exponentially distributed. The variance of bundles length is proportional to the square of the steady state length consistent with experimental data.

Zyxin localization and dynamics in neurons

N. Sele[1], A. B. Varona Ortiz[1], B. R. Schuldt[1,2], S. A. Kim[1]; [1]Amherst College, Amherst, MA, [2]Icahn School of Medicine at Mount Sinai, New York City, NY

Cytoskeletal reorganization occurs in response to environmental stimuli and leads to structural changes in synapses. Actin-regulatory proteins transduce signals received at the postsynaptic density to the cytoskeleton. In some cell types such as fibroblasts and cancer cells, zyxin has been well characterized as a promoter of actin polymerization but has not been described in the central nervous system. Here, we establish zyxin as a neuronal protein and describe its recruitment to dendritic spines in hippocampal

neurons. Zyxin was found localized in the soma and dendrites throughout neurodevelopment with expression in the growth cone and dendritic spine. Zyxin displayed robust recruitment to dendritic spines under various conditions. Mechanical force applied by shear stress triggered mobilization of zyxin to spines that was myosin IIB-dependent. Extracellular signals, such as depolarization and elevated zinc, also induced zinc recruitment to spines. These results suggest that zyxin may regulate F-actin reorganization in dendritic spines through its recruitment and may coordinate activity-dependent changes in postsynaptic structure.

Probing molecular interaction interface between neuronal drebrin and mDia2 formin

S. Srapyan, E. Grintsevich; California State University, Long Beach, Long Beach, CA

Actin cytoskeleton is critical for neuronal shape and function. Neuron-specific drebrin A and ubiquitous diaphanous formin-2 (mDia2), are key regulators of the actin cytoskeleton. Drebrin A is highly enriched in postsynaptic terminals of mature neurons (dendritic spines) and mDia2 formin is upregulated during dendritic spine initiation. Decreased levels of drebrin in dendritic spines is a hallmark of Alzheimer's disease, epilepsy, and other complex disorders. Drebrin A was previously identified as an interacting partner and inhibitor of mDia2 formin. Characterizing the molecular binding interface between formin and drebrin is necessary to better understand functional consequences of this interaction and its biological relevance. Prior work suggested that the N-terminal sequence of drebrin (Drb1-300) contains a weak interacting site of its multi-pronged interface with mDia2. The model of the complex predicted that Drb1-300 interacts with C-terminal tails of mDia2 which is involved in formin's autoinhibition and microtubule binding. Employing biochemical assays, we show that drebrin binding cannot relieve autoinhibition of mDia2 and it does not preclude formin binding to microtubules. The model of the drebrin-mDia2 complex also predicted a high affinity mDia2 binding site in C-terminal sequence of drebrin (301-706). Guided by mass spectrometry and in silico analysis we generated an array of deletion mutants in neuronal drebrin A to identify this binding site. We employed these mutants in pull-down assays with GST-tagged mDia2-FH2 domain. Consistent with the proposed model, our results identified a highly conserved sequence in the C-terminal region of drebrin as the principal site of mDia2 binding. This work contributes towards a molecular level understanding of the formin-drebrin interface.

Mechanical activation of Dia1 protects the cytoskeleton from damage, enabling cell fate commitment

F. R. Valencia[1], E. Sandoval[2], J. Du[1], E. Iu[1], J. Liu[2], S. V. Plotnikov[1]; [1]University of Toronto, Toronto, ON, Canada, [2]Johns Hopkins University, Baltimore, MD

Plasticity of cell mechanics underlies a wide range of cell and tissue behaviors allowing cells to migrate, to resist shear forces, and to upregulate contractility during wound healing. Such plasticity depends on the regulation of the actin cytoskeleton, but mechanisms of adaptive change in cell mechanics remain elusive. By combining live-cell imaging and genetic and pharmacological manipulation, we assessed how suppression of major actin elongation factors affect the dynamics of actin polymerization at focal adhesions. We found that suppression of actin elongation factor mDia1 leads to a 70% decrease in actin polymerization. Moreover, we showed that suppression of myosin contractility results in a dose-dependent decrease in actin polymerization, demonstrating mDia1's propensity to be regulated by mechanical force. By using a super-localization microscopy, we showed that actin polymerization at

focal adhesions exhibits pulsatile dynamics where the spikes of Dia1 activity are triggered by mechanical force. By combining mathematical modeling and laser nano-surgery, we showed that suppression of force-dependent actin polymerization at focal adhesions results in two-fold increase in mechanical tension on the stress fibers. Such elevated tension increases the frequency of spontaneous stress fiber damage and decreases the efficiency of stress fiber repair. Moreover, the excessive stress fiber damage in Dia1 depleted cells abrogates the differentiation of myofibroblast, highly contractile cells essential for wound healing, by suppressing nuclear localization of the SMAD family transcription factors. Remarkably, suppression of stress fiber damage in Dia1 depleted cells through downregulation of myosin contractility rescued myofibroblasts differentiation. These results demonstrate the key role of mDia1 in fine-tuning actin organization to prevent cytoskeleton damage, safeguard cells against abrupt mechanical damage and for successful differentiation of myofibroblasts.

Yeast coronin synergizes with GMF to prune actin filament branches

N. Koundinya, R. Aguilar, B. L. Goode; Brandeis University, Waltham, MA

The rapid assembly and turnover of branched F-actin networks drives a number of cellular processes, including cell motility, endocytosis, and phagocytosis. While we have gained a strong mechanistic understanding of how F-actin branches are assembled in cells by the Arp2/3 complex and its nucleation promoting factors (NPFs), we know comparatively little about how branch junctions are subsequently destabilized to promote rapid network turnover. The F-actin branches formed by Arp2/3 complex are inherently stabile structures, persisting for 10-30 minutes in vitro before spontaneously debranching, yet in vivo they can turnover in 2-20 seconds. This suggests that additional cellular factors are required to drive debranching. Previously, we identified glia maturation factor (GMF) as a conserved and high affinity ligand of the Arp2/3 complex that catalyzes F-actin debranching (Gandhi et al., 2010; Ydenberg et al., 2013). Here , we show that another binding partner of Arp2/3 complex, yeast Coronin (Crn1), works ini conjunction with GMF to promote rapid debranching. Specifically, using TIRF microscopy we show that Crn1 alone has no debranching activity; however, Crn1 enhances the effects of GMF by almost 10-fold. This synergy is mediated by the disordered ‘unique domain’ of Crn1, which varies in length and sequence across different species. The unique domain alone is both required and sufficient to synergize with GMF, and these activities depend on its Arp2/3-binding ‘CA’ like motif, related to ‘VCA’ regions of Arp2/3 NPFs. Together, our results define a new role for Crn1 in driving actin network turnover through ‘collaborative debranching’. Further, they contribute to the emerging view that both the assembly and destabilization of F-actin branches in vivo are controlled by the coordinated effects of multiple Arp2/3 ligands acting in concert.

CAP1 modulates activity of Src and changes cytoskeleton dynamics.

H.-D. Jang, D.-S. Shin, E. Choi, M. Fukai, G. No, H.-S. Kim; Seoul Natl University Hosp, Seoul, Korea, Republic of

Cyclase-associated protein 1 (CAP1) has a role in inflammation as a functional receptor of human Resistin, and is implicated in the invasiveness of human cancers as an actin-regulating protein. In this study, we identified that CAP1 is a novel interacting partner of Src and regulates its membrane localization and activation. CAP1-/- MDA-MB231 cells were defective both in cell growth and migration

even treated with recombinant human epidermal growth factor (rhEGF). In vivo, the tumor growth measured by volume in NOD/SCID mice was significantly smaller with engrafting CAP1-/- MDA-MB231 cells than with CAP1+/+ MDA-MB231 cells ($p<0.0001$). CAP1-/- MDA-MB231 cells were arrested at G1 phase with induction of p53, p21, and p27 expression, and showed low phosphorylation of Src and high phosphorylation of LIMK and cofilin, leading to significantly shorter phalloidin and less lamellipodia than CAP1+/+ MDA-MB231 cells. CAP1 plays a key role for cancer cell growth and migration by binding to Src leading to membrane localization and phosphorylation of Src.

B61/P1753

A central role for cofilin in maintaining cortical actin network integrity through filament turnover

R. S. Kadzik, D. R. Kovar[,1], E. M. Munro[,1]; University of Chicago, Chicago, IL

During polarization and cell division in the early C. *elegans* embryo, the actin cortex must undergo large scale deformations while maintaining structural integrity. Rapid turnover of cortical actin filaments is thought to play a key role in facilitating large-scale cortex deformation and flow by allowing local relaxation of network stress while preventing catastrophic tearing. ADF/Cofilin is a central agent for actin filament disassembly in eukaryotic cells. However, while much is known about cofilin function *in vitro*, it remains a major challenge to understand how cofilin controls actin filament disassembly in vivo, and how its activities are tuned for physiological performance by spatiotemporal patterning, network architecture, and contractile forces. To bridge this gap in our understanding, we are combining *in vivo* single molecule imaging of actin dynamics in the early *C. elegans* embryo with reconstitution of actin network disassembly *in vitro*. We found that increased stabilization of actin filaments, via the small molecule inhibitor Jasplakinolide, has a dramatic effect on the cortical actin network, causing catastrophic tearing of the actin cortex, and ultimately resulting in delayed or failed cytokinesis. Furthermore, strong cofilin knockdown causes similar cortical network instabilities, identifying cofilin as a central regulator of filament disassembly and turnover in the early embryo. By combining TIRF microscopy with single molecule imaging and particle tracking analysis of transgenically expressed Actin::GFP, we measured rapid turnover of cortical actin filaments, revealing a dominant filament lifetime of ~8 sec. We found that the average filament lifetime is increased at least two-fold in conditions where actin filament stability is increased, indicating that filament disassembly is inhibited. To understand how inhibition of filament disassembly induces the observed cortical tearing, we focused on how new filament assembly is affected by reduced filament turnover. Using TIRF-M of single molecule dynamics of formin (CYK-1) at the cortex, we found that formin-mediated actin filament assembly rates are significantly reduced with inhibition of filament turnover by cofilin RNAi, suggesting that a tight coordination between filament disassembly and assembly is required to maintain the structural integrity of the actin cortex. *In vitro* TIRF-M reconstitution assays with purified UNC-60A revealed that UNC-60A promotes both severing and depolymerization from both the barbed and pointed ends of actin filaments. We are currently expanding these assays to determine the mechanism for cofilin/UNC-60A mediated turnover in the early embryo on single and bundled actin filaments as well as its effect on actin monomer recycling and new filament assembly.

B62/P1754

Synthetic control of dynamic pattern formation at the cell cortex

L. A. Sepaniac, A. Michaud, W. M. Bement; Center for Quantitative Cell Biology, University of Wisconsin-Madison, Madison, WI.

The cell cortex, including the plasma membrane, underlying cytoskeleton, and various cytoskeletal regulators, undergoes dramatic remodeling to drive cell shape changes necessary for cell division, polarization, motility, and morphogenesis. Cortical dynamics are often regulated by Rho family GTPases such as Rho, Rac, and Cdc42. Rho family proteins cycle between an active, GTP-bound state, and an inactive, GDP-bound state. This cycling is primarily regulated through Guanine nucleotide exchange factors (GEFs) which promote activation of Rho via nucleotide exchange, and GTPase activating proteins (GAPs) which promote Rho inactivation via GTP hydrolysis. Rho family GTPases are often deployed in generating discrete patterns at the cortex such as patches, rings or stripes. One type of dynamic pattern that may arise is propagating, complementary waves of Rho GTPase activity and F-actin disassembly - referred to as cortical excitability. Cortical excitability is subject to both internal and external regulation, including internal signaling which prompts cell cycle progression and developmental processes. Importantly, the cytoskeletal remodeling needed for essential cellular functions such as cell migration, mitosis and cytokinesis is supported by cortical excitability. We have previously shown that cortical excitability can be experimentally induced in *Xenopus* oocytes (which are not normally excitable) via co-expression two Rho regulators essential for cytokinesis: Ect2 (a GEF) and RGA-3/4 (a GAP). To further our understanding of this excitable circuit and cortical excitability in general, I have used a synthetic biology approach. Specifically, I employed a synthetic GEF construct designed to provide Rho-based positive feedback, including the Rho GEF domain of LARG fused with an rGBD, a domain that binds specifically to active Rho. When co-expressed with RGA-3/4, a natural participant in Rho-based negative feedback, the synthetic positive feedback construct, *Rho Positive Feedback 1 (RhoP1)*, produces semi-synthetic waves of Rho activity and F-actin. The waves appear elongated and propagate slowly, with a relative amplitude of 1.18 and period of 436 sec, compared with non-synthetic waves produced via Ect2 and RGA-3/4 (relative amplitude: 0.82, period: 152 sec). Similarly, a synthetic inhibitor, dubbed "*Rho Negative Feedback 1 (RhoN1),*" containing a Rho GAP domain and tropomyosin (to bind F-actin), supports semi-synthetic, pulsatile waves when co-expressed with the natural cytokinetic GEF, Ect2. These waves show a relative amplitude of 0.17 and period of 320 sec. Further study of this circuit system and development of additional synthetic constructs will provide added information about the regulation and propagation of excitable dynamics of this circuit.

SUP-13/ARRD-15 Controls the Transition of AIP1 Isoforms in *C. elegans* Body Wall Muscle

M. Lewis[1], K. Ono[1], Z. Qin[2], R. C. Johnsen[2], D. L. Baillie[2], S. Ono[1]; [1]Emory University, Atlanta, GA, [2]Simon Fraser University, Burnaby, BC, Canada

Actin-interacting protein 1 (AIP1) (also known as WDR1) is a conserved WD repeat protein that regulates cytoskeletal remodelling by promoting actin filament severing in the presence of actin-depolymerizing factor (ADF)/cofilin. In *Caenorhabditis elegans*, the *unc-78* gene encodes AIP1 that is essential for sarcomeric actin assembly in striated muscle. Previously, Francis & Waterston isolated *sup-13* as an extragenic suppressor of *unc-78* (Waterston, 1988). The *sup-13* mutation suppresses motility defects and sarcomere disorganization of the *unc-78* mutant, such that the *unc-78;sup-13*double mutant

exhibits nearly normal muscle contractility and sarcomere assembly. We identified that *sup-13* has a nonsense mutation in *arrd-15* encoding an α-arrestin. α-arrestins are typically involved in protein trafficking, with some serving as adaptors to recruit ubiquitin ligases in regulating the degradation of specific protein targets. However, α-arrestins have not been associated with sarcomere regulation previously, and the function of ARRD-15 remains to be characterized. ARRD-15 that was endogenously tagged with green fluorescent protein (GFP) was expressed in body wall muscle and localized diffusely in the cytoplasm. Transgenic expression of GFP-ARRD-15 in the *unc-78;sup-13* mutant enhanced sarcomere disorganization, as observed in the *unc-78* mutant. *C. elegans* has a second AIP1 isoform, AIPL-1, which is partially redundant with UNC-78 and normally downregulated in mature muscle. However, when AIPL-1 was depleted by RNA interference (RNAi), the *sup-13*/*arrd-15* mutation no longer suppressed actin disorganization of the *unc-78* mutant, indicating AIPL-1 is required for the phenotypic suppression. We found AIPL-1 protein level was higher in adult body wall muscle of the *sup-13/arrd-15* mutant, suggesting the normal function of SUP-13/ARRD-15 is to downregulate AIPL-1, and the high level of AIPL-1 may be compensating for the function of UNC-78. Depletion of several components of the ubiquitin-proteasome system by RNAi partially suppressed sarcomere disorganization in the *unc-78* mutant. In addition, ubiquitinated AIPL-1 was increased in the *sup-13/arrd-15* mutant. Taken together, these data suggest the function of SUP-13/ARRD-15 is to control the transition of AIP1 isoforms in *C. elegans* body wall muscle cells by specifically targeting AIPL-1 for ubiquitin-dependent degradation.

Regulation and function of nuclear actin filament dynamics

S. Ulferts[1], R. Grosse[1,2]; [1]University of Freiburg, Freiburg, Germany, [2]Centre for Integrative Biological Signalling Studies - CIBSS, Freiburg, Germany

Although recent years allowed for the first visualizations of dynamic nuclear actin filaments in mammalian cells, their regulation, roles and functions remain poorly understood. We have previously described mainly two independent processes that involve tightly regulated and transient nuclear actin assembly: (i) as a response to ligand-induced calcium elevations, and (ii) at the exit from mitosis during daughter cell nuclear expansion. Despite the fact that both processes differ in structural appearance, temporal dynamics as well as in the participating actin-regulating factors, they converge on the level of chromatin dynamics, such as variations in the degree of chromatin compaction and mobility. The first mentioned process involves rapid GPCR-mediated elevations of cellular calcium levels propagating through the nucleus, thereby stimulating actin polymerization from the inner nuclear membrane. We identified the formin inverted formin 2 (INF2) as the downstream nucleator initiating actin polymerization. Using a nuclear-targeted actin probe in order to visualize dynamic nuclear F-actin assembly, we performed a siRNA screen for inner nuclear membrane (INM) proteins to identify a potential receptor involved in the signal transduction from GPCRs to intranuclear actin polymerization. Results showed that knockdown of SAD1/UNC84 domain protein-2 (SUN2), member of the SUN domain protein family and key component of the linker of nucleoskeleton and cytoskeleton (LINC) complex, led to a significant reduction in the number of cells susceptible to calcium mediated nuclear actin assembly. Using high resolution imaging techniques and Proximity Ligation Assay (PLA) technology, we found that INF2 indeed co-localizes with SUN2 at the nuclear envelope possibly allowing for transient protein protein interactions and signal transduction towards the nuclear compartment. Ongoing work focuses on identifying transcriptional targets controlled by SUN2-INF2 mediated nuclear actin polymerization.

The GxcM-Fbp17/RacC-WASP signaling cascade regulates polarized cortex assembly in migrating cells

D. Li; Institute of Biophysics, Chinese Academy of Sciences (CAS), Beijing, China

The actin-rich cortex plays a fundamental role in many cellular processes. Its architecture and molecular composition vary across cell types and physiological states. The full complement of actin assembly factors driving cortex formation and how their activities are spatiotemporally regulated remain to be fully elucidated. Using *Dictyostelium* as a model for polarized and rapidly migrating cells, we show that GxcM, a RhoGEF localized specifically in the rear of migrating cells, functions together with F-BAR protein Fbp17, a small GTPase RacC, and the actin nucleation-promoting factor WASP to coordinately promote Arp2/3 complex-mediated cortical actin assembly. Over-activation of this signaling cascade leads to excessive actin polymerization in the rear cortex, whereas its disruption causes defects in cortical integrity and function. Therefore, different from its well-defined role in the formation of the front protrusions, the Arp2/3 complex-based actin carries out a previously unappreciated function in building the rear cortical subcompartment in rapidly migrating cells.

B66/P1758

Determining the Role of RhoG in Macropinocytosis

B. Kasu; South Dakota State University, Brookings, SD

Macropinocytosis is non-specific bulk-fluid uptake of fluids and solutes. CRISPR-cas9 whole genome screens identified RhoG, a small g-protein, as a negative regulator of macropinocytosis. Previous studies showed RhoG silencing reduces Rac1 activation in the context of cell motility. Rac1 has also been previously established as a key regulator of macropinocytosis. Therefore, we hypothesize that RhoG regulates macropinocytosis via Rac1. Experiments with targeted knockouts are ongoing to validate macropinocytosis efficiency and test the hypothesis.

B67/P1759

Human cyclase-associated protein (CAP1) regulates barbed end actin dynamics using its WH2 domain

N. Alimov, B. L. Goode; Brandeis University, Waltham, MA

Regulation of actin turnover is critical for the formation and reshaping of filamentous actin networks with a wide range of in vivo functions. Recently, cyclase-associated protein (CAP) has emerged as a central player in the regulation of F-actin turnover through interactions of its N-terminal helical folded domain (HFD) with the pointed ends of filaments (Shekhar et al., 2019; Kotila et al., 2019). Here, using microfluidics-assisted TIRF microscopy, we show that human CAP1 also regulates dynamics at the opposite (barbed) ends of actin filaments. In the absence of actin monomers, CAP1 increased the rate of brabed end depolymerization by approximately 4-fold compared to control reactions, and in the presence of actin monomers CAP1 slowed barbed end growth. These effects were mediated by the C-terminal half of CAP (C-CAP), whereas the N-terminal half of CAP (N-CAP) mediates the previously-described pointed end effects. Thus, different regions of CAP interact with the two ends of the filament to control F-actin dynamics. A further dissection of C-CAP revealed that its actin-binding WH2 domain was necessary but not sufficient for the barbed end effects, whereas actin-binding by the CARP domain did not appear to be involved. Our current efforts are aimed at understanding whether these activities depend on the specific sequence of the WH2 domain in CAP, or instead the specific molecular

architecture of C-CAP. Further, we are exploring how the regulatory effects of CAP1 at the barbed end influence other barbed end regulators such as capping protein and formins. Together, this work identifies a new function for CAP1 in F-actin turnover, mediated by its WH2 domain interacting with the barbed ends of actin filaments.

B68/P1760

More complex decisions: IQGAP1, formin, and capping protein regulate actin filament ends

M. L. Pimm, M. Alcaide Eligio, B. Haarer, A. G. Marcin, J. L. Henty-Ridilla; SUNY Upstate Medical University, Syracuse, NY

Actin filaments are intricately regulated at their barbed ends by specific proteins and complexes that promote or inhibit filament growth through dynamic competitive interactions. Using purified proteins and TIRF microscopy we examine the mechanism underlying IQGAP1's capping activity and how IQGAP1 and the formin, mDia1, regulate actin assembly. IQGAP1 significantly slows actin filament elongation through 20-25 s transient capping events regardless of the concentration of IQGAP used. Using truncation analysis, we determined a minimal ~300 aa construct of IQGAP able to cap filaments and further identified two amino acids responsible for this activity. Next, using fluorescently labeled IQGAP or capping-deficient mutant proteins, we learned the oligomeric state. Using step photobleaching analysis and functionally tagged IQGAP proteins we determined that both IQGAP and the capping deficient mutant were functional dimers. The mutant had less association with filament ends and no change in side-binding or bundling activities. In three-color TIRF microscopy experiments, we examined single molecules of IQGAP1 and constructs of mDia1 directly interacting. In the presence of actin filaments IQGAP-mDia1 complexes were observed on filament ends and ultimately slowed actin assembly to similar levels as reactions lacking formin. Two-color TIRF assays containing actin filament seeds and unlabeled proteins allowed us to investigate the open question of whether IQGAP1 could influence formin-capping protein interactions at the barbed end. Reactions containing capping protein, IQGAP1, and formin resulted in fewer blocked ends and net growth compared to reactions containing only capping protein and mDia1. Thus, IQGAP1-mDia1 interactions may protect barbed ends from capping protein. We investigated the impacts of IQGAP1-mediated filament capping on cell morphology, actin filament structure, and cell migration. Introducing IQGAP1 on a plasmid fully rescues CRISPR knockout 3T3 cell morphology and actin filament structures similar to cells expressing endogenous IQGAP1. However, a plasmid harboring the capping deficient IQGAP did not. Cells expressing only mutant IQGAP1 also displayed significantly slower wound closure. Combined this suggests that IQGAP1's capping functions are important for regulating cell morphology, actin filament structure, and migratory behaviors.

B69/P1761

Identification of Cdc42-ITSN modulators as novel partial agonists

S. Malasala, T. Penwell, C. Boykin, Y.-H. Chen, S. Nik Akhtar, Q. Lu; East Carolina Univ/Brody Sch Med, Greenville, NC

Small GTPases of Rho family control actin cytoskeleton organization. They also play a crucial role in the regulation of cellular functions such as cell morphology, migration, endocytosis and cell cycle progression involved in a wide variety of human diseases. Their activation and inactivation are controlled by various modulators like guanine nucleotide exchange factors (GEFs). We have developed

small molecule modulators (SMMs) that target Cdc42 interaction with its selective GEF intersetcin (ITSN). Although previous studies identified their inhibitory functions, further analyses revealed that some of the SMMs display partial agonistic features. N-MAR-GTP fluorophore-based Cdc42-GEF assays demonstrated that ZCL278 and ZCL279 promoted GTP loading in the absence of Cdc42-GEF *in vitro*. However, in the presence of GEF, they reduced GTP loading. By using Swiss 3T3 cell cultures, the Cdc42 G-LISA® assay revealed time- and concentration-dependent SMMs regulation of Cdc42-GTP interactions with immobilized Cdc42 binding protein. In these cells, bradykinin activated Cdc42 and induced the characteristic actin-based microspikes (filopodia). Interestingly, both ZCL278 and ZCL279 mimicked the activating effects of bradykinin. However, they showed inhibitory effects when the cells were concurrently activated by bradykinin. Therefore, these SMMs are unique Cdc42-ITSN protein-protein interaction (PPI) modulators that are partial agonists and may have important applications in investigating small GTPase-mediated cell signaling. This study is in part supported by NIH NIGMS/OD GM146257.

The P38 kinase family gene, PMK-1, has a role in *C. elegans* Embryonic Development.

A. Wallace, S. Parkinson; Fairleigh Dickinson University, Teaneck, NJ

In order for organisms to correctly develop, it is critical for them to undergo proper cell migration. The process of cell migration is meticulously regulated but all the details on how this happens have not been fully described. Abnormalities in cell migration have been linked to numerous disorders. For example, individual and collective cell migration mechanisms are altered in cancer cells. Defective cell migration has also been linked to improper neuronal development contributing to the occurrence of numerous neurodegenerative diseases. In Caenorhabditis elegans, the WAVE/SCAR pathway has been shown to regulate epidermal cell migration during embryonic morphogenesis. WAVE receives signals from three axonal guidance receptors (SAX-3, UNC-40 and VAB-1) to nucleate branched actin and initiate cell movement. We performed an RNAi screen to identify genes that function in the WAVE pathway during embryonic morphogenesis and found PMK-1 as a potential WAVE pathway regulator. PMK-1 is a member of the P38 MAP kinase family and is an ortholog of human mitogen-activated protein kinases 11 and 14 (MAPK11 and MAPK14). PMK-1 has been suggested to play a regulatory role in cell development and differentiation. We found that loss of pmk-1 in C. elegans causes embryonic lethality, and a portion of these embryos die due to a failure in morphogenesis. The ventral cells of the epidermis fail to properly migrate and seal in the internal organs leading to dead embryos. This phenotype resembles what is observed when known WAVE pathway genes are mutated. Loss of PMK-1 in vab-1 and sax-3 mutant backgrounds showed enhanced embryonic lethality while no change was observed in unc-40 mutants. The enhanced lethality results could mean that PMK-1 is functioning in a pathway parallel to SAX-3 and VAB-1 while the unchanged lethality in an unc-40 background could mean that they are functioning together in the same pathway. We will further investigate to verify that PMK-1 is functioning in the WAVE pathway and determine where in the WAVE pathway PMK-1 functions. We will also perform experiments to find out how PMK-1 affects branched actin nucleation.

Actin and Actin Associated Proteins 2

B71/P1763

What makes an actin an actin?

P. Avasthi, **B. M. Bigge**; Arcadia Science, Berkeley, CA

Actin mediates a very long list of cellular processes that are required for life. Because of the essentiality of actin in the cell, it is widely conserved, existing in organisms from humans to plants to protists and beyond. However, most of what we know about actin comes from a fairly small selection of cells, mostly Opisthokonts with actins that are highly conserved and some others, leaving a gap in our understanding of the actin cytoskeleton, how it's regulated, how it functions, and how it evolved. To truly understand actin biology, we should embrace the diversity of actin across organisms. This could allow us to gather more information about interactions between actin and its binding partners, to discover novel actin-based functions, and to uncover insights into the evolution and emergence of the actin cytoskeleton. Before we can do that, we must take a step back to define the clear and testable properties that make an actin a bona fide actin as opposed to an actin related protein or actin like protein. Here, we investigate properties including sequence conservation, structural conservation, polymerizability, ATPase function, post translational modifications, cellular functions, predicted binding partners, and phylogeny. While some of these criteria are clear and useful for defining an actin, others are more complicated and even questionable. There might be others still that we have not yet considered. Thus, this is an ongoing process and an open discussion, and we want to hear from you: what properties do you think make an actin an actin?

B72/P1764

Mechanisms of crawling motility in chytrid fungi

S. M. Brody; University of Massachusetts Amherst, Amherst, MA

Crawling motility is critical to many aspects of animal biology, including embryonic development, immune system function and tumor metastasis. Cell motility typically is dependent on the dynamic restructuring and turnover of the actin cytoskeleton to create protrusive and contractile forces necessary to movement. For example, fibroblasts and epithelial cells move by extending their lamellipodia, a thin sheet-like protrusion, and forming tight focal adhesions with their environment. Many amoeboid cells crawl with broad actin-filled pseudopods that form weaker, non-specific interactions with their environment. Alternatively, cells can crawl utilizing thin, linear "filopodia" filled with bundled actin or plasma membrane "blebs" devoid of F-actin. Beyond animals many species of fungi and algae use crawling to navigate their environments; however, it is poorly understood how these mechanisms have evolved and diverged across phyla. By studying chytrids, early-diverging fungi that retain characteristics of animal cells lost is other fungi, we aim to better understand the evolution and conservation of mechanisms of cell motility. To this end, I am adapting assays to observe chytrid crawling under a variety of conditions, allowing me to observe the formation and dynamics of cellular structures involved in crawling and determine which types of motility chytrid species employ. Using adhesion and 2-dimensional cell-confinement assays I am also exploring how the physical environment alters cell crawling as well as characterizing the molecular and protein components necessary to crawling in each species. By elucidating the structures and components chytrid species use to crawl and

understanding their relationship to well-studied organisms of animals and fungi, we aim to develop a better understanding of the origin and evolution of crawling.

B73/P1765

The actin networks of chytrid fungi reveal evolutionary loss of cytoskeletal complexity in the fungal kingdom

S. M. Prostak, K. A. Robinson, L. K. Fritz-Laylin; University of Massachusetts Amherst, Amherst, MA.

Across Eukarya, cells use actin polymer networks for a variety of conserved functions including endocytosis, cytokinesis, and cell migration. Despite this functional conservation, the actin cytoskeleton has undergone significant diversification, including within the opisthokont lineage that encompasses animals and fungi. The actin cytoskeleton of animal cells is complex, with distinct structures including cell cortex, lamellipodia, filopodia, stress fibers, and cytokinetic rings, all regulated by a subset of over 30 proteins. In contrast, budding yeast have about half the actin regulatory proteins and fewer distinct structures—cables, patches, cytokinetic rings, and fusion foci. The many differences between the actin networks of two sister lineages raises questions about the complexity of the ancestral actin network. Chytrid fungi diverged before the emergence of the Dikarya (multicellular fungi and yeast), providing a unique opportunity to study actin cytoskeletal evolution. Chytrids have two life stages: flagellated, motile zoospore cells, and sessile sporangial cells encased in a chitinous cell wall- like the Dikarya. We discovered that zoospores of the amphibian-killing chytrid *Batrachochytrium dendrobatidis* (*Bd*) build dynamic actin structures resembling those of animal cells (actin cortex, pseudopods, and filopodia-like spikes). In contrast, *Bd* sporangia assemble perinuclear actin shells and actin patches similar to those of yeast. Treatment with small molecule inhibitors reveals that nearly all of *Bd*'s actin structures are dynamic and some require the same nucleator as their animal or yeast counterparts. Pseudopods, actin patches, and actin spikes require at least Arp2/3 complex function, while the actin cortex forms independently from Arp2/3 complex function. Our analysis of multiple chytrid genomes reveals the presence of actin regulators and myosin motors genes typical of animals, as well as those specific to fungi. The presence of animal- and yeast-like actin cytoskeletal components in the genome combined with the intermediate actin phenotypes in *Bd* suggests that the simplicity of the yeast cytoskeleton may be due to evolutionary loss. Using early branching fungi, like chytrids, has revealed a previously underappreciated evolutionary pattern, further solidifying chytrids as powerful model organisms for studying actin cytoskeletal evolution.

B74/P1766

Differential N-terminal processing of beta and gamma actin

L. Chen[1], P. Vedula[1], H. Tang[2], D. Dong[1], A. Kashina[1]; [1]University of Pennsylvania, PHILADELPHIA, PA, [2]The Wistar Institute, PHILADELPHIA, PA

Cytoplasmic beta- and gamma-actin are ubiquitously expressed in every eukaryotic cell. They are encoded by different genes, but their amino acid sequences differ only by four conservative substitutions at the N-termini, making it difficult to dissect their individual regulation. Here, we analyzed actin from cultured cells and tissues by mass spectrometry and found that beta, unlike gamma actin, undergoes sequential removal of N-terminal Asp residues, leading to truncated actin species found in both F- and G-actin preparations. This processing affects up to ~3% of beta-actin in different cell types. We used CRISPR/Cas-9 in cultured cells to delete two candidate enzymes capable of mediating this type

of processing. This deletion abolishes most of the beta-actin N-terminal processing and results in changes in F-actin levels, cell spreading, filopodia formation, and cell migration. Our results demonstrate previously unknown isoform-specific actin regulation that can potentially affect actin functions in cells

B75/P1767

The role of evolutionary amino acid conservation in cytoplasmic actin function

P. Vedula[1], M. E. Fina[2], B. A. Bell[3], S. S. Nikonov[2], D. W. Dong[1], C. M. Schroeder[4], A. S. Kashina[1]; [1]Biomedical Sciences, University of Pennsylvania, Philadelphia, PA, [2]Department of Neuroscience, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, [3]F.M. Kirby Center for Molecular Ophthalmology, Scheie Eye Institute, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, [4]Pharmacology, University of Texas Southwestern, Dallas, TX.

Cytoplasmic actins are ubiquitously expressed and are essential components of the cytoskeleton. All vertebrates express two cytoplasmic actins, β- and γ-actin, which are highly similar to each other with only several amino acid changes within their N-terminus and the C-terminal region. In anamniotes, an evolutionarily more ancient class of organisms including fish and amphibia, the cytoplasmic actins show divergence in several residues in the N- and C-terminus. However, in amniotes, which include birds, reptiles, and mammals, β- and γ-actin are nearly identical to each other, except for 4 conservative substitutions in the N-termini. These differences have been completely conserved over 320 million years of evolution. The underlying reason for this conservation, and the exact role of the 4 amino acid changes in cytoplasmic actins' function, are unknown. Here, we addressed the role of these N-terminal substitutions using a gene-edited mouse model expressing γ-actin both natively and from the nearly intact β-actin gene. These mice completely lack β-actin protein but retain the nucleotide-level elements of both cytoplasmic actin genes. Thus, any phenotypes in these mice are caused by the replacement of β-actin-specific N-terminal amino acids with those of γ-actin, making this model uniquely suited to address the biological role of these amino acid differences *in vivo*. Strikingly, while these mice undergo normal embryogenesis, the absence of β-actin protein leads to reduced long-term survival, indicating an evolutionary cost due to the loss of a highly conserved cytoplasmic actin. One of the consistent defects in these mice includes disorganization of the microvilli, actin-rich cytoplasmic protrusions present in many tissues throughout the body, prominently including the retina and the small intestine. Our results demonstrate crucial functions for the evolutionarily conserved amino acid differences between cytoplasmic actins in amniotes and indicate potentially distinct selective pressures on the evolutionarily older cytoplasmic actin orthologs in anamniotes.

B76/P1768

Evolutionary tuning of capping protein-formin competition allows simultaneous construction of two distinct actin networks

A. C. E. Wirshing, S. Gonzalez Rodriguez, B. L. Goode; Biology, Brandeis University, Waltham, MA.

Vertebrate capping protein (CapZ) and formins join each other at actin filament barbed ends in vitro and catalyze each other's displacement through associative competition. However, the physiological consequences of this mechanism and whether it is conserved in other organisms have remained unclear. To address these questions, we studied the relationship between *S. cerevisiae* capping protein (Cap1/2) and formins in vitro and in vivo. Using microfluidics-TIRF microscopy we show that yeast Cap1/2 only weakly displaces formins from barbed ends compared to CapZ. In vivo, formin-dependent actin cable

assembly was strongly attenuated by overexpression of CapZ but not Cap1/2. Further, loss of Cap1/2 resulted in Arp2/3 complex-nucleated actin patches over time taking on cable-like features, including recruitment of formins and tropomyosin. These results suggest that the properties of *S. cerevisiae* Cap1/2 have been tuned across evolution to allow robust cable assembly by formins in the presence of high cytosolic levels of Cap1/2 used to limit patch growth and shield patches from formins.

B77/P1769

An optimized F-actin probe reveals dynamic organelle-associated F-actin networks in budding yeast

A. C. E. Wirshing, B. L. Goode; Brandeis University, Wlatham, MA

Live-cell actin probes can be biased in the actin networks they label and fail to accurately detect all actin networks in a cell. Here, we show that the actin binding protein Abp140, which has been used in the budding yeast field for 20 years to visualize formin-generated F-actin cables (bundles), decorates cables in the mother cell but is largely excluded from cables in the daughter cell (bud). On the other hand, cables in both compartments are clearly visualized by phalloidin in fixed cells and by labeled tropomyosins (Tpm1 and Tpm2) in live cells. Thus, there is a population of actin cables assembled by the formin Bni1 in the bud that is poorly decorated by Abp140. Further, by expressing integrated formin chimeras (Bni1-Bnr1 and Bnr1-Bni1), we find that the lack of Abp140 on cables in the bud compartment is not dependent on a specific formin building cables in the bud. Surprisingly, cables in both compartments are clearly detected by a 17 residue fragment of Abp140 ('LifeAct') fused to a 3x-mNeonGreen tag, and the signal is much brighter than Abp140 with the same tag. We show that our optimized LifeAct probe does not alter cellular growth or actin network dynamics. Finally, using this new probe coupled with super-resolution live-cell imaging, we detect dynamic actin cables associated with organelles, which were poorly detected using Abp140. This work describes an optimized actin probe for budding yeast and opens new avenues for investigating actin-organelle interactions in this system.

B78/P1770

Direct observation of the interaction of cyclase-associated protein with actin or cofilactin filaments by high-speed atomic force microscopy

P. D. N. Nguyen[1], **S. Ono**[2], H. Abe[3], N. Kodera[1]; [1]Kanazawa University, Kanazawa, JAPAN, [2]Emory University, Atlanta, GA, [3]Chiba University, Chiba, JAPAN.

Cyclase-associated protein (CAP) is present widely among eukaryotes and regulates multiple key aspects of actin dynamics. Mutations in CAP often cause severe defects in cytoskeletal dynamics in many eukaryotes. Mutations in human CAP2 cause myopathies in cardiac and skeletal muscles. CAP binds to actin monomers and promotes exchange of actin-bound nucleotides. CAP also binds to cofilin-bound actin (cofilactin) filaments and enhances severing or depolymerization from the pointed ends. However, whether CAP binds to actin filaments at the side or only at the pointed ends is still under debate. Here, we characterized the interaction of *Xenopus* cyclase-associated protein 1 (XCAP1) with actin or cofilactin filaments directly by using high-speed atomic force microscopy (AFM). We found that XCAP1 bound to the side of bare actin filaments with no preference to the filament ends. The binding was transient with an average dwell time of ~0.7 s. The presence or absence of ATP did not affect this interaction. We often found that XCAP1 bundles actin filaments most likely by binding sides of multiple filaments as an XCAP1 tetramer. When XCAP1 was added to cofilactin filaments, dissociation of cofilin from actin filaments was induced. This resulted in enhanced filament severing by producing patches of actin and cofilactin

clusters within the filaments. Under these conditions, XCAP1 predominantly induced severing of cofilactin filaments and only rarely promoted depolymerization from the ends at much slower rates than previously published studies using microfluidics-assisted total internal reflection fluorescence microscopy. Genetic studies in the nematode *Caenorhabditis elegans* were consistent with the *in vitro* activities of CAP to promote cofilactin disassembly. Previously, we reported that mutation in *cas-1* encoding a muscle-specific CAP caused formation of excessive cofilactin aggregates (Nomura et al., 2012). In addition, we found that mutation in *cas-2* encoding a non-muscle CAP caused formation of large cofilactin rods in the syncytial gonad. These results suggest that CAP is essential for disassembly of cofilactin filaments either by depolymerization from ends or severing.

B79/P1771

Molecular control of actin cortex architecture during cell division

N. Vadnjal[1,2], S. Nourreddine[3,4], G. Lavoie[3], M. Serres[1,5], R. Peters[2], A. Jégou[6], G. Romet-Lemmone[6], F. Parmeggiani[7], P. Roux[3], E. Paluch[2]; [1]University College London, London, United Kingdom, [2]University of Cambridge, Cambridge, United Kingdom, [3]University of Montreal, Montreal, QC, Canada, [4]University of California San Diego, San Diego, CA, [5]Institut Pasteur, Paris, France, [6]Institut Jacques Monod, Paris, France, [7]University of Bristol, Bristol, United Kingdom

Animal cell shape is controlled by the actin cortex, a thin actomyosin network supporting the plasma membrane. By pulling on actin filaments, myosin motors generate contractile tension in the cortex and gradients in this tension lead to cell shape changes, such as those driving cell division. Alongside myosin, actin network connectivity, which is controlled by crosslinker levels and actin filament length, has recently been shown to be key to cortical tension regulation. Yet, how cortical network organisation is controlled at the molecular level, and how this contributes to tension regulation, remains poorly understood. To identify potential regulators of cortex tension, we firstly compared proteic composition of interphase and mitotic cortices. To isolate cortical fractions, we developed a protocol to isolate cortex-enriched blebs from synchronised cells. We detected over 922 proteins in interphase and mitotic blebs of which 238 were actin-related. Among actin-related proteins, our analysis highlighted a role for septins in the regulation of the mitotic cell shape. Interestingly, our mass spectrometry analysis indicates that cortical levels of crosslinkers, key determinants of actin network connectivity, do not display strong changes between interphase and mitosis. We thus hypothesised that other properties of actin crosslinkers might be important for the regulation of cortical actin organisation and mechanics. We focused on investigating the role of crosslinker size. Indeed, actin crosslinkers display a large variety of sizes, and protein size could affect localisation within the dense cortical actin network. To test this, we created “artificial crosslinkers” for which size can be modulated independently of other features. Artificial crosslinkers localise to the actin cortex during cell division and affect cortical mechanics, cell shape, and division dynamics. We are currently investigating how crosslinker size affects cortical localisation during cortex tension gradient formation in cytokinesis. Finally, we are testing how artificial crosslinkers modulate actin network architecture *in vitro*. Together, this work unveils new levels of regulation of cortical organisation and tension.

B80/P1772

Particle-Based Model of Mechanosensory Contractility Kit Assembly

A. I. Plaza-Rodriguez[1], L. Nguyen[2], D. N. Robinson[2], P. A. Iglesias[3]; [1]Biophysics, Johns Hopkins University, Baltimore, MD, [2]Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, [3]Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD.

Cell shape-change processes, such as proliferation, polarization, migration, and cancer metastasis, rely on a dynamic network of macromolecules. The proper function of this network enables mechanosensation, the ability of cells to sense and respond to mechanical cues. Myosin II and cortexillin I, critical elements of the cellular mechanosensory machinery, preassemble in the cytoplasm of Dictyostelium cells into complexes that we have termed contractility kits (CKs). Two IQGAP proteins then differentially regulate the mechanoresponsiveness of the cortexillin I-myosin II elements within CKs. To investigate the mechanism of CK self-assembly and gain insight into possible molecular means for IQGAP regulation, we developed a coarse-grained excluded-volume molecular model in which all protein polymers are represented by nm-sized spheres connected by spring-like links. The model is parameterized using experimentally measured parameters acquired through Fluorescence Cross-Correlation Spectroscopy (FCCS) and Fluorescence Correlation Spectroscopy (FCS), which describe the interaction affinities and diffusion coefficients for individual molecular components. Interaction affinities were verified via computational emulation of FCCS and fractional saturation curves obtained from simulations. Diffusion coefficients were corroborated via computational emulation of FCS and Mean Squared Deviation (MSD) analysis of particles in simulation. Simulations of wild-type and null-mutant conditions implied that the temporal order of assembly of these kits is dominated by myosin II dimer formation and that IQGAP proteins mediate cluster growth. Additionally, our simulations predicted the existence of “ambiguous” CKs that incorporate both classes of IQGAPs, and we confirmed this experimentally using FCCS. The model serves to describe the formation of the CKs and how their assembly enables and regulates mechanosensation at the molecular level.

Engineering Platforms for Visualizing Mechanical Regulation of the Actin Cytoskeleton

J. Levin, A. Pan, G. M. Alushin; The Rockefeller University, New York, NY

Myosin generated forces have recently been shown to modulate interactions between individual actin filaments (F-actin) and actin binding proteins (ABPs). *In vivo*, F-actin and myosins are incorporated into higher-order multi-filament networks, such as the cortex and contractile stress fibers, whose network geometry could also impact F-actin-ABP interactions. To date, it has been difficult to disentangle the contributions of force and multi-filament avidity to mechanosensitive ABP localization in cells. To address this problem, we have developed an *in vitro* system for producing varied actin filament network geometries in the presence of active myosin forces while monitoring ABP engagement with TIRF microscopy. In our modified gliding filament assay, we arrange filaments in a head-to-head configuration using two covalently conjugated capping protein heterodimers. We combine this with protein micropatterning to produce dozens of individual networks in different arrangements in parallel on a coverglass. We simultaneously observe network dynamics in the presence of myosin force generation while monitoring soluble ABP binding. We apply this method to the mechanosensor α-catenin, which exists in two different states in cells: as member of the heterotrimeric cadherin-catenin complex (a core component of adherens junctions), and as a cytoplasmic homodimer which suppresses ARP2/3 branch

formation. We observe that a monomeric α-catenin construct preferentially binds filaments under tension as previously reported. However, in a homodimeric construct, this force-activated binding competes with an avidity-based preference for binding to bundles of filaments experiencing force in parallel, where the load per filament is reduced. This could mediate distinct actin network binding preferences for α-catenin's different forms in cells, highlighting how ABPs integrate biochemical and biomechanical signals including filament tension, filament bundling, and their own oligomerization status, to tune their behavior. Our experimental platform should widely enable dissecting such multimodal activities of ABPs.

Engineering Orthogonal Actin-binding Protein Switches

U. M. Effiong, H. Khairandish, B. Belardi; University of Texas At Austin, Austin, TX.

Actin is a prominent feature of eukaryotic cells and plays critical roles in numerous subcellular processes such as endocytosis, cell motility and division. Actin's engagement with subcellular structures involves actin-binding proteins (ABP) that interface the filamentous form of actin (F-actin) with specific molecular complexes and regulate F-actin's organization and mechanics. While ABPs have been studied in detail in cells, these experiments often rely on the use of small-molecule F-actin disrupters or protein depletion. Unfortunately, neither of these tools is ideal for monitoring how ABPs-of-interest contribute to individual cellular processes as they either affect F-actin or the protein-of-interest globally. Thus, a means of directly manipulating actin binding with temporal control is a pressing need. We propose using protein switch domains that toggle between an "off" and an "on" state to accomplish this task. Here, we describe the design and engineering of three F-actin binding switch domains triggered by different stimuli to achieve switching activity over a broad range of timescales. Each design relies on installing an intramolecular association to drive the "off" state of actin-binding sequences (ABS). After the introduction of either a small molecule, a peptide, or incident light stimulus, the switch transitions to an "on" state, leading to F-actin binding. For peptide and small molecule stimuli, we successfully engineered switches that conformationally constrain two ABSs in an inactive state and that can be activated in the presence of their respective stimulus. For light-based stimulation, we engineered steric inhibition of ABSs by incorporating a light-responsive protein domain into the switch, allowing for blue light-mediated activation. We quantified i) the "off" state of the switches as the fold inhibition compared to wildtype activity and ii) the extent of activation after stimuli introduction. Our switches achieved 50-95% fold inhibition and binding activations up to 85% upon the addition of stimuli in cells. These switch designs were then utilized in cell junction and filament cross-linking studies. Actin-binding switches offer a new method for controlling actin binding in a direct, specific, and temporal manner, which can be applied to experiments seeking to probe and control the influence of actin binding on a subcellular process.

The regulatory mechanisms of dynamin-actin bundling activity

C. Wang, M. Chuang, Y. Liu; Institute of Molecular Medicine, National Taiwan University, Taipei, TAIWAN.

Dynamin is best-known as a membrane fission mechanochemical GTPase essential for endocytosis in cells. In addition to plasma membrane, dynamin is also recruited to a unique actin structure, podosome,

where it interacts with actin polymerization factors or directly bundles actin filaments. We found that the actin bundling ability of dynamin-2 (Dyn2), ubiquitously expressed dynamin isoform, could only be observed in buffer with low ionic strength *in vitro*. This result indicates that the actin bundling ability of Dyn2 needs to be activated in cells under physiological, higher ionic strength condition. Previously, a podosome scaffold protein, Tks5, has been found to bind directly to Dyn2, whereas the Src kinase-mediated phosphorylation of Dyn2 at Y597 regulates its podosome-targeting in cells. Nonetheless, how Tks5 interaction and Dyn2^{Y597} phosphorylation regulates the actin bundling activity of Dyn2 remains unclear. In this study, we found Tks5 binds directly to Dyn2 with two SH3 domains. Interestingly, the "mini-Tks5", two SH3 domains that directly bind to Dyn2, promoted the actin bundling activity of Dyn2 in buffer with high ionic strength. Moreover, mini-Tks5 prevented Dyn2 disassembly induced by GTP addition and even increased the GTP-hydrolysis activity of Dyn2. Mini-Tks5 was also observed to increase the diameter of Dyn2-actin bundles under transmission electron microscopy. Additionally, we discovered that Dyn2^{Y597} phosphorylation and mini-Tks5 synergistically prevented GTP-induced Dyn2 disassembly and resulted in Dyn2-actin bundles with larger diameter in buffer with high ionic strength. Together, we discover that Tks5 interaction and Src kinase-mediated Dyn2^{Y597} phosphorylation collaboratively enhance the activities of Dyn2 on bundling actin filaments thus promote podosome maturation in cells.

Tropomyosin and engagement of the integrin LFA-1 cooperate to promote actomyosin-dependent force generation at the T cell immune synapse

D. C. Schrock[1], M. Heydecker[1], R. Weigert[1], E. Hardeman[2], P. Gunning[2], J. A. Hammer[1]; [1]NIH, Bethesda, MD, [2]UNSW, Sydney, Australia

Efficient target cell killing by CD8+ T cells requires integrin-dependent adhesion to, and the exertion of force on, the target cell (Basu et al Cell, 2016). T cell: target cell interaction is mediated by a highly-organized interfacial structure called the immunological synapse (IS) that is composed of three concentric zones termed the distal, peripheral, and central supramolecular activation clusters (dSMAC, pSMAC, and cSMAC). This organization is established and maintained by an Arp2/3 complex-generated branched actin network in the dSMAC and a formin-generated linear actin network in the pSMAC. Bipolar filaments of myosin 2A (M2A) organize the linear pSMAC actin network into concentric, contractile actin arcs, and this structure co-localizes with the ring of LFA-1 that drives T cell: target cell adhesion by binding to ICAM-1 on the target cell surface. Inhibition of either formin (mDia1) or M2A impairs the movement of T cell receptor (TCR) microclusters toward the cSMAC, dampens TCR signaling, and impairs T cell: APC adhesion. Tropomyosins are actin-binding proteins that associate with linear, formin-generated filaments, where they serve to promote actomyosin force generation by recruiting and activating type 2 myosins. Here we show that mouse CD8+ T cells express tropomyosins 3.1 and 3.2 (Tpm3.1/3.2) and that Tpm3.1/3.2 colocalize with the pSMAC actomyosin arcs. Importantly, abrogating Tpm3.1/3.2 function using either a small molecule inhibitor (ATM3507) or CRISPR-mediated gene deletion attenuates the recruitment of M2A to the IS and disrupts the concentric organization of the pSMAC actin arcs. Conversely, ligating LFA-1 with ICAM-1 dramatically increases the amount of M2A recruited to the synapse and the concentric organization of the pSMAC actin arcs. Together, these results argue that Tpm3.1/3.2 and LFA-1 ligation cooperate to promote actomyosin-dependent force generation at the T cell IS. These results also add to the growing appreciation for the role that integrin ligation plays in promoting the function of both T cells and B cells. Finally, we hypothesize that the

pSMAC actomyosin arcs are responsible for the exertion of force on the target cell that promotes target cell lysis. Current efforts are directed, therefore, at evaluating the efficiency of target cell killing by CD8+ T cells isolated from mice lacking Tpm3.1/3.2.

B85/P1777

Effects of tropomodulin 2 on dendritic spine reorganization

B. Kuruba[1], N. Starks[1], G. Wayman[1], M. Mikhaylova[2,3], **A. Kostyukova**[1,3]; [1]Washington State University, Pullman, WA, [2]Humboldt Universität zu Berlin, Berlin, Germany, [3]University Medical Center Hamburg-Eppendorf, Hamburg, Germany

Neurons communicate through a structure between an axon and a dendrite termed a synapse. The ability of the brain to adapt to environmental or activity-dependent changes is regarded as synaptic plasticity. Dendritic spine morphology is tightly connected to the synaptic plasticity and the strength of the input. Actin remodeling is required for the formation, maturation and reorganization of spines. Actin filaments are highly dynamic structures with a slow growing (pointed) and fast growing (barbed) ends. Very few studies have been conducted on the role of pointed-end binding proteins in regulation of dendritic spine morphology. In this study, we focus on highlighting the role played by tropomodulin 2 (Tmod2), a brain-specific isoform, on the dendritic spine post-development reorganization. Tmod2 regulates actin polymerization by binding to the pointed end via several distinct actin and tropomyosin (Tpm) binding sites. Tmod2 can also nucleate actin polymerization. We studied the effects of Tmod2 overexpression in primary hippocampal neurons on number, morphology and mobility of spines and number of other actin-based structures, e.g., filopodia and spinules. We showed that Tmod2 overexpression led to the decrease in number of thin, mushroom, and stubby spines but did not affect number of branched spines. The overexpression resulted in the increase in lengths of thin and mushroom spines. While there was no effect on number of filopodia, number of spinules increased. Eliminating the actin nucleation ability of Tmod2 by mutating one of the two actin-binding sites resulted in the increase in the number of mushroom spines. Destroying Tpm-binding ability of Tmod2 by mutating both Tpm-binding sites increased the mobility of thin spines/filopodia drastically. We assume that the ability of Tmod2 to bind at the pointed ends that depends on the presence of both Tpm-binding sites affects positively spine maturation.

B86/P1778

Delving into Tropomyosin-Actin Species Specificity and Physical Consequences of Novel Heterodimerization

C. Nie[1], R. D. Mullins[1], N. A. Petek-Seoane[1], J. Rodriguez[2]; [1]Cellular and Molecular Pharmacology, University of California San Francisco, San Francisco, CA, [2]University of California San Francisco, San Francisco, CA.

The actin cytoskeleton mediates a wide breadth of functions in the cell such as adhesion, cell motility, and tension sensing. Non-muscle tropomyosins are dimeric coiled-coil proteins that are critical regulators of nearly all actin cytoskeleton dynamics. In humans, four tropomyosin genes code for upwards of 40 tropomyosin isoforms through differential splicing. Fascinatingly, these isoforms are non-redundant in their regulatory roles within the cell, but the structure-function relationship of these non-muscle isoforms is not well understood. Recently, our lab has described three isoforms expressed by Drosophila Schneider 2 (S2) cells, named 1A, 1J, and 2A. In vitro experiments revealed to us that isoform

1A can bind actin as a homodimer, typical of tropomyosins. However, 1J and 2A were both unable to bind actin until they were made to heterodimerize (one coil of each). Tropomyosin heterodimerization was only reported before in the context of cardiac smooth muscle, but in the smooth muscle it merely improves binding and is not a prerequisite for binding outright as it is for our isoforms. We also observed a large species-specific affinity discrepancy for actin in these tropomyosins. This is novel because the high sequence identity of eukaryotic actins typically allow for most actin-binding protein (ABP) studies to utilize easy-to-purify heterologous systems (actin and ABP from different species). Our goal in this work is to investigate the rationale behind heterodimerization and the species-specificity of our S2 tropomyosins. To achieve this we will use a combination of in vitro biochemistry techniques and cryo-electron microscopy (cryo-EM) to investigate how the structure and interactions of novel tropomyosins allow them to bind actin. Our cryo-EM work has so far demonstrated that tropomyosin isoform 1A interacts with actin in the exact fashion as muscle tropomyosins, binding along a positive groove of actin. But we are experiencing difficulty in reconstructing the heterodimer, possibly due to low affinity in our heterologous system. Concluding from our current results and looking forward, we aim to purify S2 actin and perform homologous studies wherein the actin and tropomyosin are sourced from the same species. This will likely yield more biologically relevant results and improve our cryo-EM data collections.

B87/P1779

Characterization of a novel *Caenorhabditis elegans* tropomyosin isoform with poor actin affinity

K. Morisaki[1], E. Watabe[2], K. Ono[1], H. Kuroyanagi[2], S. Ono[1]; [1]Departments of Pathology and Cell Biology, Emory University, Atlanta, GA, [2]Laboratory of Gene Expression, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, JAPAN.

Tropomyosin is an actin-binding protein found in fungi and metazoans, which regulate actin filament stability and actomyosin contraction. In metazoans, multiple tropomyosin isoforms are expressed, and many of them are involved in diverse actin-dependent processes in an isoform-specific manner. In mammals, more than 40 tropomyosin isoforms are produced, and point mutations in several isoforms cause cardiovascular and skeletal muscle diseases. However, many tropomyosin isoforms remain poorly characterized. To investigate the biological significance of tropomyosin isoforms, we use the nematode *Caenorhabditis elegans* as a model organism. In *C. elegans*, the *lev-11* gene is the sole tropomyosin gene that is essential for embryonic development, reproduction, and regulation of muscle contractility. The *lev-11* gene is controlled by two separate promoters and extensive alternative splicing, and previous studies have demonstrated production of six tropomyosin isoforms with two alternative seventh exons (E7a and E7b). Here, we report identification of a novel seventh exon, E7c, of the *lev-11* gene. We cloned a full-length cDNA encoding a novel low-molecular-weight tropomyosin isoform, LEV-11U, containing the E7c sequence. Interestingly, LEV-11U poorly bound to actin filaments *in vitro*, whereas other isoforms strongly bound to actin filaments. Tropomyosin is a coiled-coil dimer, and several charged residues have been identified as actin-binding sites in mammalian isoforms. Sequence alignment showed that several actin-binding residues were not conserved in the E7c-encoded sequence. Tropomyosin also contains conserved non-canonical residues at hydrophobic core, such as alanine clusters, which are reported to be important for its flexible coiled-coil structure. Molecular dynamics simulations showed that the radius of an unstable core of E7c was statistically larger than that of E7b, indicating that the E7c-encoded region poorly formed stable coiled-coil structure. These results indicate that alternative splicing contributes to production of a biochemically distinct tropomyosin isoform.

B88/P1780

The binding and elongation properties of tropomyosin Tm1A to actin filaments are highly context dependent

N. A. Petek-Seoane, J. Rodriguez, D. Mullins; University of California, San Francisco, san francisco, CA.

Tropomyosins are coiled-coil proteins that copolymerize along actin filaments and therefore regulate the accessibility of actin filaments to actin-binding proteins. This gatekeeping property of nonmuscle tropomyosin effectively regulates the morphology and dynamics of actin networks in cells. Despite the abundance of nonmuscle tropomyosins, little is known about the binding properties or elongation dynamics of tropomyosin along actin filaments. Recently a number of groups, including our own, have begun to study the biophysical properties of tropomyosin assembly on actin filaments using both single filament TIRF and microfluidic assays. We find that unlike any other known actin-binding protein, tropomyosin shows a strong preference for the origin (species) of the actin. We therefore created a system derived entirely from *Drosophila melanogaster* to study the binding of *Drosophila* tropomyosin Tm1A. We show that Tm1A binding to *Drosophila* actin filaments is dependent on the experimental set up. In a microfluidic assay, we use a variety of tethers (mDia, capping protein, or phalloidin-stabilized seeds) and show that Tm1A preferentially binds to the pointed end of filaments when actin is tethered by mDia, however both the capping protein and seed tethered actin filaments do not show any preferential region for initial tropomyosin binding. We show that tropomyosin binds more rapidly to filaments tethered by the pointed end of the actin filament, and slowest to capping protein tethered filaments. Additionally, elongation of Tm1A on capping protein tethered actin filaments is considerably slower than either seed or mDia tethered actin filaments. Interestingly, when we look at untethered actin by TIRF we see that capped filaments are also slower to bind and elongate tropomyosin filaments suggesting that this is not an artifact of the microfluidic assay. Together these data suggest that tropomyosin binding and elongation to actin filaments cannot be widely compared and contrasted in the literature, due to the large amount of variability in experimental outcome when only a few, seemingly minor, assay components are altered.

Actin Dynamics in Disease

SEPT9 isoform-specific interactomics in colorectal cancer

K. Makhmudova, G. Hu, E. Jeffery, S. Bandyopadhyay, G. Sheynkman, S. Ebrahim; University of Virginia, Charlottesville, VA

Background: *SEPT9* codes for a GTP-binding protein septin 9 (SEPT9) that is involved in cytoskeletal organization and membrane dynamics. *SEPT9* is associated with many human cancers, and acts as a tumor suppressor gene in colorectal cancer (CRC). There are multiple alternatively spliced mRNA variants of *SEPT9*, but hypermethylation of the promoter region of only one isoform, *SEPT9_i2*, abrogates this tumor suppressor function, ultimately resulting in malignant tumor formation. However, the underlying mechanism by which SEPT9_i2 contributes to CRC progression remains unknown. Objective: We seek to identify binding partners unique to SEPT9_i2 that will provide new insights into the mechanisms that underlie its strong association with intestinal pathology. Methods: Different SEPT9 isoforms have distinct molecular interaction domains at their N-termini. An N-terminal extension (NTE) is present in the longer SEPT9 isoforms, including Sept9_i2, but not the shorter isoforms such as

Sept9_i5. The NTE encodes binding domains that mediate direct interactions with actin, microtubules, myosin and membranes. SEPT9_i2 and SEPT9_i5 show distinct subcellular localization. We dissected the isoform-specific interactomes of SEPT9_i2 and SEPT9_i5 in DLD-1 colon adenocarcinoma cells. Briefly, cells were transfected with GFP-tagged SEPT9_i2 and _i5-cDNA as well as a GFP-only control. The successful expression of the tagged SEPT9 constructs was verified by Western blotting and immunofluorescence. Affinity-based co-immunoprecipitation was performed for each isoform-specific and control cell lysates, followed by mass spectrometry analysis. Results: Major hits unique to SEPT9_i2 included F-actin-capping protein subunit alpha-2 (CAPZA2) - a stabilizing protein of growing actin filaments, and multivesicular body subunit 12 (MVB12A) protein. Given that MVB12A is potentially involved in down-regulation of oncogenic epithelial growth factor receptor (EGFR), this is a promising clue on tumor suppression mechanism by SEPT9_i2. Our future plans include validation of direct interaction using reciprocal Co-IP. Conclusion: Our preliminary data indicate distinctive isoform-specific binding patterns that correlate with the hypothesis of antitumorigenic potential of SEPT9_i2. To our knowledge, this is the first attempt to profile isoform-specific interactome of SEPT9 in the context of CRC.

B90/P1782

Potential biophysical role of actin-binding protein TRIOBP in metastasis of human pancreatic cancer

M. J. McCormick, A. E. Massey, R. Olszewski, T. B. Friedman, A. X. Cartagena-Rivera; National Institutes of Health, Bethesda, MD

TRIOBP (TRIO and F-actin-Binding Protein) encodes three protein isoform classes (TRIOBP-1, TRIOBP-4 and TRIOBP-5). Variants of this gene have been implicated in deafness, schizophrenia and cancer. TRIOBP binds to and stabilizes actin filaments, thus influencing cytoskeletal structure. The actin cytoskeleton plays a crucial role in epithelial-mesenchymal transition and cancer progression, notably through adhesion, motility, contractility, and invasion. TRIOBP is often studied in neuroblastoma, but little has been explored about its activity in other cancers. The purpose of this study is to investigate a possible role of TRIOBP in pancreatic cancer metastasis. We selected a panel of human pancreatic adenocarcinoma (PDAC) cell lines, including primary tumor cells (BxPC-3 and PANC-1) and metastatic cells derived from patient ascites (HPAF-II and AsPC-1). These were cultured alongside the normal pancreatic ductal epithelial cell line, HPDE. We characterized TRIOBP expression with immunofluorescence (IF), western blot (WB), droplet digital PCR (ddPCR) and atomic force microscopy (AFM). ddPCR results revealed that TRIOBP-1 mRNA levels, when compared to normal cells, were significantly higher for metastatic cells and lower for primary tumor cells. These expression patterns were consistent with WB results, which show a significant increase in TRIOBP protein of metastatic cells when compared to primary tumor cells. ddPCR also revealed a remarkably higher amount of TRIOBP-1 expression compared to TRIOBP-4 and TRIOBP-5. Therefore, observed measurements in WB and IF using the TRIOBP antibody are thought to represent changes mostly in TRIOBP-1. Cells were IF-stained to visualize TRIOBP protein and F-actin. Confocal imaging showed that *in vitro* monolayers had TRIOBP mainly located in the perijunctional actin cytoskeleton. In isolated and polarized migratory cells, TRIOBP seemed to be mainly localized to retracting F-actin bundles at the trailing edge of the cell. Therefore, TRIOBP may preferentially localize to contractile F-actin structures such as these. AFM measurements of monolayers revealed that stiffness of the primary tumor cell perijunctional actin was the same as that of normal cells or lower, just as WB results showed that these cells had similar-to-less TRIOBP protein.

However, these regions were softer for metastatic cells. This analysis of PDAC cell lines shows a potential role of TRIOBP in cancer migration and invasion, possibly involving F-actin architectures.

B91/P1783

Disruption of MRTF-SRF interaction impairs membrane dynamics and motility of breast cancer cells

V. Yu, I. Eder, D. Gau, D. Boone, P. Roy; University of Pittsburgh, Pittsburgh, PA

Mortality associated with breast cancer (BC) is due to the metastatic spread of tumor cells. Dysregulated actin cytoskeleton is a feature of tumor cells that leads to aberrant cell motility and cancer metastasis. Myocardin-related transcription factor (MRTF) belongs to a family of actin-regulated transcriptional co-factors of serum-response factor (SRF) that control gene expression in both SRF-dependent and -independent manners. In the present study, we sought to investigate the role of SRF-dependent function of MRTF in motility of breast cancer cells. Using sub-lines of MDA-MB-231 breast cancer cells that are genetically engineered to express either wild-type or functionally defective mutants of MRTF, we herein demonstrate that disruption of MRTF-SRF interaction leads to a prominent inhibition of random as well as chemotactic cell migration. Kymography analyses of membrane dynamics showed that blocking MRTF-SRF interaction dramatically suppresses the dynamic behavior of the leading edge of migrating cells. In order to gain insight into potential molecular mechanisms of MRTF's regulation of cell migration, we next performed RNA sequencing of various MRTF-engineered sublines of MDA-MB-231 cells followed by Ingenuity Pathway Analysis (IPA) which revealed "Actin Cytoskeleton Signaling" pathway and the "Actin Nucleation" pathways to be significantly perturbed by MRTF expression. We further identified transcriptional repression of the formin family of actin nucleating and elongating proteins in breast cancer cells when MRTF-SRF interaction is abrogated, suggesting that formin-directed actin assembly may be one of the potential mechanisms of how MRTF-SRF interaction promotes cell motility.

B92/P1784

Vesicle-associated actin assembly by formins promotes TGF-beta- induced ANGPTL4 trafficking and secretion

D. Frank[1], C. Moussie[2], L. Lorenzen[1], C. Schwan[1], R. Grosse[1,3]; [1]Unisversity of Freiburg, Freiburg, Germany, [2]University of Marburg, Marburg, Germany, [3]Centre for Integrative Biological Signalling Studies - CIBSS, Freiburg, Germany

Vesicle trafficking has emerged as an important process driving tumor progression through various mechanisms, such as cargo endocytosis, recycling and secretion into the tumor microenvironment. TGFβ-mediated secretion of Angiopoietin-like 4 (ANGPTL4) is important for cancer development. Here we identify the formin Formin-like 2 (FMNL2) to be necessary for ANGPTL4 trafficking and secretion in response to TGFβ signaling. We show that protein kinase C-dependent phosphorylation of FMNL2 downstream of TGFβ stimulation is required for cancer cell invasion as well as ANGPTL4 vesicle trafficking and secretion. Moreover, using live-cell super-resolution microscopy, we could observe that ANGPTL4 trafficking is actin-dependent with FMNL2 polymerizing actin directly at ANGPTL4-containing vesicles. These secretory vesicles are associated with Rab8a and myosin Vb. This work uncovers a formin-controlled process that transiently polymerizes actin directly at intracellular vesicles to facilitate their mobility. This mechanism may be important for the regulation of cancer cell metastasis and tumor progression.

L-plastin Knockdown reduces the invasion but increases the migration of PC3 prostate cancer cells

S. Majumdar, H. Aljohani, L. T. Senbanjo, **M. A. Chellaiah**; University of Maryland SOD, Baltimore, MD.

L-plastin Knockdown reduces the invasion but increases the migration of PC3 prostate cancer cells

Chellaiah MA, Majumdar S, Aljohani H, Senbanjo LT Department of Oncology and Diagnostic Sciences, School of Dentistry, University of Maryland, Baltimore Metastatic cancer cells use the actin-bundling process to constantly remodel the actin cytoskeleton for adhesion, migration, and invasion. L-plastin is an actin-bundling protein that belongs to the plastin family. L-plastin has been identified in several malignant colon, prostate, and breast tumors and contributes to cancer cell invasion in a phosphorylation-dependent manner. Our initial characterization of the PC3 prostate cancer (PCa) cell line derived from bone metastases demonstrated L-plastin expression in PCa cells but not in other PCa cell lines tested. Hence, this study aimed to identify L-plastin's role in the migration and invasion of PC3 cells. Immunostaining analysis demonstrated a punctate distribution of L-plastin and patchy actin staining in PC3 cells with a minimal colocalization between L-plastin and actin at the invadopodia. However, overexpression in PC3 cells increased L-plastin's colocalization and actin at the invadopodia and during the invasion. In a wound-healing assay, these cells displayed a significant reduction in migration. L-plastin and invadopodia connections were confirmed using the L-plastin knockdown strategy in PC3 cells (PC3/Si). PC3/Si cells demonstrated an increased migration, corresponding to punctate podosome-like structures. However, a decrease in the number of invadopodia contributed to a significant reduction in the invasion. Moreover, tumorsphere formation was significantly reduced in PC3/Si cells than in PC3 cells. In conclusion, our observations suggest that L-plastin regulates the formation of invadopodia required for prostate cancer invasion. Furthermore, our results highlight that it could be a novel therapeutic target for androgen-independent metastatic prostate cancer.

B94/P1786

TRIM9 modulates cytoskeletal dynamics, membrane remodeling, and motility in melanoma

K. Lukasik, S. Gupton; UNC Chapel Hill, Chapel Hill, NC.

Normal 0 false false false EN-US X-NONE X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Table Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0in 5.4pt 0in 5.4pt; mso-para-margin-top:0in; mso-para-margin-right:0in; mso-para-margin-bottom:8.0pt; mso-para-margin-left:0in; line-height:107%; mso-pagination:widow-orphan; font-size:11.0pt; font-family:"Arial",sans-serif;} Cell shape change and motility are essential in development, immune responses, wound healing, and metastasis. Cell shape change involves remodeling of both the actin cytoskeleton and the plasma membrane in response to extracellular cues, like netrin. How these cellular systems are regulated and coordinated is unknown. Here we are investigating *how the brain-enriched E3 ubiquitin ligase TRIM9 regulates actin and plasma membrane dynamics in response to the morphogen netrin in melanoma.* We previously identified TRIM9 as a potent regulator of netrin-dependent actin dynamics and exocytosis in developing neurons. We found that TRIM9 negatively impacts the actin polymerase VASP by non-degradative ubiquitination. Deletion of murine *Trim9* impairs neuronal migration, axon turning, axonal and dendritic branching, VASP ubiquitination, and VASP dynamics at filopodia tips, and increased exocytosis and filopodial stability. TRIM9 is expressed in other motile cells, but the non-neuronal role of

TRIM9 remains unknown. In addition, TRIM9 has been identified a possible prognostic biomarker in melanoma. Here we demonstrate that many human melanoma lines express TRIM9, supporting published work from other groups. Using Total Internal Reflection Florescence microscopy (TIRF) and confocal microscopy, we show that TRIM9 and VASP colocalize at lamellipodia, filopodia tips, and focal adhesions. TRIM9 also localizes to lysosomes in human 1205Lu melanoma cells. In addition, 1205Lu cells lacking TRIM9 exhibit an increased velocity but reduced directional persistence. Current studies are investigating how loss of TRIM9 alters parameters of lamellipodia, filopodia, focal adhesions, and exocytosis to define the role of TRIM9 in melanoma motility.

B95/P1787

The Role of the mDia Formins in Breast Cancer Invasion

A. Ramirez; Albert Einstein College of Medicine, Bronx, NY

The actin cytoskeleton is regulated by the p21 Rho-family of small GTPases through downstream effectors including the mammalian diaphanous-related formins 1 and 2 (mDia1, mDia2). The mDia formins modulate the actin cytoskeleton by nucleation and assembling linear actin filaments, but they also recruit proteins containing SH3 domains such as Src-family of non-receptor tyrosine kinases, important in driving cell motility, including cancer invasion. To successfully invade and metastasize, breast cancer cells form actin-based, invadopodia protrusions that are capable of degrading the extracellular matrix. There is limited understanding in the control of mDia formins by upstream RhoGTPase isoforms during cancer cell invasion that contribute to breast cancer metastasis. Here, we determined the upstream RhoGTPase paralogs regulating mDia1 and mDia2 at invadopodia and their subsequent downstream functions during breast cancer cell invasion. We show that mDia1 and mDia2 are localized in discrete and differential compartments at invadopodia and impact invadopodia formation and function. We show specific upstream paralog GTPases regulate invadopodia through targeting mDia1 versus 2 within these compartments, by controlling cell adhesion to the substratum and by modulating Src-kinase mediated function. Our approach to studying this mechanism utilized a novel, direct multiplex Förster Resonance Energy Transfer (FRET) biosensor approach, wherein, a pair of spectrally orthogonal FRET biosensors was visualized simultaneously in single living cells. We developed a set of FRET biosensors capable of reporting the activity status of mDia1 and mDia2, and have spectrally shifted these biosensors into near infra-red (NIR) so that they may be used simultaneously with our cyan-yellow FRET biosensors for the upstream GTPases. We report for the first time, specific, localized activities of mDia1 and 2 and their upstream regulator RhoGTPase activities in single breast cancer cells at invadopodia. We delineate the functions of these molecular signaling nodes using our newly developed multiplex biosensor approach and report differential roles of mDia1 versus mDia2 at breast cancer invadopodia, that control cell-substrate adhesion and matrix degradation, respectively, mediated by specific upstream RhoGTPases, RhoA, RhoC and Rac3. In summary, our multiplex FRET biosensor technology for the mDia formins makes it possible to directly visualize the activity of RhoGTPases together with mDia1 or mDia2 at invadopodia. Our results point to regulation of differential invadopodia functions by mDia1 versus mDia2, signaled by different upstream RhoGTPase paralogs that control integrin-substrate adhesion and matrix degradation, which ultimately impact breast cancer cell invasion.

Characterization of the transfer of mitochondria via different types of tunneling nanotubes (TNTs) and its role in the progression of Glioblastoma

I. Sáenz-de-Santa-María[1], J. Y. Tinevez[2], A. Pepe[1], C. Zurzolo[1]; [1]Cell Biology and Infection, Institut Pasteur, Paris, FRANCE, [2]Head of Image Analysis Hub, Institut Pasteur, Paris, FRANCE.

Glioblastoma (GBM) is the most aggressive primary brain tumor in adults and lacks effective therapy. Tunnelling nanotubes (TNTs) that connect cancer cells point to a new mechanism of molecular interconnection of tumors. TNTs are membranous bridges that directly connect the cytoplasm of distant cells and exchange molecules such as mitochondria. It has been shown the diversity of TNT morphology and composition between and within cell types. Here, we investigated what roles the compositional elements of the TNTs have in the transfer of mitochondria and address the relation between the formation, the structure, and the function of TNTs in GBM. We show, for the first time the presence of different types of TNTs in GBM cell line vs GBM stem-like cells (GSLCs) in classical 2D-culture and in 3D-tumor organoids. We analyzed the ultrastructure organization of TNTs using correlative fluorescence cryo-electron microscopy (cryo-EM). Furthermore, we characterized the dynamics of the transfer of mitochondria through thick and thin TNT in GB/GS-cells by fluorescence live-cell imaging using cells transduced with different plasmids for visualizing the microtubules, actin filaments and mitochondria in different colors. Here we provide a detailed analysis of this phenomenon using software TrackMate-Kymograph extension to perform 2D automated mitochondria tracking inside the TNT and provide fully quantitative readouts, such as, average and maximal velocity, and directionality of the transfer of mitochondria, and other parameters related to the TNT: e.g., thickness and length over time. Our data in U251 GBM cell line indicate the presence of two different types of TNTs, thin actin-based TNTs and thick TNTs formed by both microtubules and actin, in contrary to the observed in GSLCs, formed only by actin TNTs. The transfer of mitochondria occurs principally via microtubules positive TNTs with an average of transfer 5.14 nm/s and a max velocity of 17.5 nm/s. However, the transfer of mitochondria via thin TNTs is faster reaching a max velocity 74.5 nm/s. The ultrastructure of the TNT via cryo-EM indicates that thin TNTs are composed of a bundle of open-ended individual tunneling. These results provide new evidence about the different composition and dynamics of the transfer of mitochondria via these structures in GBM and could be facilitate the development of effective therapy.

Actin-Binding Protein Profilin-1 is an Important Regulator of Vascular-Immune Cell Crosstalk

A. E. A. Gondringer, A. Larregina, P. Roy; University of Pittsburgh, Pittsburgh, PA

Dysregulated expression of actin-binding protein profilin-1 (Pfn1) is associated with a number of vascular pathologies. The objective of the present study was to examine the immunological consequence of endothelial loss of Pfn1 function *in vivo*. For these studies, we utilized a novel mouse model engineered for tamoxifen-inducible endothelial cell (EC) specific deletion of the *Pfn1* gene ($Pfn1^{-/-(EC)}$), and performed serum-analyses of metabolic function and circulating cytokines/chemokines, immune cell composition analyses in whole blood as well as in spleen by fluorescence activated cell sorting (FACS), and immunohistochemistry-based assessment of organ pathology. Our studies showed that widespread deletion of endothelial Pfn1 leads to severe health complications as evidenced by labored breathing, lethargy, and abnormal peritoneal fluid accumulation within 3 weeks of gene ablation ultimately compromising survival. $Pfn1^{-/-(EC)}$ mice exhibited reduced liver and kidney function,

findings further supported by evidence for structural alterations, vascular collapse, EC death and prominent immune cell infiltration in the liver of these animals. Loss of endothelial Pfn1 resulted in elevated circulating levels of pro-inflammatory cytokines and chemokines (VEGF, IL1β, IL6, G-CSF, CCL2, CCL5) with concomitant reduction of anti-inflammatory cytokines and chemokines (IL-1α, IL5, CXCL5). Consistent with these findings, $Pfn1^{-/-(EC)}$ mice exhibited a dramatic increase (~10x) of circulating leukocytes alongside a significant increase in splenic myeloid cells as well as circulating macrophages. In vitro co-culture studies further support a role for endothelial Pfn1 in negatively regulating macrophage-like differentiation of monocytes through a paracrine action, with additional preliminary evidence pointing to a role of cell-secreted extracellular Pfn1 itself as a suppressor of monocyte-to-macrophage differentiation. Collectively, these findings highlight a previously unrecognized function of Pfn1 as an important mediator of vascular-immune cell crosstalk.

Flotillin-1/-2 localizes at enteropathogenic *Escherichia coli* pedestals

P. Mcleod, J. Guttman; Simon Fraser University, Burnaby, BC, CANADA.

Flotillin-1/-2 localizes at enteropathogenic *Escherichia coli* pedestals

Petra McLeod and Julian A. Guttman
Department of Biological Sciences, Centre for Cell Biology, Development, and Disease (C2D2), Simon Fraser University, Burnaby, BC, Canada

Enteropathogenic *Escherichia coli* (EPEC) are extracellular pathogens that manipulate the actin cytoskeleton of epithelial cells to generate actin-rich pedestal-like structures at sites of bacterial/host cell contact. Key to pedestal formation is the bacterial effector protein Tir, and more specifically Y474 in Tir, as bacteria mutated at that site are defective for pedestal formation. Although pedestals protrude from the natural surface of the epithelial cells, they require the endocytic protein clathrin and an assortment of clathrin-associated protein for their formation. Flotillin-1/-2 is a clathrin-independent endocytic protein found within lipid rafts of the plasma membrane. Here we examined transfected GFP-tagged Flotillin-1/-2 during EPEC infections and found this protein localized along the sides of the pedestal stalk. EPEC mutants that cannot form pedestals did not recruit flotillin even when bacteria were in contact with the epithelial cell surface. Our results indicate that Flotillin-1/-2 are additional endocytic proteins hijacked by EPEC for non-endocytic functions.

A genetic complementation approach examining antimicrobial sensitivity of fungal actin orthologs

M. A. Fagbolade, D. M. Gordon; Biological Sciences, Mississippi State University, Mississippi State, MS.

Actin is a highly conserved cytoskeletal protein present in all eukaryotic cells. In the yeast *Saccharomyces cerevisiae*, *ACT1* is an essential gene as it codes for the sole form of actin with roles in endocytosis, nuclear segregation, and polarized cell growth. Recent studies centered around the antifungal compound, occidiofungin, have indicated that the biological target of this natural product is actin. Whereas this compound demonstrates fungicidal activity against many yeast and filamentous fungi, occidiofungin has low efficacy against *Fusarium oxysporium* and *Penicillium digitatum* fungal species exhibiting a >10-fold resistance profile relative to *S. cerevisiae*. At the amino acid level, *F. oxysporium* and *P. digitatum* actin share 92% and 91% identity with *S. cerevisiae* actin, respectively. To determine if these amino acid differences, contribute to the altered susceptibility measured for

occidiofungin, a haploid *ACT1* shuffle strain was generated for testing the functionality of *ACT1* gene products from *C. glabrata*, *C. albicans*, *F. oxysporium*, and *P. digitatum*. Functional complementation of the *ACT1* gene products was found for cells expressing *C. glabrata* and *C. albicans* actin as determined by measuring growth kinetics, actin protein expression levels, and cell morphology and nuclear positioning analysis. Data for susceptibility testing to occidiofungin by minimum inhibitory concentration also indicate a similar sensitivity profile as *S. cerevisiae*. Expression of *ACT1* from *F. oxysporium* and *P. digitatum* resulted in a poor growth profile with the accumulation of abnormal sized cells. Analysis identified codon usage differences as a potential contributing factor, and studies using codon optimized *ACT1* genes are ongoing. This scholarship was funded by the American Society for Cell Biology through the International Federation for Cell Biology.

Cofilin-actin Rod Dynamics and Efficacy of CXCR4 and CCR5 Receptor Antagonists in Prevention and Reversal of Rod Pathology in Cultured Rodent and Human Neurons

L. H. Tahtamouni[1], T. B. Kuhn[2], S. A. Alderfer[3], L. S. Minamide[2], K. P. Walsh[4], A. E. Shaw[2], O. Yanouri[5], M. Ruff[6], **J. R. Bamburg**[2]; [1]Biology and Biotechnology, The Hashemite University, Zarqa, JORDAN, [2]Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, [3]Chemical and Biological Engineering and School of Biomedical Engineering, Colorado State University, Fort Collins, CO, [4]Biochemistrya and Molecular Biology, Colorado State University, Fort Collins, CO, [5]Molecular, Cellular and Integrative Neuroscience, Colorado State University, Fort Collins, CO, [6]Creative BioPeptides, Inc., Potomac, MD.

Cofilin-saturated F-actin (cofilactin) bundles (rods) are a pathological feature in brains of individuals who suffered from Alzheimer's and other neurodegenerative diseases and disorders. Rapid rod formation (minutes) is triggered in >80% of cultured rodent hippocampal neurons by excitotoxic glutamate or ATP depletion by a rapid pathway implicating mitochondria. In contrast, slower (hours) rod induction is triggered in ~20% of hippocampal neurons by disease-specific factors (e.g. soluble oligomers of Amyloid-β (Aβ), proinflammatory cytokines, and others), which require cellular prion protein (PrP^C) and active NADPH oxidase (NOX). Using live-cell imaging with fluorescently tagged rod components, we measured an extrapolated time to 50% recovery from photobleaching for core cofilin and actin at ~1 and ~4 hr, respectively. Concentrations for 50% inhibition of rod formation (EC_{50}) by FDA-approved CXCR4 and CCR5 antagonists (30 -100 nM) are over 3000-fold higher than those of all-D-amino acid penta/octa peptides (RAPs) targeting these receptors. RAPs reverse preformed rods with a time to 50% reduction of ~45 min. For more clinically relevant applications, we developed a human neuronal culture system for rod analysis. Neurons derived from H1 human ES cells lack NOX expression and do not form rods when treated with PrP^C-dependent rod inducers. However, a human iPSC line, WTC-11, in which neuronal differentiation by Ngn2 is readily inducible with doxycycline, express NOX, but during their first several weeks of culture, have insufficient PrP^C for rod induction. PrP^C-insufficiency was overcome by its adenoviral-mediated expression, which by itself induces rods but the response is enhanced by Aβ treatment. Long-term cultures are maintained in glial-conditioned medium. By culture day 35, axonal and dendritic markers show process distinction with spines and synapses beginning to form. By day 55, the WTC-11 rod response to Aβ is not significantly different with or without expression of exogenous PrP^C. RAPs inhibit and reverse Aβ-induced rods in human neurons with the same efficacy (sub-pM EC_{50}) as in rodent neurons, suggesting these orally administered, inexpensive small peptides that can cross the blood-brain barrier would be highly effective in reducing brain rod pathology in human disease.

Determining the effect of a patient mutation in moesin on protein phosphorylation and T cell migration

A. Albis, O. Stebbins, L. Avery; Biology, Saint Michael's College, Colchester, VT.

X-linked moesin associated immunodeficiency (X-MAID) is a rare immunodeficiency characterized by lymphopenia and recurrent opportunistic infections. X-MAID is caused by a single point mutation in the protein moesin (moesin^{R171W}). Moesin is an actin-binding protein that connects the cell membrane to the cortical actin network. When phosphorylated and in its open conformation, moesin is actively linking the cytoskeleton to the plasma membrane. When dephosphorylated and in its closed conformation, the protein is autoinhibited, no longer providing linker activity. Changing conformation regulates cell shape, rigidity, and thus migratory capabilities. The ability to migrate is a critical role of T cells in the body, as they must move through tissues to reach sites of inflammation and infection. T cells expressing moesin^{R171W} exhibit an abnormally round and rigid structure when stimulated with chemokine, predicted to inhibit T cell transmigration. Therefore, the aim of this study is to investigate the effect of the X-MAID mutation on protein phosphorylation status and T cell transmigration, a critical gap in knowledge. To address this gap, we use a Jurkat T cell line that expresses moesin^{WT} and moesin^{R171W} under an inducible promoter. When treated with chemokines and analyzed by western blot, we revealed differences in phosphorylation between the mutant and wild type T cells. Furthermore, we performed transwell assays to assess the migratory capabilities of mutant and wildtype T cells in response to chemokines. Understanding of the molecular and cellular phenotypes of X-MAID T cells is essential for better understanding cytoskeletal regulation during migration and developing potential therapeutics.

cd13 controls myeloid cell- cell fusion

M. Ghosh, F. Mcgurk, S. Nair, K. Morais, L. Shapiro; Center for Vascular Biology, UCONN Health, Farmington, CT.

While over a million total joint arthroplasties take place per year to treat end-stage arthritis, 40-70% of these will eventually undergo painful aseptic revision surgery due to implant degeneration. Despite advances in biomaterials, implants ultimately corrode to produce particles that initiate a foreign body response characterized by macrophage fusion into destructive, pro-inflammatory, multinucleated giant cells (MGCs) that directly define the pathology of osteolytic loosening of prosthetic implants. MGC formation initially requires cytokine-induced differentiation of precursors into macrophages, leading to membrane fusion to form very large, active MGCs with multiple nuclei sharing a common cytoplasm. While some fusion-regulatory proteins are known, mechanistic understanding of the underlying molecular events is largely theoretical and somewhat controversial, emphasizing the need for further study. Our previous observations have clearly shown that the myeloid cell transmembrane protein, CD13 is a remarkably multifunctional molecule that assembles the molecular machinery enabling diverse cellular processes such as cell-cell adhesion and the endocytosis and recycling of cell surface proteins. In the current study, we show that *in vitro* induction of MGC formation from isolated CD13^{KO} progenitors generated considerably larger MGCs with many more nuclei and increased cytokine secretion than those generated from controls. We confirm these studies in an *in vivo* implant model, demonstrating that a lack of CD13 exacerbates MGC formation and inflammatory cytokine levels both at the implant site and

systemically. Mechanistically, we identified that the post-translational degradation of the critical fusion proteins dynamin, Dendritic Cell-Specific Transmembrane Protein (DC-STAMP) and tetraspanins, CD9 and CD81 was dysregulated in $CD13^{KO}$ MGC, leading to sustained expression levels that promote macrophage fusion. This agrees with our published studies implicating CD13 in osteoclast fusion during bone resorption, suggesting CD13 acts as a component of a common fusion machinery. Therefore, we have identified CD13 as a negative regulator of cell-cell fusion in both osteoclast and MGC formation, and thus is a novel target for therapeutic intervention in pathological conditions mediated by destructive cell-cell fusion such as osteoporosis and medical implant failure.

A Human Disease-Causing Mutation Results in Loss of Leiomodin 2 Protein Through Nonsense-mediated mRNA Decay.

C. T. Pappas, G. P. Farman, T. M. Larrinaga, R. M. Mayfield, C. C. Gregorio; University of Arizona, Tucson, AZ.

Leiomodin 2 (Lmod2) is an actin-binding protein involved in the assembly of actin filaments in muscle. Lmod2 plays a critical role in muscle function as loss of Lmod2 in murine models results in dilated cardiomyopathy (DCM) and rapid death. We previously described the first known human disease-causing mutation in LMOD2 (pW398*), which led to severe neonatal DCM requiring heart transplantation (Ahrens-Nicklas, Pappas *et al*., 2019). Analysis of the explanted heart revealed extremely short thin filaments, and cardiomyocytes with greatly reduced maximal calcium-activated force output. The mutation is predicted to result in expression of a truncated protein, however, we did not detect LMOD2 protein in the patient's explanted heart. We further discovered that nonsense-mediated mRNA decay underlies the loss of mutant LMOD2 protein. We also found that introduction of GFP-Lmod2 into *Lmod2* constitutive KO mice just after birth prevents onset of DCM, with the mice living to adulthood, rather than dying at ~ day 21. A surprisingly small amount of Lmod2 (<20% of endogenous levels) is required to maintain *in vivo* cardiac function. Additionally, introduction of GFP-Lmod2 with a mutation (p.W405*) homologous to that found in the patient (generated from cDNA so it is not susceptible to degradation due to *nonsense-mediated mRNA decay*) partially restores cardiac morphology and function in *Lmod2* KO mice. Therefore, recovery of even a small amount of wild type, or mutant, LMOD2 could have therapeutic potential for patients with *LMOD2* nonsense mutations.

B104/P1796

A model for endolysosome genesis, trafficking, and phagosome maturation in mammalian photoreceptors

S. Ramachandra Rao[1,2], J. Slone[1], J. Vu[1], T. Huang[1], S. J. Fliesler[1,2]; [1]State University of New York, University At Buffalo, Buffalo, NY, [2]VA Western New York Healthcare, Buffalo, NY

Purpose: Retinal photoreceptors (PRs) are polarized, light-sensing neurons that depend on the endolysosomal system to maintain homeostasis, and vision. The unique arrangement of PRs in the retina allows rigorous investigation of neuronal organelle trafficking. Using an autophagy reporter mouse line (CAG-RFP-EGFP-LC3B), we previously demonstrated rapid PR phagosome-lysosome fusion. Mature PR phagolysosomes are distributed along the cell body, and in the F-actin-rich PR inner segment (IS)-myoid region. Here, we studied actin and microtubule-dependent mechanisms of endolysosome genesis/trafficking and phagosome maturation in mammalian PRs. **Methods:** C57BL/6J, C57BL/6NTac,

and CAG-RFP-EGFP-LC3B mice were treated with vinblastine sulphate (a microtubule-depolymerizing agent) for 6 h. Eyes from control and vinblastine-treated mice were harvested, fixed, and retinal wholemounts were prepared. Wholemounts were treated with anti-LAMP2 (a lysosome marker) and a fluor-tagged secondary IgG, and phalloidin-AF568 (to detect F-actin). We developed a high-throughput confocal image acquisition/analysis workflow to assess phagosome and autolysosome distribution in the PR IS-myoid region. **Results:** Control C57BL/6J retinas exhibited the typical distribution of lysosomes, limited to the PR IS-myoid and cell body. Vinblastine treatment inhibited microtubule-dependent lysosome trafficking in those retinas, and caused lysosome accumulation exclusively in the F-actin-rich IS-myoid region. Retinas of C57BL/6N mice (a model of *Crb1*-associated retinopathy) are characterized by loss of PR tight junctions and exhibit disrupted F-actin (lesions) in the IS-myoid region. Those retinas exhibited normal lysosome distribution in lesion-free regions, while lesioned areas showed significantly lower endolysosome content. Vinblastine treatment of C57BL/6N mice confirmed loss of PR endocytic capacity in the IS-myoid region of lesion areas, indicated by complete loss of endolysosome accumulation. Surprisingly, vinblastine treatment of CAG-RFP-EGFP-LC3B mice caused accumulation of RFP/LAMP2-positive mature phagolysosomes in the IS-myoid, without causing phagosome maturation defects. **Conclusions:** We propose a model wherein F-actin-dependent endocytosis occurs specifically in the PR IS-myoid, followed by microtubule-dependent trafficking throughout the cell body. Phagosome-lysosome fusion occurs rapidly in the IS-myoid region. Our data implicate lysosomal pathway defects in *CRB1*-associated retinopathy.

Localised actin dynamics at the ciliary tip regulate the pace of photoreceptor disc formation

R. Megaw[1], A. Moye[2], Z. Zhang[3], F. Newton[1], F. McPhie[1], L. McKie[1], F. He[4], V. Arshavsky[5], L. Machesky[6], T. Wensel[4], P. Mill[1]; [1]MRC Human Genetics Unit, University of Edinburgh, Edinburgh, UNITED KINGDOM, [2]Baylor College of Medicine, houston, TX, [3]Vera and Marrs McLean Department of Biochemistry and Molecular Biology, Baylor College of Medicine, Edinburgh, TX, [4]Verna and Marrs McLean Department of Biochemistry and Molecular Biology, Baylor College of Medicine, Baylor College of Medicine, Houston, TX, [5]Duke University School of Medicine, Edinburgh, NC, [6]The Beatson Institute for Cancer Research, University of Glasgow, Glasgow, UNITED KINGDOM.

As signalling organelles, primary cilia regulate G protein-coupled receptor (GPCR) concentration on their membrane by ectocytosis, a process which requires highly-localised actin dynamics at their tip to alter membrane shape. Mammalian photoreceptor outer segments are an expanse of folded membrane at the tip of a highly-specialised connecting cilium, in which photosensitive GPCRs like rhodopsin are concentrated. In an extraordinary feat of biology, outer segments are shed and remade every week. Failure to do so, due to genetic mutations causes retinitis pigmentosa (RP), an untreatable, blinding disease. The mechanism by which photoreceptor cilia generate outer segments is therefore fundamental for vision yet poorly understood. Here, we show the membrane deformation required for outer segment disc genesis is driven by dynamic changes in the actin cytoskeleton in a process akin to ectocytosis. Further, we show *RPGR*, a leading causal gene of RP, regulates activity of actin binding proteins crucial to this process. Humanized disease-causing mutations in *Rpgr* mouse models compromise this, disrupting the actin dynamics required for disc formation, leading to photoreceptor death and visual loss. Manipulation of actin dynamics partially rescues the phenotype, suggesting this pathway can be targeted therapeutically. These findings help define how actin-mediated dynamics control outer segment turnover.

B106/P1798

Salmonella invasion protein A (SipA) binds F-actin with high affinity, potently inhibits depolymerization, and increases thermal stability

L. A. Runyan[1], E. Niedzialkowska[2], E. Egelman[2], D. S. Kudryashov[1]; [1]The Ohio State University, Columbus, OH, [2]University of Virginia, Charlottesville, VA

Salmonella enterica subspecies *enterica* causes over 100 million human infections annually, with cases ranging from food poisoning to typhoid fever. An essential part of *Salmonella's* pathogenicity is its ability to invade and proliferate within non-phagocytotic host intestinal cells, which is accomplished by hijacking the host cell's cytoskeleton. Host cell invasion by *Salmonella* is endowed by its pathogenic effector proteins, many of which are delivered directly to the host cell's cytoplasm via the type III secretion system. Among these effector proteins is *Salmonella* invasion protein A (SipA), which contributes to the formation of lamellipodia-like ruffles in the host cell, enveloping the bacteria and leading to its engulfment and entry into the cell. SipA's C-terminal part (425 - 684) has been identified as the actin-binding region. It has been demonstrated that SipA decreases critical concentration, induces polymerization, and inhibits depolymerization when applied in roughly equimolar concentrations to actin. However, during infection, bacteria are unlikely to deliver a sufficient amount of toxins to reach equimolar ratios with actin, even locally. Using a combination of cryo-EM reconstruction and biochemical approaches, we found that SipA binds F-actin with nearest neighbor exclusion at a 1:2 SipA:Actin stoichiometry with a K_d in the nanomolar range. The C-terminal tail of SipA is inserted in between the two actin strands, accounting for its ability to potently displace phalloidin and jasplakinolide. SipA increased the thermal stability of F-actin and notably inhibited the depolymerization of pyrene actin by ADF in a cooperative manner when SipA concentration was ~100 times lower than F-actin, likely due to combined inhibition of severing and depolymerization. These data indicate that SipA cooperatively stabilizes the actin filament structure and, while being present in low doses, may affect F-actin interactions with host partners and pathogenic effector proteins necessary for the invasion and proliferation of *S. enterica*.

B107/P1799

Spinocerebellar ataxia mutations localizing to the spectrin-repeat domains of β-III-spectrin disrupt actin binding and dendritic arborization

S. A. Denha, N. R. DeLaet, A. W. Abukamil, A. E. Atang, A. W. Avery; Oakland University, Rochester, MI

Mutations in the *SPTBN2* gene encoding the cytoskeletal protein β-III-spectrin cause the neurodegenerative disease spinocerebellar ataxia type 5 (SCA5). SCA5 mutations localize to the β-III-spectrin actin-binding domain (ABD) and the neighboring spectrin-repeat domains (SRDs). Recently, we found that increased actin-binding affinity is a shared molecular consequence of ABD-localized mutations. Here, we report the molecular consequences of SCA5 mutations in SRDs 2 and 3, and study the functional impact of SRD mutations in neurons using *Drosophila*. Biochemically, we show that a 13 amino acid deletion in SRD 3, termed the American mutation (AM), increases actin-binding affinity. A five amino acid deletion in SRD 3, termed the French mutation (FM), also increases actin-binding affinity, but additionally results in a significant decrease in B_{max}. In contrast, R480W missense mutation in SRD 2, has little or no impact on actin binding. In *Drosophila* genetic rescue assays, pan-neuronal expression of fly β-spectrin transgenes containing human SRD 2 and 3 mutations rescue lethality caused by a *βspec*

loss-of-function allele. Interestingly, this indicates that the SRD mutants retain sufficient functionality in neurons to support animal viability. In contrast, conditional expression of SRD 2 and 3 β-spectrin mutants in class IV dendritic arborization sensory neurons dominantly induce arborization defects, suggesting a cellular mechanism of pathology. Altogether, our current analyses of SRD 2 and 3 mutations indicate that these mutations differentially impact actin binding and dendritic arborization. Moreover, our data suggest the interesting possibility that SRD 3 may play an important role in directly mediating or indirectly regulating β-III-spectrin actin binding. We are currently exploring the molecular mechanism of how SRDs influence actin binding. Additionally, we are testing if the SRD 2 and 3 mutations impact other properties of β-III-spectrin, such as heterodimerization with α-II-spectrin.

Motors: Myosins in Cellular Protrusions

B109/P1800

Impact of MYO3A Motor Properties on Actin Protrusion Length and Dynamics

J. A. Cirilo, Jr.[1], X. Liao[2], B. J. Perrin[2], C. M. Yengo[1]; [1]Department of Cellular and Molecular Physiology, Penn State Univ/Milton S Hershey Medical Ctr, Hershey, PA, [2]Department of Biology, Indiana University-Purdue University Indianapolis, Indianapolis, IN.

Vertebrate class III myosins exist in two isoforms, MYO3A and MYO3B, and localize to the tips of stereocilia in the inner ear. Mutations within the motor domain of MYO3A that alter its intrinsic motor properties have been associated with non-syndromic hearing loss, suggesting that the motor properties of MYO3A are critical for its function within stereocilia. Indeed, class III myosin transgenic knockout mouse models display dysregulated stereocilia length and morphology. In this study, we aimed to understand how the motor properties of MYO3A are fine-tuned for stereocilia elongation and length regulation. To address this question, we generated chimeric MYO3A constructs that lack the kinase domain (ΔK) and replace the MYO3A motor and first two IQ motifs with the motor and first two IQ motifs of other myosins (5A, 10, 15A, 1A, NM2A, and 7A). The resulting chimeras contained an N-terminal GFP, followed by the new motor and 2IQ of the other myosins and the MYO3A tail. Transfection into COS7 cells revealed duty ratio as a critical motor property that dictates the ability to tip localize within filopodia, while in vitro actin gliding velocities correlated with filopodial extension velocities. Filopodia length was unaltered, suggesting membrane tension becomes a dominant opposing force at longer lengths. Furthermore, we utilized similar constructs for two MYO3A hearing loss mutants, H442N and L697W. Interestingly, we found that H442N demonstrated an increase in tip localization within filopodia and an increase in filopodia extension velocity, while maintaining similar filopodial lengths. However, L697W resulted in similar tip localization, slower extension velocity, and shorter filopodia. Taken together, our data suggests a model in which tip-localized myosin motors exert force that slides the membrane tip-ward, which, along with actin polymerization forces, combat membrane tension to lead to protrusion elongation. We propose that both “gain of function” and “loss of function” mutations in MYO3A can impair stereocilia length regulation, which is crucial for stereocilia formation during development and normal hearing.

B110/P1801

Mechanistic Insights into the Regulation of Human Myosin-7a

A. Hollo[1,2], N. Billington[1,3], Y. Takagi[1], A. Kengyel[2], J. R. Sellers[1], R. Liu[1,3]; [1]NIH, Bethesda, MD, [2]University of Pecs, Pecs, HUNGARY, [3]Department of Biochemistry and Molecular Medicine, Morgantown, WV.

Human myosin-7a (Myo7a) is an actin-based motor protein essential for vision and hearing. It plays critical roles in the development and functions of actin rich protrusions such as filopodia, microvilli, and stereocilia. Previous studies using *Drosophila* homolog showed that myosin-7a is a monomeric, high duty ratio motor and can move processively upon dimerization. However, characterization of full-length mammalian myosin-7a has been limited by the difficulty of expressing and purifying stable, intact protein. Here, we report the production of a complete human myosin-7a holoenzyme in insect cells and study its regulation by intra- and intermolecular mechanisms. Distinct from *Drosophila* myosin-7a which primarily associates with calmodulin, we found that human myosin-7a utilizes regulatory light chain (RLC), calmodulin and calmodulin like protein 4 (CALML4) as the light chain subunits. CALML4 is recently discovered highly enriched in stereocilia and identified as a deafness candidate gene. We show that CALML4 does not bind to Ca^{2+} but plays a key role in regulating the dynamic binding of calmodulin to myosin-7a in response to Ca^{2+} signaling. The cochlea expresses two myosin-7a splicing isoforms differed by a short N-terminal extension. Using combined optical trapping, biochemistry, and *in vitro* motility assays, we show that the N-terminal extension greatly influences the enzymatic and mechanical behaviors of mammalian myosin-7a. We propose that the hair cell regulates its mechanosensitivity by adjusting the expression levels of the two myosin-7a isoforms. Finally, using single molecule motility assays, we show that purified full-length myosin-7a alone does not move processively on actin *in vitro*, but in the presence of MyRIP, a known myosin-7a binding protein in neuroretina, it exhibits processive movements. The motor-adaptor complex moves slowly along actin filaments (~ 4 nm/s) with prolonged actin attachment time (~ 150 s). Together, our results provide new molecular insight into how myosin-7a functions in hair cell stereocilia and neuroretina. The production of intact human myosin-7a protein enables future studies to understand the molecular details of human vision and hearing loss caused by myosin-7a defects.

Select autosomal dominant DFNA11 deafness mutations activate Myosin 7a

P. Acharya, G. Thapa, T. Nguyen, S. W. Crawley; Biological Sciences, University of Toledo, Toledo, OH.

Myosin-7a (Myo7a) is a motor protein that plays a critical role in the organization and function of stereocilia, specialized actin-based microvilli found on the apical surface of sensory epithelial hair cells of the inner ear that mediate hearing. Mutations in Myo7a underlie the pathology of various forms of hearing loss including autosomal recessive USH1B and DFNB2 and autosomal dominant DFNA11. Despite its importance, the cellular conditions that promote human Myo7a activity are not well understood. We used cultured kidney epithelial cells (LLC-PK1-CL4) as a model to investigate the mechanisms governing Myo7a activation, since they build prominent apical microvilli that act as surrogates to the native stereocilia found on inner ear hair cells. We observed that under basal conditions, Myo7a exhibited poor targeting to the apical microvilli of LLC-PK1-CL4 cells. In contrast, the addition of a calcium ionophore to the cells promoted Myo7a trafficking to the tips of microvilli, suggesting that this myosin may be regulated by calcium through the calcium-sensitive light chains associated with its lever arm. To explore this, we screened a directed site saturation library of lever arm mutants of Myo7a and identified specific

point mutations within the terminal fifth IQ motif (IQ5) that potently activated Myo7a targeting. Within IQ5, mutation of positions G849, I851, A852, and R853 had the most profound effect on promoting activity. This led us to test and discover that the autosomal dominant DFNA11 mutation R853C activates Myo7a, redefining the molecular etiology of this form of genetic deafness. Finally, we have identified that other autosomal dominant DFNA11 mutations found directly in the motor domain of Myo7a can also potently activate this myosin, giving us a possible structural roadmap to understand how the lever arm could inhibit motor activity. Together, these studies will shed light on the molecular basis of Myo7a-based sensory mutations, which may spur new clinical strategies for patient treatment.

B112/P1803

Myosin-7a mesa trail mutations activate the motor to cause autosomal dominant deafness

G. Thapa, P. Acharya, T. Nguyen, S. W. Crawley; Biological Sciences, University of Toledo, Toledo, OH.

Myosins are a large family of actin-based motor proteins that are involved in a diverse array of physiological functions, including muscle contraction, hearing, and vision just to name a few. As a result of this, mutations in this family can result in a variety of diseases depending on which myosin is impacted. Myosins are defined as a family by a conserved N-terminal motor domain that hydrolyzes ATP, converting chemical energy into mechanical work. Following the motor domain, myosins have a neck region comprised of a variable number of “IQ” motifs that associate with light chains. Upon ATP hydrolysis, the light chain-stabilized neck acts as a rigid lever arm that amplifies the small conformational changes that occur in the motor domain into a large displacement of the C-terminal tail. Importantly, the lever arm can also act as a point of regulation of certain myosins, through either phosphorylation or calcium binding to the light chains. Our lab has been studying Myosin-7a (Myo7a), a motor protein that plays critical role in the organization and function of the actin-based stereocilia of the inner ear that mediate hearing. We have discovered that the motor activity of Myo7a is potently regulated by its lever arm in a calcium-dependent manner, and that there are mutations that cause autosomal dominant deafness within the lever arm that interfere with this regulation. These mutations leave the myosin “constitutively on” even under low calcium conditions. We further discovered that there are autosomal dominant deafness mutations directly within the core motor domain of Myo7a that have the same effect of activating the motor, suggesting that the lever arm may fold back and directly interact with the motor to control its activity. Interestingly, these Myo7a motor domain mutations map to identical structural regions that lead to hypertrophic cardiomyopathy (HCM) in β-cardiac myosin. One of these regions in β-cardiac myosin forms a structural face known as the “mesa trail” that is involved in holding the myosin in an inactive state. Specifically, the mesa trail of β-cardiac myosin is proposed to interact with the lever arm-proximal S2 region of the myosin, locking it in an off state. Accumulating data suggests that HCM mutations in the β-cardiac myosin mesa trail are pathogenic because they prevent this interaction, resulting in a myosin that is constitutively available for muscle contraction. Given the similarities we see between Myo7a and β-cardiac myosin, we are currently testing the hypothesis that the lever arm of Myo7a folds back and interacts with a similar mesa trail found in Myo7a. These studies are expected to show that two physiologically divergent myosins, Myo7a and β-cardiac myosin, use a quasi-conserved structural basis to control their motor output.

Protrusion growth driven by myosin-generated force

G. N. Fitz, M. L. Weck, C. Bodnya, O. L. Perkins, M. J. Tyska; Vanderbilt University, NASHVILLE, TN

Actin-based protrusions are found on the surface of all eukaryotic cells, where they support diverse biological activities essential for life. Models of protrusion growth hypothesize that actin filament assembly provides the mechanical force for bending the plasma membrane outward. However, membrane-associated myosin motors are also abundant in protrusions, though their potential for contributing growth-promoting force remains unexplored. Using a novel inducible system that docks myosin motor domains to membrane binding modules with temporal control, we found that the application of myosin-generated force to the plasma membrane is sufficient for driving robust elongation of protrusions. Protrusion growth scaled with motor accumulation, required active, barbed end-directed force, and was independent of cargo delivery or the recruitment of canonical barbed end elongation factors. Application of growth-promoting force was also supported by structurally distinct myosin motor domains and membrane binding modules. We conclude that myosin-generated force can drive protrusion growth and this mechanism is likely active in diverse biological contexts.

B114/P1805

Ectopically expressed, "stiff-necked" MYO10 is capable of carrying out some of the functions of wild-type MYO10

E. L. Mecchi, D. F. Carpio, A. N. Snyder, M. Kim, O. A. Quintero-Carmona; Department of Biology, University of Richmond, Richmond, VA.

Myosin X (MYO10) is an unconventional myosin important in the formation and maintenance of actin-based protrusions known as filopodia. Like other myosins, it is hypothesized that the coordination of the release of ATP hydrolysis products, actin-binding, and a conformational change moves the lever-arm element relative to the motor domain leading to force-generation and motility. The lever arm consists of two distinct regions. The first region at the N-terminus is an alpha-helical region containing three IQ motifs and is capable of binding accessory proteins known as light chains, such as calmodulin and calmodulin-like proteins. It is hypothesized that the occupancy of the IQ motifs may be regulated by cytoplasmic calcium concentration, and that light-chain binding stiffens the lever arm allowing for more productive force-generation. The second region of the lever arm consists of a an additional extended stable single alpha-helix, hypothesized to extend the length of the lever arm, providing MYO10 with the appropriate geometry for efficient movement along the fascin-bundled actin found in filopodia. To begin to explore the role of the light chains, IQ motifs, and calcium in the regulation of MYO10 function, we generated a chimeric, GFP-tagged *Bos taurus* MYO10 molecule where the IQ-motif containing region of the lever arm was swapped for an equivalent length of the *Mus musculus* stable single alpha-helix (GFP-MYO10^{SN}). We hypothesized that if stability/stiffness of the IQ-domain region of the lever arm is important to MYO10 function, then swapping out the IQ domains for a similar length of stable alpha-helix would generate a protein with similar functional properties to what has been reported for wildtype MYO10 (GFP-MYO10^{WT}). When expressed in multiple cell types, GFP-MYO10^{SN} labeled the tips of filopodia in a manner similar to GFP-MYO10^{WT}. Filopodial extension velocities were similar between GFP-MYO10^{SN} and GFP-MYO10^{WT}. Expression of GFP-MYO10^{SN} in COS7 cells led to an increase in the number of filopodia at the periphery of the cell, as had been observed with GFP-MYO10^{WT} expression, but to a lesser extent than GFP-MYO10^{WT}. This is potentially due to some impairment in function, as the

filopodial initiation rate for GFP-MYO10^{SN} was less than what was observed for GFP-MYO10^{WT}. We hypothesize that this version of MYO10 may be less sensitive to changes in intracellular calcium concentration and/or light chain function, allowing us to make use of it to investigate the role(s) of the IQ motifs and the light chains in regulation of MYO10 functions as they relate to filopodia formation and regulation in cultured cells.

B115/P1806

Investigations into the calcium and light-chain regulation of MYO10 function in filopodial formation

A. N. Snyder, K. E. Reda, D. F. Carpio, E. L. Mecchi, M. Kim, O. A. Quintero-Carmona; Department of Biology, University of Richmond, Richmond, VA.

Myosin functions are regulated via light chains proteins, which interact with the IQ-motif containing regions of the lever arm. MYO10 is an unconventional myosin thought to play a functional role in the establishment of actin-rich protrusions known as filopodia. The force-transducing lever arm domain of MYO10 contains 3 IQ motifs capable of binding light chains such as calmodulin and calmodulin-like protein, & we chose to investigate whether alterations in intracellular calcium concentration or calmodulin function resulted in changes in MYO10 activity or filopodial stability. To test this hypothesis, we treated cells with ionomycin (a calcium ionophore) or W7 (a calmodulin antagonist) & assayed MYO10 and filopodial properties. Time-lapse imaging of a fluorescent calcium sensor (G-GECO1.2) verified that the treatment of cells with ionomycin increased intracellular calcium concentrations, while W7 treatment did not. Using scanning electron microscopy, we observed that filopodia on the dorsal surface of HeLa cells retract in response to ionomycin or W7. In both instances the effect can be partially reversed by washing out the drug. MYO10 localizes to the tips of filopodial protrusions, & quantitative immunofluorescence microscopy revealed that endogenous MYO10 localization to filopodial tips is sensitive to ionomycin or W7 treatment. Similar to the SEM results, washout of either drug resulted in an increase in MYO10 localization to filopodial tips. To investigate the potential role of the IQ motifs and light chains in regulating MYO10 localization, we used quantitative fluorescence microscopy to examine the localization of ectopically expressed MYO10 after ionomycin and W7 treatment using two different GFP-MYO10 constructs. The first construct was wildtype GFP-*Bos taurus* MYO10. The second construct was a chimeric GFP-*Bos taurus* MYO10 where the IQ motif containing region of the lever arm was replaced with an equivalent length of the stable single alpha-helix from the *Mus musculus* MYO10 lever arm. We predicted that swapping the IQ motif region with a stable alpha helix would make the chimeric MYO10 resistant to perturbations caused by changes in calcium concentration or light chain function. Tip localization of wild type GFP-MYO10 was sensitive to either ionomycin or W7 treatment, and could be recovered with washout, similar to what was observed for dorsal filopodia and endogenous MYO10 tip localization. “Stiff-necked,” chimeric GFP-MYO10 did not behave like wild type GFP-MYO10 with respect to tip localization, and was not completely resistant to ionomycin or W7 treatment. Taken together, these results indicate that more investigation is required to fully understand the role of calcium and light-chain function in the regulation of MYO10 activity in filopodial formation.

Motors: Myosins in Intracellular Transport

B116/P1807

Regulation of myosin V association and dissociation with an organelle-specific adaptor complex

H. Hahn[1], N. I. Pashkova[2], M. Cianfrocco[1], L. Weisman[1]; [1]University of Michigan, Ann Arbor, MI, [2]Department of Biochemistry, University of Iowa, Iowa City, IA.

Motor proteins contribute to the regulated distribution of intracellular cargoes. Here we focus on Myo2, an essential myosin V in the yeast *S. cerevisiae*. Myo2 moves multiple cargoes in yeast, which are carried to distinct locations at specific times. Myo2 achieves these itineraries via cargo-specific adaptor complexes. Myo2 is essential for the inheritance of the yeast vacuole. Early in the cell-cycle, Myo2 attaches to a portion of the vacuole via the Vac17 adaptor protein to bring it to the bud. However, little is known about how the assembly is regulated at the molecular level. To determine how Myo2 binds to Vac17, we focused on a region of Vac17 that is important for interaction with Myo2. We previously identified eight surface residues on Myo2 that bind specifically to Vac17. To gain insight into how this region interacts with Vac17, we used AlphaFold Multimer to predict the interface of this interaction. Notably, the model identified the eight known residues on Myo2 and predicted an additional five new sites in this region. This large region may contribute to the stabilization of the complex. The model also predicted that Vac17 directly binds to Myo2 in an extended state with twelve residues directly contacting Myo2. This region includes Vac17-I140 which was previously identified in a genetic screen designed to identify residues on Vac17 that directly contact Myo2. We also tested two additional residues on Vac17. Mutation of one, Vac17-R135E, resulted in a 35% defect in vacuole inheritance and when combined with an adjacent predicted contact site, Vac17-R135E, K138E resulted in 100% inheritance defect. Together these findings provide additional support for the AlphaFold model of the contact interface. Notably, the stretch of residues within the predicted Vac17 contact site include two serines, and similarly the predicted binding site on Myo2 includes a threonine. We are generating phospho-defective and phosphomimetic mutations of these residues to test whether phosphorylation of residues within the predicted contact contribute to the regulation of Myo2 association with Vac17. Thus, tests of the AlphaFold model suggest that aspects of the model are accurate and likely to reveal amino acids that contribute to regulation of Myo2 association and dissociation with the yeast vacuole.

Cingulin and Paracingulin Recruit Nonmuscle Myosins II to junctionsto Mechanoregulate the Apical membrane of Epithelial Cells

F. Rouaud[1], W. Huang[2], A. Flinois[1], K. Jain[1], E. Vasileva[1], T. DiMattia[1], M. Mauperin[1], D. A. D. Parry[3], V. Dugina[4], C. Chaponnier[1], I. Mean[1], S. Montessuit[1], A. Mutero-Maeda[1], J. Yan[1], **S. Citi**[1]; [1]University of Geneva, Geneva, SWITZERLAND, [2]University of Singapore, Singapore, SINGAPORE, [3]Massey University, Palmerston North, NEW ZEALAND, [4]Moscow State University, Moscow, RUSSIAN FEDERATION.

The apical junctional complex of epithelial cells consists of tight and adherens junctions and is associated with a highly organized actomyosin cytoskeleton, which instructs the shape and mechanical properties of the apicolateral plasma membrane. Nonmuscle myosin-2 (NM2) isoforms show distinct localizations at apical junctions, but the mechanisms underlying the spatial sorting of NM2s are unknown. We show that cingulin and paracingulin, cytoplasmic protein components of apical junctions, interact with nonmuscle myosins-2 through their C-terminal coiled-coil rod sequences. Cingulin interacts with NM2B

in an antiparallel arrangement to inhibit the assembly of the NM2B rod. In cultured epithelial cells cingulin recruits NM2B to tight junctions and binding of cingulin to NM2B is required for the junctional accumulation of ZO-1 and phalloidin-labelled actin filaments. Overexpression of either paracingulin or cingulin promotes the junctional accumulation of either NM2A and NM2B, or NM2B alone, respectively, whereas neither KO or overexpression of cingulin and paracingulin affect NM2C. Binding of cingulin, and to a lesser degree, of paracingulin to NM2s is required for the maintenance of TJ membrane tortuosity and apical membrane stiffness in MDCK cells. Finally, analysis of paracingulin-KO Eph4 cells shows that interaction of paracingulin with NM2s prevents tension-dependent fragmentation of AJ complexes into distinct junctional puncta. These results provide a molecular mechanism for the localization of NM2A and NM2B at junctions and indicate that cingulin and paracingulin transmit force from the actomyosin cytoskeleton to the apical junctional complex to fine-tune junctional architecture and the mechanics of the apical and junctional plasma membranes.

B118/P1809

Automated serial section electron microscopy and 3D reconstruction reveals role for Nonmuscle Myosin II (NM2) proteins in regulation of organelle structure and cargo transport within the thick ascending limb of the mouse kidney

B. Busselman[1], K. Otterpohl[1], J. Zimmerman[1], M. Mukherjee[1], M. Terasaki[2], I. Chandrasekar[1]; [1]Sanford Research, Sioux Falls, SD, [2]University of Connecticut Health Center, Farmington, CT

Mutations in *MYH9*, the gene that encodes the molecular motor nonmuscle myosin IIA protein (NM2A), result in kidney disease in one-third of human patients. Based on our previous work that demonstrated a novel role for NM2 motors in mammalian endocytosis, we hypothesized that NM2 isoforms might play a critical role in renal epithelial transport. To test our hypothesis, we generated an inducible pan renal tubular *Myh9&10* conditional knockout (cKO) mouse model. Loss of *Myh9&10* in adult mice resulted in progressive kidney disease of tubular origin. We determined that accumulation of the urinary glycoprotein uromodulin within expanded ER tubules and loss of ion cotransporter NKCC2 in epithelial cells of the thick ascending limb (TAL) of Henle's loop were the main cellular mechanisms that led to upregulation of ER stress/UPR pathways and kidney disease. We attempted to understand the molecular mechanisms involved in organelle transport *in situ* using mouse kidney sections. We employed immunostaining, light microscopy, and standard transmission electron microscopy, as well as an innovative automated serial section scanning electron microscopy method. TEM confirms ER tubule expansion as well as the unique nature of the organelle structure within the thick ascending limb epithelia in control kidneys. Additionally, RNA scope of kidney sections reveals UMOD mRNA throughout the TAL epithelia in control kidneys, while *Myh9&10* cKO kidneys with excessive UMOD protein accumulation in expanded ER tubules exhibit downregulated UMOD mRNA expression. To explore ER structure in an unbiased manner, we performed three-dimensional reconstructions of serial section SEM images and confirm that in control mouse kidneys, TAL epithelial cell mitochondria are partially encapsulated within basolateral plasma membrane infoldings that are positive for Na+ K+ ATPase by immunostaining. ER tubules are regularly present in the narrow space between mitochondria and membrane infoldings and are continuous with the expansive ER network present throughout the cell. In control TAL cells, we also observe widely distributed tubular vesicles in close contact with ER tubules. In *Myh9&10* cKO kidneys, spherical vesicular bodies with similar electron density are seen in close contact with morphologically abnormal ER, which appears to contain a larger number of sheets than control cells. While the plasma membrane appears intact in *Myh9&10* cKO TAL cells, the organization of

mitochondria within membrane infoldings is perturbed and ER-mitochondria-PM contact appears reduced. Overall, our findings indicate a distinct and complex ER-Mitochondria-PM structure interaction within the TAL epithelia *in situ* which requires the molecular motor nonmuscle myosin II for its organization and function.

B119/P1810

A type I myosin critical for clathrin-mediated endocytosis is a force-generating motor

R. T. A. Pedersen[1,2], A. Snoberger[3], S. Pyrpassopoulos[3], D. Safer[3], D. G. Drubin[1], E. M. Ostap[3]; [1]Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, [2]Department of Embryology, Carnegie Institution of Washington, Baltimore, MD, [3]Pennsylvania Muscle Institute and Department of Physiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA.

Actin filaments generate force through assembly, which produces pushing force, and through associated myosin motors, which produce pulling forces or tension. These modes of force generation work together in a wide variety of cellular processes, but how they are coordinated in these processes is an important, unanswered question. Clathrin-mediated endocytosis depends on both actin assembly and type I myosin activity to bend the plasma membrane into a pit that is subsequently released as a cytoplasmic vesicle, but the role of myosin motor activity in this process is unknown. Some myosin-1 motors generate forces of biologically relevant magnitude. If the myosin-1 motors involved in clathrin-mediated endocytosis possess this property, they might actively assist actin assembly in invaginating the plasma membrane. Other myosin-1 motors behave as tension-sensitive anchors. If endocytic myosins have this property, they are more likely to participate in endocytosis through organizing or anchoring actin filaments.
To distinguish between these possibilities, we studied the force-dependent kinetics of the ATPase cycle for the *Saccharomyces cerevisiae* endocytic myosin-1 Myo5, a motor whose role in endocytosis has been meticulously studied *in vivo*. Transient kinetic experiments conducted on Myo5 in solution revealed that Myo5 is a low-duty-ratio motor that is activated about 10-fold by heavy chain phosphorylation. Myo5 has a rapid working stroke compared to related myosins: its ADP release rate, which is rate limiting for detachment, is 74-100 per second, around 20 times faster than the related motors Myo1b and Myo1c. Single molecule analysis of Myo5 using an optical trap revealed that the Myo5 step size is 3.4 nm. The kinetics of the working stroke agree well with the bulk kinetic measurements. By applying resistance to the Myo5 working stroke using an isometric force clamp, we found that Myo5 stepping kinetics are relatively force insensitive. Quantitatively, the force sensitive kinetics of Myo5 are more comparable to muscle myosin than to related type I myosins. We propose that Myo5 acts as a force producer to augment actin assembly forces rather than as a tension-sensitive anchor during clathrin-mediated endocytosis.

B120/P1811

Conserved ankyrin repeat proteins promote myosin-1 localization and function in fission and budding yeast

A. H. Willet, J. Chen, L. Ren, K. L. Gould; Cell and Developmental Biology, Vanderbilt University, Nashville, TN.

Endocytosis is an essential cellular process where extracellular contents such as nutrients are taken up by the cell. To do so in yeast, the cell forms pits in the plasma membrane with force generated by a branched actin network nucleated by the Arp2/3 complex. One component of endocytic patches is the

myosin-1 family of motors. These are monomeric membrane tethering proteins with a N-terminal motor domain and C-terminal TH1, TH2, SH3 and in yeast a CA domain that activates Arp2/3. To better understand the interactions and function of fission yeast Myo1, we performed a large-scale purification coupled with mass spectrometry analysis and identified an uncharacterized non-essential protein containing ankyrin repeats that we named Mai1 (myosin-1 ankyrin repeat interactor). Coimmunoprecipitation of a series of Myo1 C-terminal truncations showed that the Myo1 motor domain alone is sufficient for Mai1 interaction. Further, whereas Myo1-mNG normally localizes to endocytic actin patches, a dramatic relocalization of Myo1 to coat the entire plasma membrane occurred in cells lacking *mai1*. Additionally, in *mai1Δ* cells, the Myo1 light chains, Cam1 and Cam2, also redistributed along the plasma membrane, but other endocytic proteins (Fim1, Wsp1 and F-actin) did not. Preliminary in vitro experiments confirmed previous work showing that immunopurified Myo1 bundles F-actin in vitro. However, Myo1 immunopurified from *mai1Δ* cells does not although it still binds F-actin, via a second actin binding motif in the C-terminus of Myo1, as found in other myosin-Is. Myo1 membrane binding is thought to be mediated by the TH1 domain. Thus, we hypothesize that Mai1 promotes the interaction of the Myo1 motor domain with F-actin and in the absence of F-actin binding, Myo1 localization defaults to the membrane in a TH1 domain-dependent manner. We found that a Mai1 ortholog exists in *S. cerevisiae* and it regulates the localization of both *S. cerevisiae* myosin 1s. Thus, Mai1 represents a novel, conserved myosin-I regulator.

B121/P1812

In Vitro Characterization of Myosin 5 on Biomimetic Actin Networks Using Micropatterning

D. Han[1,2], P. Bleicher[1], Y. Takagi[1], J. Sellers[1]; [1]National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, [2]Brown University, Providence, RI.

Myosin 5 is a processive motor protein involved in cellular transport processes along actin filaments. In order to study myosin 5's biophysical characteristics in networks of actin similar to those found within cells, we used micropatterning techniques to grow organized actin networks on a glass coverslip. GFP-labeled myosin 5 was added to the assay after full polymerization of the actin. Its activity was recorded using TIRF microscopy, and ImageJ's TrackMate was used to quantitatively characterize its movement. We compared myosin 5's velocity, run length, and dwell time in the micropatterned assay to a single filament assay under the same conditions. While there were not significant differences in the measurements between the assays, the velocities and run lengths were found to be consistently higher in the micropatterned assay. The paths that were generated by TrackMate also showed jagged trajectories in the micropatterned assay which were absent in the single filament assay. By capturing the movement of the actin filaments in tandem with myosin 5's movement under greatly reduced ATP concentrations, we showed that the thermal fluctuations of the actin network had an additive effect to the apparent velocity and run length in the micropatterning assay. Additionally, these thermal fluctuations are the most likely reason for the jagged paths taken by myosin 5. Unlike myosin 2, myosin 5 did not show any ability to alter the structure of the actin network while interacting with it. In conclusion, we found that micropatterned assays are an effective system to study actin-myosin interactions. Myosin 5's velocity, run length, and dwell time in the micropatterned assay was comparable to single filament assay studies, and differences in myosin 5's movement could be attributed to thermal fluctuations of the actin network.

Motors: Kinesins in Organelle Dynamics

B122/P1813

Optogenetic motor inhibitors reveal the contributions of kinesins-1, -2, -3, and dynein to endosome and lysosome transport

S. Nagpal, S. Wang, K. Swaminathan, A. Hendricks; Department of Bioengineering, McGill University, Montreal, QC, CANADA.

Multiple kinesins and dynein are often simultaneously associated with intracellular cargoes. To dissect the roles of these motors, we developed optogenetic tools to temporally control the activity of kinesin-1 (KIF5), -2 (KIF3A/B), -3 (KIF1), and dynein. Inhibitory peptides were cloned onto the LOVTRAP optogenetic system that is comprised of two components, the mitochondria-bound Z-dark and the photo-responsive LOV2 which unbinds from Z-dark when illuminated with blue light. The inhibitory peptides for kinesin motors are based on their native autoinhibitory domains. For dynein inhibition, we used the CC1 domain from p150glued that prevents the formation of an active dynein-dynactin complex. In agreement with previous studies, early endosomes are most sensitive to inhibition of kinesin-1, kinesin-3, and dynein, while late endosome and lysosome motility is altered by inhibition of kinesins -1, -2, -3, and dynein. However, while sustained inhibition of either kinesins or dynein results in reduced motility in both directions, transport is enhanced on both early and late endosomes when kinesin-1 or dynein is transiently inhibited. These results indicate that on vesicles transported by many motors, motility can be directed by modulating the activity of a single type of motor on the cargo.

B123/P1814

The sets of kinesins and dyneins transporting endocytic cargoes governs their response to tau

A. G. Hendricks[1], D. Beaudet[1], L. Balabanian[1], C. L. Berger[2]; [1]McGill University, Montreal, QC, CANADA, [2]University of Vermont, Burlington, VT.

As endosomal cargoes progress through the degradative pathway, the types and numbers of kinesins and dyneins driving their transport changes. In turn, these sets of motors dictate how cargoes move and respond to microtubule-associated proteins. We isolated early (30 minutes) and late (90 minutes) phagosomes and counted the motors bound to them using immunofluorescence and stepwise photobleaching. While kinesin-1 (KIF5B), kinesin-2 (KIF3A/B), kinesin-3 (KIF16B), and dynein associate with both early and late phagosomes, early phagosomes have fewer kinesin-1, kinesin-2, and dynein bound. The sets of motors on early phagosomes are heterogenous and there are fewer motors bound to each phagosome compared to late phagosomes. Early phagosomes exhibit long, directed runs towards the microtubule minus end *in vitro*, in contrast to late phagosomes which switch directions frequently. On tau-decorated microtubules, the long, dynein-driven runs of early phagosomes and are strongly inhibited. While on late phagosomes, tau preferentially inhibits kinesin forces to bias their bidirectional motility towards the microtubule minus end. In agreement, high-resolution tracking of organelles in cells expressing tau show that early endosomes are inhibited more strongly by tau than lysosomes. Further, a phosphomimetic (Y18E) mutation to tau partially relieves inhibition of lysosomes, while early endosomes are strongly inhibited by both unphosphorylated and phosphomimetic tau. Through counting the motors bound to cargoes, reconstituting their motility *in vitro*, and tracking their motility in living cells, we show that sets of motors associated with endocytic cargoes changes throughout maturation, altering the effect of tau on their motility.

B124/P1815

Role of microtubule motor adaptor proteins in controlling mitochondrial inheritance and quality

M. J. Gillen[1,2], R. Cox[1]; [1]Biochemistry and Molecular Biology, USUHS, Bethesda, MD, [2]Henry M. Jackson Foundation for the Advancement of Military Medicine, Inc., Bethesda, MD.

Conflict of Interest The authors have no conflicts of interest

Mitochondria are an essential cell component that are exclusively maternally inherited. Mitochondria have their own genomes, mitochondrial (mt) DNA and accumulating mtDNA mutations is a significant cause of mitochondrial disease. However, studies have shown mitochondria with deleterious mtDNA are typically not passed on to progeny at a rate expected if mitochondrial inheritance was random, suggesting there is a purifying mechanism from one generation to the next. Drosophila and mouse studies have shown this potential selection occurs early in development and at least partly happens during oogenesis. Germline cyst formation is conserved from humans to Drosophila. Since mitochondria are moved via motor proteins along microtubules, we are interested in whether mitochondrial movement during follicle development in Drosophila potentially contributes to a quality control mechanism to filter damaged organelles deposited into the oocyte. To do this, we are studying the Milton/Miro cargo adaptor complex that links mitochondria to the motor protein kinesin and dynein. Miro is an atypical GTPase with a transmembrane domain that inserts in the mitochondrial outer membrane. Milton is an adaptor protein that binds to Miro. Our previous work showed that Class II *milton* alleles cause uncontrolled mitochondrial movement into the oocyte starting with region 3 of the germarium and continuing until approximately mid-oogenesis. This phenotype is phenocopied by germ cells lacking Kinesin heavy chain. Studies of the vertebrate Milton homolog, TRAK1 and 2, have shown TRAK1 binds Kinesin and Dynein/Dynactin to control mitochondrial movement, however, this has not yet been established for Drosophila Milton. We will present our data examining all the Milton isoforms and how altering isoform levels controls mitochondrial movement during oogenesis. One goal of this study is to understand the basic mechanism of how Milton and Miro control mitochondrial movement along microtubules. In addition, this study could help identify part of the mitochondrial quality control system governing mitochondrial inheritance. This could have implications for maternally inherited forms of mitochondrial disease.

Endoplasmic reticulum and peroxisomes hitchhike on motile endosomes.

S. Abeling, **A. Morrissey**, B. Driscoll, E. Wagner, J. Salogiannis; Molecular Physiology and Biophysics, Larner College of Medicine At the University of Vermont, Burlington, VT.

Cargos (mRNA, organelles, and vesicles) are driven long distances on microtubules via molecular motors. The canonical view of microtubule-based transport is that adaptor proteins are required to recruit these cargos to the motors. Our group along with others discovered an alternative mode called membrane

hitchhiking: some organelles achieve motility by tethering to or 'hitchhiking' on moving endosomes. The mechanisms of hitchhiking are not well understood, but likely require tethering between membranes at contact sites. Hitchhiking represents a paradigm shift in how we think about cargo motility. Here, we present molecular and genetic data to determine how it is achieved. In the filamentous fungus Aspergillus nidulans, peroxisomes cotransport on Rab5-positive early endosomes. To accomplish this, peroxisomes utilize novel endosomal binding proteins, PxdA and DipA. We performed a mutagenesis screen and identified additional factors involved in peroxisome hitchhiking. In mammalian cells, we find that coordinated movement of peripheral ER tubules rely on attachment to Rab1- and Rab6-positive endosomes. Using a rapalog-inducible system, stopping the movement of specific endosomal populations concomitantly reduces the movement of ER tubules. Taken together, our data suggests that membrane hitchhiking occurs in multiple organisms and represents a novel mechanism for how cargos move along microtubules.

Co-operation of KIF1C and dynein in bidirectional cargo transport

A. J. Zwetsloot[1], C. Stone[2], C. Lau[2], F. Abid Ali[2], A. Carter[2], **A. Straube**[1]; [1]Centre for Mechanochemical Cell Biology, University of Warwick, United Kingdom, [2]MRC Laboratory of Molecular Biology, Cambridge, United Kingdom

The kinesin-3 KIF1C and cytoplasmic dynein are fast long-distance transporters with opposite polarity. Here we show that both motors can bind simultaneously to cargo adapters hook3, BICD2 and BICDR1 to form co-motile complexes, with quaternary complexes of dynein, dynactin, hook3 and KIF1C (DDHK) forming most efficiently. Using a rapamycin-induced cargo transport assay in cells, we found hook3 driven intracellular transport is rapid, bidirectional, and sensitive to the concentration of active KIF1C and dynein. DDHK complexes show bidirectional motility in single molecule microscopy assays, and provide evidence for co-dependence of opposite polarity motors as KIF1C increases both the initiation and the distance of minus end-directed runs, both by acting as a processivity tether and because KIF1C facilitates the recruitment of a second dynein to dynactin and hook3. Based on intensity measurements of motile complexes we propose a stoichiometry of two dynein dimers, two KIF1C dimers, two hook3 dimers and one dynactin in DDHK complexes. Directional switching of DDHK complexes was relatively rare, suggesting that the tight coupling of the motors primarily supports processive unidirectional transport and prevents a tug-of-war.

Regulation of kinesin-2 motors in the sensory cilia of *C. elegans*

W. Mul, A. Mitra, E. J. G. Peterman; Vrije Universiteit Amsterdam, Amsterdam, Netherlands

Most eukaryotic cells contain a primary cilium, which acts as an antenna to sense the environment and is involved in a wide range of signalling pathway essential for development. Cilia consist of a microtubule-based axoneme that acts as a track for bidirectional intraflagellar transport (IFT) of ciliary components, necessary for correct functioning of the cilia. In *C. elegans*, movement of anterograde IFT trains from ciliary base to tip is driven by the concerted action of two kinesin-2 motor proteins, kinesin-II and OSM-3. The slower kinesin-II navigates the IFT trains through the densely packed transition zone and proximal segment, handing over the IFT trains to the faster OSM-3 motors for transport further along the cilium. The regulatory mechanism that controls the cooperation between kinesin-II and OSM-3

remains elusive, although previous studies have suggested that the kinases DYF-5 and DYF-18 (RCK and CCRK orthologs) play a crucial role. Here, we perform quantitative fluorescence microscopy in mutant *C. elegans* strains that lack DYF-5, in order to understand how this kinase affects kinesin-2 motor cooperation. We find that the cilia of these dyf-5 knockout (KO) animals are longer and vary markedly in length. In addition, kinesin-II is distributed differently along the cilia of these animals: throughout the cilium in the mutant, in contrast to the beginning of the proximal segment in wild-type. Moreover, we find that kinesin-II often accumulates at the tip of the cilium in the mutant. Next, we looked into the single-molecule dynamics of kinesin-II in WT and dyf-5 KO animals. We observed that the velocity of the individual kinesin-II motors appears to be reduced in the absence of DYF-5 and that motors pause at the accumulation sites. These results provide mechanistic understanding in the role of kinases in kinesin-2 motor regulation.

KIF3B promotes a perpendicular PI3K signaling gradient that regulates the Shh protein gradient and suppresses polydactyly

S. Wang, **Y. Tanaka**, Y. Xu, S. Takeda, N. Hirokawa; University of Tokyo Grad Sch Med, Tokyo, Japan

Digit determination in limb buds is driven by a posteriorizing Sonic hedgehog (Shh) protein gradient; however, the formation mechanism is largely unknown. Here, we propose a diffusion-and-trapping hypothesis for Shh nanoparticle gradient formation by analyzing the preaxial polydactyly phenotype of KIF3B motor hypomorphic mice. In the limb buds, a distal-to-proximal gradient of fibroblast growth factor (FGF)-phosphatidylinositol 3-kinase (PI3K) signaling and a posterior-to-anterior gradient of Shh nanoparticles were disorganized. This phenotype was reproduced by transplanting FGF8b-soaked beads. At the subcellular level, KIF3B transported the phosphatase and tensin homolog (PTEN)-like phosphatase Talpid3 to terminate PI3K signaling. High and low PI3K signaling strengths differentially sort endocytosed Shh nanoparticles toward unconventional exosomes and cytonemal punctata, respectively. These results indicate that the distal and proximal layers constitute diffusion-and-trapping kinetics of Shh nanoparticles, which sustainably form a horizontal gradient along the edge of developing limb buds. (W.S. and Y.T.: Equal contribution)

B129/P1820

Kinesin-1 autoinhibition facilitates the initiation of dynein cargo transport

R. Qiu, J. Zhang, X. Xiang; USUHS/HJF, Bethesda, MD

Kinesin-1 is normally autoinhibited, but the functional significance of kinesin-1 autoinhibition would need to be further dissected. In filamentous fungi and neurons, kinesin-1 transports multiple cargoes including cytoplasmic dynein to the microtubule plus ends. In filamentous fungi, dynein motors accumulated at the microtubule plus ends interact with early endosomes transported there by kinesin-3 rather than by kinesin-1. Dynein then drives the movement of early endosomes away from the microtubule plus ends. From a genetic screen for *Aspergillus* mutants defective in dynein-mediated early endosome transport, we identified a kinesin-1 mutation *kinA*^{K895*} that affects the C-terminal IAK motif well-known to be involved in kinesin-1 autoinhibition. To verify that dynein-mediated early endosome transport is negatively affected by the loss of IAK-mediated autoinhibition rather than the loss of other C-terminal residues, we made the *kinA*$^{\Delta IAK}$ and the *kinA*^{K895E} mutants. These mutants exhibited a defect in dynein-mediated early endosome transport similar to that of the *kinA*^{K895*} mutant. All the mutant

proteins accumulate abnormally near the microtubule plus ends, indicating a loss of kinesin-1 autoinhibition. Besides dynein, RabE-labeled secretory vesicles are also cargoes of kinesin-1 in *A. nidulans*. We show that kinesin-1 autoinhibition does not play a critical role in transporting secretory vesicles to support hyphal growth. Dynein also accumulates normally at the microtubule plus ends in the *kinA*^{K895*} mutant. However, the frequency but not the speed of dynein-mediated early endosome transport is significantly decreased, indicating that kinesin-1 autoinhibition facilitates dynein to initiate its cargo transport. Furthermore, kinesin-1 autoinhibition promotes dynein cargo initiation in a way mechanistically distinct from LIS1-promoted dynein switching from its autoinhibited form. Thus, while dynein activation involves dynactin, cargo adapter and LIS1, this study adds kinesin-1 autoinhibition as a new regulatory factor in vivo.

B130/P1821

Rapid accumulation of RhoGEF at the cleavage furrow is driven by centralspindlin-mediated transport and retention at plus-end tips

B. Warecki, **L. Tao**; University of Hawaii at Hilo, Hilo, HI

Cytokinesis, the physical division of one cell into two, requires accurate positioning of the cleavage furrow between segregating chromosomes. Failure to properly position the cleavage furrow can result in aneuploidy and is a hallmark of cancer cells. However, key aspects of the molecular mechanisms that govern where the cleavage furrow forms remain poorly understood. Furrow formation is specified by localization of the RhoA-activator RhoGEF, which leads to local membrane ingression. RhoGEF binds to the conserved motor protein complex centralspindlin. This has led to multiple models for how centralspindlin activity positions RhoGEF at the cleavage furrow: 1) centralspindlin sequestration of RhoGEF at microtubule plus-end tips, or 2) direct centralspindlin-mediated RhoGEF transport along microtubules. Here, using a combination of in vivo and in vitro experiments, we show that centralspindlin utilizes both mechanisms to position RhoGEF. We find that purified full-length centralspindlin directly transports its native cargo RhoGEF along single microtubules. Furthermore, we find that RhoGEF binding to centralspindlin may stimulate centralspindlin motor activity. Following transport, centralspindlin retains RhoGEF at the plus-end tips for an extended time. Additionally, we find that this retention on microtubules is an inherent behavior of centralspindlin. Thus, centralspindlin can stockpile at microtubule plus-ends to bind diffuse RhoGEF. Collectively, these results demonstrate that centralspindlin's motor activity and strong association with microtubules rapidly generate a high concentration of RhoGEF at areas where plus-end tips are abundant, such as at overlapping aster microtubules at the cell equator, to specify the position of cleavage furrow formation.

Armadillo repeat-containing kinesin ARK represents the versatile plus-end-directed transporter in plants

M. Yoshida[1], M. Hakozaki[1], G. Goshima[2]; [1]Nagoya University, Nagoya, Japan, [2]Nagoya University, Toba, Japan

Kinesin-1 (also known as conventional kinesin) and cytoplasmic dynein are widely utilised for microtubule-based transport in animal cells. Intriguingly, plants do not possess kinesin-1, despite that bidirectional transport along microtubules is still observed in plant cells. A plant motor required for plus-end-directed ("anterograde") transport of various cargos, similar to kinesin-1 in animals, has not been

identified. In this study, we investigated the function of plant-specific armadillo repeat-containing kinesin (ARK) in the moss *Physcomitrium patens* and provided evidence that ARK is the long sought-after versatile anterograde transporter of plants. Firstly, ARK was shown as a processive motor *in vivo* and *in vitro*. Next, in *ARK* mutants, we found that microtubule plus-end-directed motility of nuclei, chloroplasts, mitochondria, and secretory vesicles is drastically suppressed. Ectopic expression of the rigor mutant or tail-deleted ARK in the mutant indicated that organelle distribution requires ARK's motility and the tail. Furthermore, the suppression of cell tip growth, the most prominent macroscopic phenotype of the *ARK* mutants, was attributed to the mislocalisation of actin regulators, including GEFs of Rho-type GTPase. Expression and forced apical transport of RopGEF3 suppressed the growth phenotype of the *ARK* mutant. The result indicates that the anterograde motility of ARK supports the polarised cell growth through localising actin regulatory molecules to the growth site. This scheme is similar to what has been revealed in other cell types, including fission yeast, filamentous fungus, and epithelial cells. Thus, long-distance transport of polarisation factors along microtubules may be a general scheme for polarised growth in a wide range of eukaryotic cells.

B132/P1823

A DNA tensiometer technique for studying detachment kinetics of microtubule motors involved in bidirectional transport.

C. R. Noell, R. Jiang, A. Gicking, W. O. Hancock; Pennsylvania State University, State College, PA

Bidirectional transport is essential for cargo trafficking in cells and is required for proper growth and cell division. Kinesin and dynein are microtubule motors responsible for bidirectional cargo transport in cells. Defects in microtubule motor-based transport are linked to many neurodegenerative diseases including Alzheimer's, Parkinson's, spinal muscular atrophy, amyotrophic lateral sclerosis, and Huntington's disease; thus, understanding the mechanisms underlying bidirectional transport is crucial to understanding transport deficiencies in disease states and developing potential treatments. Despite important advances in understanding the mechanochemical properties of individual motors, many questions remain regarding how motors work as teams, and how kinesins and dyneins coordinate with one another. The 'tug-of-war' model is a widely supported model for bidirectional transport; however, this model cannot account for the motor coordination and other regulatory factors involved. Previous modeling work identified the load-dependent detachment rate as the key parameter that determines whether kinesin or dynein wins in a motor tug-of-war. Recent experimental and theoretical work showed that vertical forces inherent to the geometry of the widely-used single-bead optical tweezers significantly accelerated motor detachment rates. Consistent with this, when kinesin and dynein were connected through DNA linkages such that forces are only parallel to the microtubule, these two-motor complexes remained attached for much longer times than seen in optical tweezer experiments. In this work we propose a novel technique that uses ssDNA as a pN-scale spring, to accurately determine motor stepping characteristics and detachment kinetics in the absence of vertical forces, mimicking physiological conditions. Here we show preliminary data of our DNA tensiometer work in the study of bidirectional transport.

The kinesin KIF16B regulates MT1-MMP fast recycling inmacrophages

S. Hey, C. Wiesner, **S. Linder**; University Clinic Eppendorf, Hamburg, Germany

Membrane-Type 1 Matrix Metalloproteinase (MT1-MMP) serves critical functions during many physiological processes (e.g. vascular development, immune cell migration), through cleaving of components of the extracellular matrix (ECM) and also of cell surface-associated proteins. It is thus crucial for the capability of macrophages to proteolytically invade into different tissues. However, matrix proteolysis allows also cancerous cells to spread faster during metastasis, most likely by using the microchannels created by spreading macrophages. These tumor associated macrophages (TAMs) are linked with poor prognosis for cancer patients. Limiting the capability of TAMs to degrade the ECM thereby could serve as a potential therapy to limit cancer invasion. By using primary human macrophages, we aim to unravel the processes that regulate MT1-MMP surface exposure in more detail. One major regulatory step in this regulation is the recycling of endocytosed MT1-MMP back to the cell surface. Our work focuses on identifying the protein network that regulates the fast recycling processes of MT1-MMP. Previously, we could show that exocytosis of MT1-MMP is controlled by Rab8a and driven by kinesin-1 and -2. We could also show that the fast recycling by Rab14 positive vesicles is crucial for regulating the surface associated pool of MT1-MMP. However, the respective motor protein driving these vesicles remained unidentified. We now identify KIF16B as the major kinesin regulating MT1-MMP fast recycling processes in primary human macrophages. Using live cell imaging, siRNA mediated depletion, expression of mutant proteins and also of rescue constructs, as well as FACS measurements and surface biotinylation assays, we demonstrate that KIF16B-mediated recycling of MT1-MMP is a critical mechanism for regulation of MT1-MMP surface levels and thus also of the ECM degradation ability of macrophages. Furthermore, we show that a KIF16B depletion in macrophages can also reduce the growth of tumor spheroids *in vitro*, highlighting the close relation between immune cells and cancer cell invasion.

Microtubules in Development

B135/P1825

Microtubule organization regulation by SCAPER homolog in *C. elegans* DA9 neuron

Y. Xie, S. Yogev; Yale University, New Haven, CT.

Neurons rely on the highly dynamic microtubule (MT) cytoskeleton to execute essential processes such as neuronal development, axon guidance, synapse formation, intracellular trafficking, and signal transduction. Neurodegenerative diseases like Alzheimer's disease, and neuronal injuries are often associated with gradual loss of dendritic and axonal microtubule mass. Extensive studies have shown how neuronal MT are regulated, however, how MT organized, specifically how MT numbers are precisely regulated for specific functions in individual neurons is not well understood. To study how MT mass is regulated, we performed a forward genetic screen for disorganized microtubule networks and found a mutant in the *C. elegans* homolog S Phase Cyclin A-associated protein in the ER (SCAPER), displayed microtubules disorganization. Here, we use genetic and superresolution microscopies to illustrate the essential functions of SCAPER on microtubule organization regulation. We find that endogenous and overexpression of SCAPER show punctate structures overlapping with MT minus-end marker Patronin (PTRN-1) in cell body and neuron projections. The loss-of-function allele of *scaper* we

generated by CRISPR causes MT number decrease in *C. elegans* DA9 neuron. Specifically, *scaper* loss-of-function causes enlarged spacing of the MT minus-ends labeled by PTRN-1. In the distal axon, discontinuance of MT has been observed. We propose that the sparse MT minus-end and distal MT gaps are due to lack of MT mass. Meanwhile, overexpression of SCAPER induces microtubule number increase. Moreover, we also determine that SCAPER N-terminal domain is required for MT organization function, and there are uncharacterized domains essential for SCAPER specific localization in C-terminus. Therefore, we hypothesize that SCAPER functions for MT nucleation and regulates MT organization.

B136/P1826

Doublecortin contributes to neuronal migration through suppression of neurite branching and modification of the tubulin code

M. Sébastien, E. Prowse, H. Mary, A. Hendricks, G. J. Brouhard; McGill University, Montréal, QC, CANADA.

Doublecortin is a neuronal microtubule-associated protein (MAP) that binds directly to microtubules via two Doublecortin (DC) domains. The DC domains are very sensitive to the nucleotide state, longitudinal curvature, and protofilament number of the microtubule lattice, indicating a role in the regulation of microtubule structure in neurons. Mutations in Doublecortin cause lissencephaly and subcortical band heterotopia (also known as double-cortex syndrome), which are diseases caused by impaired neuronal migration. To better understand the role of DCX in neuronal migration, we developed a model system based on induced pluripotent stem cells (iPSCs). We knocked out the *Dcx* gene in a male iPSC line using CRISPR/Cas9 gene editing and differentiated the cells into cortical neurons. Compared to control neurons, the DCX-KO neurons showed reduced velocities of nuclear displacements, consistent with a neuronal migration phenotype. The reduced velocities correlated with an increase in the number of branches early in the neuronal development process, a result that is consistent with data from a DCX-KO mouse model. Neurite branching is regulated by a host of MAPs and other protein factors, as well as by microtubule dynamics itself. Microtubule dynamics were unchanged in DCX-KO neurons, however, with similar growth rates, lifetimes, and numbers, as measured by live-cell imaging of EB3-mCherry electroporation. Rather, we observed changes in microtubule post-translational modifications, also known as the tubulin code, namely a significant reduction in polyglutamylation. Polyglutamylation is usually abundant in neurons and regulates, for example, microtubule severing enzymes and intracellular trafficking by molecular motors. Consistently, we observe that lysosomes in DCX-KO neurons show an increase in anterograde processive motility. We propose that the reduction of polyglutamylation leads to increased neurite branching and thus reduced neuronal migration. Our results indicate an unexpected role for DCX in the homeostasis of the tubulin code.

B137/P1827

The Role of Kinesin-1 Mediated Microtubule Sliding in Regulation of Insulin Secretion

K. M. Bracey, M. Fye, G. Gu, I. Kaverina; Cell and Developmental Biology, Vanderbilt University, Nashville, TN.

Pancreatic beta cells have to secrete only a sub-population of available insulin granules to reduce blood sugar to normal levels but yet avoid hypoglycemia. This requires tight coordination between intracellular insulin storage and secretion. We have previously shown that cytoskeletal polymers microtubules (MTs) critically govern this coordination.Molecular motors use MT tracks to transport and park insulin granules

at specific cellular locations. In beta cells, MT network is complex, with interlocked, non-radial network in the cell interior, where secretory insulin granules are trapped by looped transport, and the sub-membrane MT bundle, which promotes insulin granule withdrawal from the secretion sites. Due to these features, MT network limits insulin secretion in healthy beta cells. Given a spike in glucose concentration the microtubule network is remodeled to allow for robust secretion. Here, we report that motor-dependent repositioning of existing MTs is an essential feature of glucose-triggered MT remodeling.Using real-time imaging of microtubules labeled with single-molecule fiducial marks, we demonstrate that high levels of glucose rapidly induce MT movements. Kinesin-1, a molecular motor that is highly expressed in beta cells and activated downstream of glucose signaling, is capable of transporting MTs along MT tracks, a process known as MT sliding. We found that glucose-triggered MT movements are abolished by inactivation of kinesin-1 or introducing mutations preventing attachment of MTs as a cargo. We show that microtubule sliding is important for cellular distribution of MT minus ends and is influencing the overall MT directionality and architectural features. This means that kinesin-1 likely has a dual role in insulin secretion regulation: directly, via insulin granule transport, and indirectly, via remodeling MT network.Ongoing work will utilize kinesin-1 mutant incapable of microtubule sliding but capable of insulin granule transport, combined with computational simulations, to reveal the specific contributions of MT sliding into regulation of insulin granule positioning and secretion.Overall, here we show a novel mechanism whereby glucose stimulation induces MT network remodeling, and, subsequently, MT-dependent control of insulin granule transport for secretion.

B138/P1828

ER network stability promotes organized microtubule disassembly during Compartmentalized Cell Elimination

K. Juanez, M. P. Jones, P. Ghose; University of Texas At Arlington, Arlington, TX

Programmed cell death is vital for development and homeostasis. Morphologically complex cells are characterized by elaborate processes, such as axons and dendrites in neurons. While complex cells are common, their programmed as well as pathological or injury induced elimination is poorly understood. Microtubule (MT) disassembly is linked to region-specific neurite pruning, but the exact nature of this relationship is unknown. We discovered a ‘tripartite’ killing program with stereotyped cellular dynamics that eliminates the morphologically complex tail-spike cell (TSC) and the sex-specific CEM neurons in the *C. elegans* embryo. This program, called Compartmentalized Cell Elimination (CCE), is characterized by three cell regions dying in three disparate ways. Notably, the single process/dendrite of these cells displays two very different elimination morphologies in its two segments. The proximal segment fragments in a manner strikingly reminiscent of developmental pruning or injury-induced Wallerian degeneration of axons; whereas the distal segment retracts, much like nutrient-deprived axons. Here we report that MTs have stereotyped dynamics throughout the development and death of the TSC. Through forward genetic screens, we found that genes promoting endoplasmic reticulum (ER) network stability, *atnl-1*/Atlastin and *lnp-1/*Lunapark, which encode the homologs of human Atlastin GTPase and Lunapark, promote process dismantling during CCE. We find that *atnl-1*/Atlastin and *lnp-1*/Lunapark promote the function of the conserved MT-severing ATPase SPAS-1/Spastin in facilitating CCE. Human Atlastin, Lunapark and Spastin are all associated with neurodegenerative conditions. Fluorescent reporters for the ER, SPAS-1/Spastin and MTs dynamically change in distribution as the TSC develops and dies and MTs show abnormally gross enrichment in the TSC process in ER network stability and SPAS-1/Spastin mutants, suggesting hyperstability of MTs. We propose that the stable ER network and

ER network stability proteins anchor SPAS-1/Spastin to allow for precisely targeted and organized MT disassembly, culminating in the highly defined dynamic demise of the TSC process during CCE. Our findings shed new light on the localized elimination of complex cells and illuminate the link between MTs, pruning and neurodegeneration through an unexpected connection with the ER.

B139/P1829

A distinct gamma-tubulin complex is required for spermiogenesis in Drosophila

E. Wight[1], J. V. Chen[1], C. Zheng[1], G. Callaini[2], T. L. Megraw[1]; [1]Florida State University, Tallahassee, FL, [2]University of Siena, Siena, ITALY.

We investigated the functions of variant γ-tubulin complex proteins that are expressed in the Drosophila testis, and their potential to form unique complexes that function distinctly from conventional γ-tubulin complexes. The γ-Tubulin Ring complex (γ-TuRC) is the primary microtubule nucleator at centrosomes, the main microtubule organizing center (MTOC) in dividing cells. The molecular structure of the conserved γ-TuRC was recently solved at high resolution. The γ-TuRC is comprised of a ring of γ-tubulin and Gamma-tubulin Ring Interacting Proteins, (GRIPs, aka GCPs). While γ-TuRCs are highly conserved throughout eukaryotes and associate with a variety of proteins that bind/anchor them at MTOCs, heterogeneity in the γ-TuRC core has been relatively unexplored. Three unique GRIP proteins that contains conserved GCP interacting domains are expressed in testis, collectively called t-GRIPs. In the testes, t-GRIPs form a distinct complex whose subunits favor interactions with each other over their conventional counterparts, and t-GRIPs have a distinct function in the maturation of post-meiotic spermatids into motile sperm. The 'conventional' GRIP proteins are also expressed in testis, and mutations in those genes disrupt cell division. In contrast, mutations in *t-GRIPs* do not impact cell division but impair post-division spermiogenesis and male fertility. Moreover, ectopically expressed t-GRIPs are absent from spermatocyte centrosomes, indicating that they do not associate with conventional GRIPs *in vivo*. However, when over-expressed in early embryos, we detect weak interactions between GRIPs and t-GRIPs, resulting in centrosome recruitment and disruption of division cycles. In post-meiotic spermatids, a splice variant of centrosomin, CnnT, recruits γ-TuRCs to the surface of the mitochondria converting them to a MTOC. However, CnnT recruits conventional GRIPs but not t-GRIPs to spermatid mitochondria. The t-GRIPs localize to an MTOC called the centriolar adjunct and are required to recruit γ-tubulin there. In *t-grip* mutants, no overt perturbations of the flagellar axoneme account for the lack of spermatid motility; rather, the maturation and integrity of the major mitochondrial derivative is impaired. Overall, this work indicates that variant γ-TuRCs may serve functional roles in diverse MTOCs to assist the specialized needs of different cell types.

B140/P1830

Cep215/Cdk5rap2 is essential for morphological differentiation of astrocytes

D. Kang[1], W. Shin[1], G. Kim[2], Y. Sung[2], K. Rhee[1]; [1]Biological Sciences, Seoul Natl University, Seoul, KOREA, REPUBLIC OF, [2]Medical Science, University of Ulsan College of Medicine, Seoul, KOREA, REPUBLIC OF.

Cep215/Cdk5rap2 is a centrosome protein which is involved in microtubule organization. Cep215 is also placed at specific subcellular locations and organizes microtubules outside the centrosome. Here, we report that Cep215 is involved in morphological differentiation of astrocytes. Cep215 was specifically localized at the glial processes as well as centrosomes in developing astrocytes. Morphological differentiation of astrocytes was suppressed in the *Cep215*-deleted P19 cells and in the Cep215-

depleted embryonic hippocampal culture. We confirm that the microtubule organizing function of Cep215 is critical for the glial process formation. However, Cep215 is not involved in the regulation of cell proliferation nor cell specification. Based on the results, we propose that Cep215 organizes microtubules for glial process formation during astrocyte differentiation. We also generated the knockout mice in which the *Cep215* gene was totally removed. The *Cep215* KO mice showed microcephaly as previously reported in *Cep215*$^{an/an}$ mutant mice.

B141/P1831

Drug-binding sites on tubulin as potential targets for novel anti-parasitic drugs

R. F. Luduena[1], J. A. Tuszynski[2], J. Zattoni[3]; [1]Biochemistry and Structural Biology, University of Texas Hlth San Antonio, San Antonio, TX, [2]Physics, University of Alberta, Edmonton, AB, CANADA, [3]Ingegneria Meccanica e Aerospaziale, Politecnico di Torino, Turin, ITALY.

The amino acid sequences of α-and β-tubulin are highly conserved in evolution, perhaps due to the complex conformational properties of tubulin that could mediate the dynamic properties that play a major role in microtubule function; also, tubulin has to interact with adjacent tubulin molecules. The colchicine binding site (CBS), largely located on β, is highly conserved. Nevertheless, there has been some divergence in the sequence of the CBS. There are differences in the CBS sequence in the human β isotypes and we have previously made colchicine analogues that can distinguish among them. It is noteworthy that the *Colchicum* plant, which makes colchicine, and the bees that pollinate it, have evolved alterations in the CBS, presumably to make these tubulins more resistant to colchicine. We propose here that organisms with unique sequences in the CBS could be vulnerable to colchicine analogues that might interact poorly with mammalian tubulin. One such is *Naegleria*, the "brain-eating ameba", which has two β isotypes, one flagellar and one mitotic, whose CBS sequences differ from each other and from those of other eukaryotes. There may be other pathogenic eukaryotes whose CBS could be examined. It is possible that appropriate modeling and designing of drugs to bind to the CBS of the tubulins from these organisms might result in drugs relatively non-toxic to humans and other mammals but quite toxic to the target organisms. At the same time, the complex functional requirements of the tubulin molecule may make it difficult for the target organism to evolve resistance to these drugs and still retain viability. The CBS is not the only promising target. We have used the amino acid sequences of the two α and two β tubulin isotypes of *Naegleria* to compare and contrast with the corresponding sequences for the human isotypes of tubulin whose binding sites for several ligands are well-characterized. We have identified the following compounds as providing potential scaffolds for derivatization: chalcone, epothilone, cevipabulin, dictyostatin, peloruside and dinitroaniline. With a homology model currently under development, candidate drug entities with specific and selective mode of action against *Naegleria* are being designed.

B142/P1832

Understanding how cancer cells hijack TUBB3 as a mechanism of chemoresistance

L. Wood, J. Moore; University of Colorado, Aurora, CO.

The microtubule network is integral to several hallmarks of a cancer cell such as migration, invasion, and uncontrolled proliferation. These cellular activities rely on remodeling of the microtubule network to perform specific functions and because of this reliance one of the most successful and potent chemotherapeutic classes is microtubule targeting agents. Tubulin isotypes are α and β proteins,

encoded by different genes, that vary in amino acid sequence and cell-type specific expression patterns. Ectopic expression of the β-tubulin-III (*TUBB3*) isotype accounts for 5-10% of the total tubulin pool in some cancers and correlates with resistance to taxane-based chemotherapies. Despite the correlation between *TUBB3* mRNA levels and taxane resistance, two major questions remain: 1) do isotype mRNA levels accurately reflect isotype protein levels in cancer cells? And 2) how might increased TUBB3 protein levels promote resistance to paclitaxel? To address the first question, we created GFP fusions to human β-tubulin isotypes and used these to validate a panel of isotype specific antibodies through immunoblotting. These antibodies allowed us to determine relative levels of TUBB3 and other β-tubulin isotypes in cancer cell lines known to have different levels of *TUBB3* mRNA . To address the second question, we used our panel of cell lines to test whether the level of TUBB3 protein determines response to physiological doses of paclitaxel in proliferation assays and the formation of the mitotic spindle. Our results show that concentrations of paclitaxel that inhibit proliferation also induce defects in mitotic spindle formation, with the magnitude of these defects being inversely proportional to the level of TUBB3 expression. We hypothesize that paclitaxel resistance is related to a cell's basal microtubule dynamics, which in turn are determined by the blend of β-tubulin isotypes. We are testing this hypothesis by measuring microtubule dynamics in cells lines with different isotype blends and in cells where we shift the isotype blend through knockout or ectopic expression of TUBB3, or alternative isotypes. These studies will define the impact of TUBB3 in cancer cells and give new insights into how changes in isotype expression translates to polymer composition and overall activity of the microtubule network.

Diversification of alpha-tubulin for germline roles with functional consequences in cancers

R. Chen[1], L. M. Rice[2], C. M. Schroeder[1]; [1]Department of Pharmacology, UT Southwestern Medical Center, Dallas, TX, [2]Department of Biophysics and Biochemistry, UT Southwestern Medical Center, Dallas, TX.

Microtubules are polymers required for fundamental cell processes in eukaryotes, including DNA segregation, cell motility, and cargo transport. The polymers are composed of αβ-tubulin dimers, and the ability of microtubules to dynamically grow and shrink depends on proper lateral and longitudinal contacts between individual dimers. The requirement for tubulin to preserve these polymerization interfaces and maintain dynamics imposes a strong selective constraint on tubulin structure. Most organisms express multiple paralogs of α-tubulin and β-tubulin, which consistently have very little variation in amino acid sequence. However, there is unexpected, recurrent evolution of α-tubulin paralogs that are highly divergent in amino acid sequence and specifically expressed in the germline. Although their function is unknown, the misexpression of these divergent α-tubulins in cancer correlates with decreased probability of survival. **We hypothesize that divergent α-tubulins tune microtubule dynamics for germline-specific processes and may endow cancerous cells with increased proliferative and migratory activity.** To test if sequence divergence in α-tubulin has led to distinct microtubule dynamics, we focused our studies on divergent α-tubulins found in humans: TUBA3E and TUBA3D. We identified their syntenic loci among many species and determined that TUBA3E and TUBA3D originated at least 160 million years ago and were largely retained across evolutionary time, implying a well-conserved function. We next exogenously expressed TUBA3D and TUBA3E in a cancer cell line to test if they have functionally diverged from canonical tubulin in a somatic context. Surprisingly, we discovered that TUBA3D readily incorporates into microtubules whereas TUBA3E does not. Furthermore, we found that both TUBA3E and TUBA3D alter microtubule growth speeds in distinct ways, suggesting that

sequence divergence has resulted in functional diversification from canonical α-tubulin. Interestingly, TUBA3E and TUBA3D differ by only six residues. To determine the molecular basis of TUBA3E and TUBA3D's distinct effects, we individually mutated TUBA3E residues to their TUBA3D counterparts and discovered that a single point mutation accounts for differences in TUBA3E localization when compared to TUBA3D. **Given both TUBA3D and TUBA3E'S functional diversification from canonical tubulin, we hypothesize divergent α-tubulins evolved specialized cytoskeletal dynamics for germline-specific processes and we are currently uncovering how their adaptation impacts cancer cell biology.**

Analysis of factors required for *Centrocortin* mRNA localization to centrosomes in *Drosophila* embryos

C. Husbands, H. Zein-Sabatto, D. A. Lerit; Department of Cell Biology, Emory University, Atlanta, GA.

Centrosomes are highly organized and dynamic organelles and are the primary microtubule organizing center in animal cells that play a key role in ensuring proper cell division. Within centrosomes, a compartmentalized matrix of protein and RNA, known as the pericentriolar material (PCM), surrounds the centrioles. Centrosomes function in a multitude of roles throughout the cell cycle, including intracellular trafficking, spindle assembly, and polarization. Recent work from our group implicates mRNA localizes to the PCM and contributes to centrosome function, raising the possibility of post-transcriptional links between centrosome dysfunction and disease. One of these centrosomal localizing mRNAs within syncytial *Drosophila* embryos, *Centrocortin* (*Cen*) mRNA, is significantly enriched at the centrosome, where it is organized into micron-scale ribonucleoprotein complexes (RNPs). We previously showed *Cen* mRNA mislocalization disrupts nuclear division due to disorganization of microtubules and increased nuclear fallout that resulted in embryonic lethality. We are investigating the contribution of the minus-end directed dynein motor complex and associated regulatory cofactors to *Cen* mRNA localization to centrosomes. It is also possible that one or more specific sequences within the *Cen* gene are responsible for localization. Prior work, for example, indicates Cen translation is required for *Cen* mRNA localization to centrosomes, and *Cen* mRNA and protein colocalize within *Cen* RNPs. We are investigating this model and identifying cis-sequences within the *Cen* coding region important for *Cen* mRNA localization to centrosomes. This study aims to identify possible interacting sequences imperative for *Cen* centrosomal localization, aspects of which may be impaired in centrosomal disease and dysfunction.

miR-1regulates mitotic spindles to mediate mitosis in early development

K. Hammond[1], M. Testa[1], N. Sampilo[2], J. Song[1]; [1]University of Delaware, Newark, DE, [2]Invitae, Iselin, NJ.

Title: miR-1regulates mitotic spindles to mediate mitosis in early development

Kayla Hammond[1], Nina Faye Sampilo[2], Michael Testa[1], and Jia L. Song[11]Department of Biological Sciences, University of Delaware, Newark, DE 19716[2] Invitae - Metropark (formerly Genosity), Iselin, NJ

AbstractMicroRNAs (miRNAs) are small non-coding RNAs that regulate gene expression by binding to the 3'UTR and silencing translation of their target genes. miR-1 is a highly conserved miRNA that is known to regulate cardiac development, skeletal muscle proliferation and differentiation, blood vessel formation. However, not much is known about miR-1's role in early development. In the sea urchin embryo, miR-1 overexpression (OE) significantly delayed development, leading to a high percentage of embryos arrested at the cleavage stage, as well as embryonic lethality. Preliminary results show that

miR-1 OE results in misaligned mitotic spindles and defective cytokinesis, potentially leading to embryonic arrest. Using a candidate approach, we bioinformatically identified *Cdc42* and the *NuMA-LGN-Gαi* complex as potential miR-1 targets. Cdc42 has been known to play a part in the binding of microtubules to the kinetochores of chromosomes, as well as to play a role in actin polymerization, which is crucial for proper cytokinesis. The NuMA-LGN-Gαi complex is involved in anchoring astral microtubules to the cell cortex. Both miR-1 and its potential target transcripts have been shown to localize in close spatial proximity within the dividing cell. Cdc42 and LGN localize to the mitotic spindles, while NuMA and Gαi localize to the Microtubule Organizing Center (MTOC). miR-1 has been shown to localize to the mitotic spindle and cell cortex. We hypothesize that miR-1 regulates mitosis in part by its suppression of its targets *Cdc42* and the *NuMA-LGN-Gαi* complex. Using dual luciferase assay and site-directed mutagenesis, we demonstrated that miR-1 directly suppresses *Cdc42*. This work provides a deeper understanding of post-transcriptional regulation of an evolutionarily conserved miRNA and its role in mitosis.

B146/P1836

Centriole asymmetry break and inactivation in skeletal muscle cell

M. R. Pimentel, M. Faria, M. Bettencourt-Dias; Instituto Gulbenkian De Ciencia, Oeiras, PORTUGAL.

Skeletal muscle cells are the largest in our body, composing up to 40% of its mass. These postmitotic cells nucleate microtubules mainly from the Golgi and Nuclear Envelope, but what happens to their centrosome remains unknown. We followed centrioles during skeletal muscle differentiation and observed that Plk1 is promptly lost, prior to PCM decrease and eventual centriole disappearance. Interestingly, we noticed a break in mother-daughter centriole asymmetry with several of the respective components lost or relocalized. Depletion of proteins that were relocalized partially rescues centriole loss in differentiated cells. Our data suggest that centrosomes might be actively shut down during muscle differentiation.

B147/P1837

Muscle mechanisms that regulate postsynaptic development at the *Drosophila* neuromuscular junction: microtubules and BMP signaling

V. E. von Saucken[1,2], N. J. Torres-Santiago[2], S. E. Windner[2], M. K. Baylies[2]; [1]Tri-Institutional MD-PhD Program, Weill Medical College/Cornell University, New York, NY, [2]Developmental Biology Program, Sloan-Kettering Institute for Cancer Research, New York, NY.

Muscle-neuron communication at the neuromuscular junction (NMJ) has largely focused on the motor neuron's presynaptic machinery. However, the factors regulating specialized postsynaptic structures in the muscle are unclear and critical to understanding synaptic development and function. The postsynapse at the NMJ consists of membrane infoldings called the subsynaptic reticulum (SSR) in invertebrates. A potential regulator of SSR size is microtubule (MT)-based trafficking, as studies reveal that disrupting MT-mediated transport in the neuron or muscle effectively blocks NMJ growth during development. In addition, BMP (bone morphogenetic protein) pathway activation and signaling via downstream effector Mad in the motor neuron is known to regulate NMJ size and maintenance. In the muscle, *Mad* knockdown leads to reduced NMJ size; however, the mechanisms of how BMP signaling shapes the postsynapse is incomplete. Here we investigate the roles of the muscle's intracellular trafficking machinery and BMP receptor signaling in regulating postsynaptic development using the

simple and highly accessible *Drosophila* larval NMJ. In the multi-nucleated larval muscle, each nucleus serves as a MT organizing center, resulting in nuclear MT asters/arrays. We studied perinuclear MT density and orientation in established mutants with disrupted axon guidance ($DLar^{C12/2127}$), which have high variability in NMJ size and position. We show that NMJ proximal nuclei (<15 µm to the NMJ) are smaller and surrounded by fewer MTs than more distal nuclei (15-50 µm). However, the proportion of MTs oriented toward the NMJ is increased in NMJ proximal nuclei. MT projection to the NMJ strongly correlates with NMJ size, indicating that this pattern depends on NMJ signaling. To explore postsynaptic BMP signaling, we used muscle-specific *Mad* knockdown via RNAi. We find that, in addition to the change in SSR size, *Mad* knockdown alters the size of NMJ proximal nuclei. Our initial findings suggest preferential allocation of the muscle's MT network to the postsynaptic region and a critical role for the BMP pathway in shaping the postsynaptic environment. This ongoing work will provide important insights to the regulation of postsynaptic growth and maintenance and its dysfunction with disease and aging.

B148/P1838

Microtubule polymerase XMAP215/Mini spindles and cytoplasmic dynein are required for the oocyte determination in Drosophila

W. Lu, M. Lakonishok, V. I. Gelfand; Cell and Developmental Biology, Northwestern University Feinberg Sch Med, Chicago, IL.

In many species, only one oocyte is specified among a group of interconnected germline sister cells. In *Drosophila melanogaster*, 16-cell interconnected cells form a germline cyst, where one cell becomes the oocyte, while the rest become nurse cells that provide the oocyte with mRNAs, proteins, and organelles through intercellular cytoplasmic bridges via microtubule-based transport. In this study, we find that a microtubule polymerase Mini spindles (Msps), the *Drosophila* homolog of XMAP215, is essential for defining and maintaining of the oocyte fate determination. Knockdown of *msps* blocks the oocyte growth and causes gradual loss of oocyte determinants. *msps* knockdown abolishes microtubule polymerization in the oocyte and results in the absence of microtubules growing from the oocyte to the nurse cells. We demonstrated that cytoplasmic dynein, the main microtubule minus-end directed motor, is required for *msps* mRNA transport to the oocyte, and thus accumulation of translated Msps protein in the oocyte. The dynein-dependent concentration of Msps causes more microtubule plus-ends to grow from the oocyte to nurse cells, further enhancing dynein-dependent nurse cell-to-oocyte transport. Thus, the dynein-Msps duo creates a positive feedback loop that transforms a slight stochastic difference in microtubule polarity among sister cells into a clear oocyte fate determination.

B149/P1839

Self-organized intracellular twisters in *Drosophila* oocytes

R. Farhadifar[1], S. Dutta[2], G. Kabackaoglu[1], R. Blackwell[1], W. Lu[3], V. Gelfand[3], S. Shvartsman[1], M. Shelley[1]; [1]Center for Computational Biology, Flatiron Institute, New York, NY, [2]Lewis-Sigler Institute, Princeton University, Princeton, NJ, [3]Department of Cell and Developmental Biology, Northwestern University, Chicago, IL.

Cytoplasmic streaming is essential for transporting and mixing nutrients, proteins, and organelles within large plant and animal cells. The large ~300um *Drosophila* oocyte has recently gained attention for experimental and theoretical studies of this phenomenon. We present a quantitative study of streaming

in *Drosophila* oocytes that combines PIV of 3D time-lapse movies, with biophysical modeling and simulation. We observe a diverse family of 3D vortical flows across different oocytes, which differ in position and orientation, and which last tens of minutes. We show that a model of cytoskeletal activity at the periphery, organized by its interaction with interior fluid, explains the observed streaming structures. The emerging picture sheds light on a class of intracellular flows in large cells and highlights the wealth of questions at the interface of geometry, active matter, and basic biology.

B150/P1840

Tau and MAP6 Organizes Individual Microtubules into Stable and Labile Domains

K. Kirimtay, W. Huang, D. V. Wang, P. W. Baas; Drexel University, Philadelphia, PA

Previous studies on cultured juvenile rodent neurons documented that each microtubule in the axon consists of two distinct domains. The domain toward the plus end of the microtubule is dynamic and labile, while the domain toward the minus end of the microtubule is more stable. These two domains differ in their content of post-translationally modified tubulin subunits as well as their interactions with myriad proteins such as molecular motors and microtubule-severing enzymes. Curiously tau, long believed to be a critical stabilizer of axonal microtubules, was found to be enriched on the labile domain of the microtubule and crucial for enabling that domain to become long without being stabilized. Our goals in the present study were two-fold, first to investigate whether the same is true of tau in adult axons (which is more relevant to tau's prominent role in neurodegenerative diseases) and secondly to better understand mechanistically how tau keeps a substantial portion of the axonal mass from being stabilized. For the former, we introduced contemporary antisense oligonucleotides into the adult mouse brain, documented the diminution of tau over several days, and studied the effects on microtubule levels and stability. Even with the different tau isoforms in adult neurons compared to juvenile (3R and 4R in adult, but only 3R in juvenile), the results are consistent with labile domains of axonal microtubules becoming shorter and less dynamic when tau levels were lowered. Next, we ectopically co-expressed in fibroblasts fluorescently tagged tau and MAP6, a protein enriched on the stable domains of axonal microtubules and found these two proteins to segregate into domains on microtubules, with tau-rich domains being relatively labile and MAP6-rich domains being relatively stable. This was also consistent with the photobleaching experiments in which MAP6 bound to microtubules stably but binding and unbinding of tau was highly dynamic. This was true regardless of the which isoforms of tau or MAP6 were expressed. On this basis, we propose that in both juvenile and adult neurons, tau's principal role in regulating microtubule stability in the axon is to cooperatively concentrate on dynamic regions of microtubules and keep them dynamic by outcompeting genuine stabilizers such as MAP6.

B151/P1841

Cytoplasmic microtubule stability does not influence ciliary assembly

L. L. Dougherty, P. Avasthi; Dartmouth College, Hanover, NH

Cilia are dynamic antenna-like structures protruding from the plasma membrane that provide an important signaling and sometimes motile component to cells. Both the structure and assembly of cilia are heavily microtubule-based. Upon exiting the cell cycle, the microtubule superstructure of the cilium will assemble and disassemble upon cell cycle re-entry. Since proteins needed for cilium structure and function need to be synthesized in the cell body and trafficked to the cilium, microtubule-based trafficking mechanisms within the cell body is of interest. When there is an acute need for cilium

assembly, cytoplasmic microtubules are known to depolymerize. It has been speculated that this depolymerization occurred for the purpose of freeing tubulin dimers for availability to assemble into ciliary structures. Here we have found that cytoplasmic microtubule disassembly is not required for ciliary regrowth following ciliary excision due to the inability to affect cilium growth when depolymerization is inhibited. Using mechanical and chemical perturbations, we find that cytoplasmic microtubule organization is independent of ciliary assembly.

B152/P1842

Microtubule glutamylation is dispensable for centriole stability in *C. elegans*

N. Peel, B. Shah, J. Lee, D. Chawla; THE COLLEGE OF NEW JERSEY, Ewing, NJ

Glutamylation, the covalent attachment of glutamic acid to tubulin in the polymerized microtubule, is enriched on long-lived microtubules. It is thought to contribute to centriole stability, cilia motility and axon function. Glutamylation of the microtubules is catalyzed by a family of tubulin tyrosine ligase like (TTLL) enzymes. Comprehensive in vivo analyses of the function of tubulin glutamylation have proved challenging because of the existence of a large family of TTLL enzymes in many species. To investigate the function of tubulin glutamylation we have generated a *ttll-4(tm3310)*; *ttll-11(tm4059); ttll-15(tm3871) ttll-5(tm3360) ttll-9(tm3889)* 'quint' mutant that lacks all five *C. elegans* glutamylating TTLL enzymes. The objective of our study is to use this quint mutant to determine the essential functions of tubulin glutamylation. We find that the quint mutant shows normal embryonic viability and brood size. The localization of centriole markers ZYG-1, SPD-2 and SAS-4 is normal, moreover the centrosome organizes a spindle that is competent for cell division. Our data therefore suggest that, contrary to expectations, in *C. elegans* microtubule glutamylation is not essential for centriole stability. Interestingly we have found, that our quint mutant shows enhanced colchicine and cold-sensitivity, suggesting that microtubule stability in inclement conditions is altered by the loss of glutamylation. We are currently undertaking a detailed analysis of microtubule dynamics to determine the underlying cause of altered microtubule properties in the quint mutant.

B153/P1843

Specific domains of Ninein and its associations with partners Dynein and Ensconsin are necessary for Ninein localization and microtubule organization in the *Drosophila* larval fat body

M. M. L. Tillery[1], Y. Zheng[2], T. L. Megraw[1]; [1]Florida State University, Tallahassee, FL, [2]Xiamen University, Fujian, China

The rich diversity of non-centrosomal MTOCs (ncMTOCs) has begun to be appreciated in a range of cell types across a variety of organisms. The composition, function, and subcellular localization of ncMTOCs is unique to meet the specific needs of the cells in which they are located. Our lab recently reported a novel perinuclear ncMTOC in *Drosophila* larval fat body cells that organizes circumferential and radial microtubules (MTs) and is required for maintaining nuclear centricity and coordinating endosomal trafficking. MT assembly in fat body cells requires the parallel activities of the MT minus-end stabilizer Patronin/CAMSAP and the MT anchor Ninein (Nin).

Nin functions at both centrosomal and non-centrosomal MTOCs. In the fat body, Nin localizes to the nuclear surface mostly independent of MTs while a fraction localizes intranuclearly. Neither of the *Drosophila* Nesprins Msp300 or klarsicht are required for Nin localization. In other systems, Nin interacts with the dynein complex and Ensconsin/MAP7 (Ens), so we explored their relationship with Nin in the

fat body. We found that loss of core dynein subunits, but not the inhibition of dynactin, causes Nin to localize inside the nucleus of fat body cells. Domain mapping revealed this localization relies on the presence of a central domain of Nin (aa 454-570). Interestingly, this region is also responsible for localizing Nin intranuclearly in a wild-type dynein background. Nin physically interacts with Ens via a region in the C-terminus of Nin (aa 550-777). In the fat body, overexpression of Nin forms ectopic ncMTOCs that recruit Ens. When Nin constructs containing amino acids 550-777 are overexpressed with Ens, significantly more robust ncMTOCs are formed adjacent to the nucleus that affect nuclear integrity, resulting in the apparent leakage of chromosomes into the cytoplasm. Our preliminary genetic and cell biological data suggests that Nin requires both dynein and Ens for its role at the fat body ncMTOC.

B154/P1844

Investigating the role of tubulin-tyrosine ligase (TTL) in DREADD-mediated enhancement of sensory axon growth

A. Islam, V. J. Tom; Drexel University, Philadelphia, PA

Injury to the mature nervous system often results in permanent functional deficits. One factor limiting recovery is that neurons lose the intrinsic ability to regenerate their axons after development. Our lab showed that activating adult dorsal root ganglia (DRG) neurons using chemogenetics, i.e., designer receptors exclusively activated by designer drugs (DREADDs), in vivo, increases the ability to regenerate axons into the spinal cord after a dorsal root crush injury. This was associated with more axons turning off white matter and into grey matter and other neurons, potential synaptic partners. This increased growth and turning may be attributed to microtubules, components of the cytoskeleton important for development, shape and motility, and organelle transport. Microtubules have two distinct domains, either stable or labile, depending on the type of post-translational modifications. While mature neurons contain a high concentration of stable (acetylated) microtubules in their axons, increasing stable microtubules may lead to forced polymerization of tubulin, causing abnormal axon growth. Meanwhile, labile (tyrosinated) microtubules are much more dynamic and is necessary for normal growth-cone motility and axon extension. Our findings showed that when neurons are activated via DREADDs, there is an increase in labile, tyrosinated microtubules that mediates the improved axon outgrowth from activated neurons. This increase in tyrosination after neuronal activation may be caused by tubulin-tyrosine ligase (TTL), a protein which tyrosinates tubulin. We hypothesize that TTL is involved in improved axon outgrowth upon neuron activation. We are investigating how TTL expression is affected by DREADD-mediated neuronal activation and its role in enhanced axon regeneration. Elucidating the mechanisms involved in axon regeneration after neuron activation will identify potential molecular targets to increase the regenerative capability of adult neurons after injury.

B155/P1845

Characterization of a novel microtubule-binding protein CLIPR76 and its role in cardiomyocyte development

A. T. Bryant, J. S. V. McCourt, G. Ugrinova, C. Whalen, H. V. Goodson; University of Notre Dame, Notre Dame, IN

Characterization of the Novel Microtubule-Binding Protein CLIPR76 and Its Role in Cardiomyocyte Development

Microtubules (MTs) are critical filaments in the eukaryotic cytoskeleton and contribute to cellular

functions such as cellular migration, intracellular trafficking, and key processes in the cell cycle, including chromosomal segregation and cytokinesis. These functions are achieved through the coordination of MT-based motor proteins, such as dynein and kinesin, and non-motor proteins, such as cytoplasmic linker proteins (CLIPs) and their relatives (CLIPRs). We have identified a new CLIPR protein called CLIPR76 that is encoded by the *CLIP4* gene and spans 166 kb with the longest open reading frame encoding a 76 kDa protein. Bioinformatics analysis of the NCBI Reference Sequence Database suggests that there are at least three isoforms of CLIPR76 in humans, though which isoforms exist as protein is unclear. Overexpression of isoform-specific CLIPR76 constructs in the mouse fibroblast cell line NIH3T3 indicate that isoforms 1 and 3 localize to MTs whereas isoform 4 localizes to the endoplasmic reticulum (ER). Preliminary RT-qPCR data using a primer common to all isoforms of CLIPR76 shows that CLIPR76 mRNA is most highly expressed in striated muscle, such as cardiac and skeletal muscle, in murine tissues. Furthermore, CLIPR76 protein is highly upregulated when murine C2C12 myoblast cells are induced to differentiate into skeletal muscle. In order to further elucidate the role of CLIPR76 in striated muscle development, we have shifted our model system from murine C2C12 cells to human induced-pluripotent stem cells (iPSCs) differentiated into beating cardiomyocytes (a cardiac version of striated muscle). We are conducting immunofluorescence experiments on differentiating cardiomyocytes using our CLIPR76 antibody and markers for various organelles, such as ER, and cytoskeletal filaments, such as actin and modified MTs, to assess CLIPR76 localization. CRISPR knockout of *CLIP4* is currently underway in the lab to assess the effects of depleting CLIPR76 in developing cardiomyocytes. Additionally, we are utilizing qualitative real-time PCR to determine the relative levels of CLIPR76 mRNA at various developmental timepoints with primers specific to each isoform. In parallel, we are planning experiments to identify peptides specific to each isoform via immunoprecipitation with our CLIPR76 antibody followed by mass spectrometry analysis. Microtubules are a key element in the cardiomyocyte cytoskeleton where they function as scaffolds for myofilaments and aid in the positioning and organization of organelles; our work with CLIPR76, a novel MT-binding protein that also binds membranes (ER), seeks to further elucidate the role of CLIPR76 in cardiac muscle development.

B156/P1846

Stem cell pluripotency - a microtubule cytoskeleton regulated state?

J. Greaney[1], A. Hawdon[1], Y. Li[1], A. Aberkane[1], G. Stathatos[2], R. Parton[3], **J. Zenker**[1]; [1]Monash University, Clayton, Australia, [2]University of Melbourne, Melbourne, Australia, [3]University of Queensland, Brisbane, Australia

How equipotent cells develop into complex tissues containing many diverse cell types is one of the most fundamental as well as most important question in biology. The organisation of a cell's interior, the cytoskeleton and organelles, is pivotal for every cell's functionality. However, unlike most differentiated cells, our knowledge about the contribution of the sub-cellular architecture to pluripotency remains scarce.Using cutting-edge live imaging, we discovered polarised non-centrosomal microtubules as central player for the pluripotent state of the *in vivo* early mammalian embryo and human induced pluripotent stem cells (hiPSCs). Contrary to the textbook view that microtubules radiate symmetrically from the centrosome to the periphery of a cell, the microtubules of the preimplantation embryo grow from the so called "interphase bridges" asymmetrically from one side of the cell to the other. These non-centrosomal microtubules, anchored and nucleated by the non-centrosomal microtubule minus end marker calmodulin-regulated spectrin-associated protein 3 (CAMSAP3), initiate an asymmetry of organelles and molecules, including RNAs, as cells become more specialised *in vivo* and *in vitro*. We

further establish that the CAMSAP3-dependent microtubules rearrange upon differention in a germ layer-specific manner. Dissecting how intrinsic cellular regulation contributes to pluripotency might lead to a revolutionary era of regenerative and reproductive medicine.

Microtubule Dynamics: Post-translational Modifications

B157/P1847

Differential modifications of the C-terminal tails of α-tubulin isotypes and their importance for kinesin based microtubule transport *in vivo*

M. Bao, R. Dörig, D. Beuchle, P. M. Vazquez-Pianzola, B. Suter; University of Bern, Institute of Cell Biolody, Bern, SWITZERLAND.

Microtubules (MTs) are built from α-/β-tubulin dimers and used as tracks by kinesin and dynein motors to transport a variety of cargos, such as mRNAs, proteins, and organelles, within the cell. Tubulins are subjected to several post-translational modifications (PTMs). Glutamylation is one of them, and it is responsible for adding one or more glutamic acid residues as branched peptide chains to the C-terminal tails of both α- and β-tubulin. However, very little is known about the specific modifications found on the different tubulin isoforms *in vivo* and the role of these PTMs in cargo transport along MTs *in vivo*. In this study, we found that in *Drosophila*, glutamylation of the α-tubulin isoforms occurs specifically on the C-terminal ends of TBA1 and TBA3 in the ovaries. In contrast, the ovarian isoform TBA4 is not glutamylated. The C-terminal ends of TBA1 and TBA3 are glutamylated at several glutamyl side chains in various combinations. *Drosophila TTLL5* is required for the mono- and poly-glutamylation of ovarian TBA1 and 3. Furthermore, glutamylation of the α-tubulin is essential for the efficient localization of Staufen/*osk* mRNA and to give directionality to the fast ooplasmic streaming, two processes known to depend on kinesin-mediated processes during oogenesis. In the nervous system, the kinesin-dependent neuronal transport of mitochondria also depends on *TTLL5*. Additionally, α-tubulin glutamylation affects the pausing of the transport of individual mitochondria in the axons. Our results demonstrate the *in vivo* role of *TTLL5* in differential glutamylation of α-tubulin isoforms and point to the *in vivo* importance of α-tubulin glutamylation for kinesin-dependent processes.

B158/P1848

Genetic manipulation of α-tubulin detyrosination/tyrosination reveals a direct role in the regulation of chromosome congression and segregation fidelity during human cell division

H. Girão[1,2], H. Maiato[1,2,3]; [1]Instituto de Investigação e Inovação em Saúde (i3S), Universidade do Porto, Porto, Portugal, Porto, PORTUGAL, [2]Instituto de Biologia Molecular e Celular, Universidade do Porto, Porto, Portugal, Porto, PORTUGAL, [3]Cell Division Group, Experimental Biology Unit, Department of Biomedicine, Faculdade de Medicina, Universidade do Porto, Porto, Portugal, Porto, PORTUGAL.

Tubulin undergoes several enzymatic posttranslational modifications (PTMs) that generate chemical landmarks that affect microtubule behavior and protein interactions. One key PTM consists on the removal of the C-terminal tyrosine residue of α-tubulin on microtubules by tubulin carboxypeptidases. Free detyrosinated tubulin released from microtubules is then re-tyrosinated by tubulin tyrosine ligase (TTL). Several studies relying on TTL overexpression or unspecific α-tubulin carboxypeptidase inhibitors have implicated the α-tubulin detyrosination/tyrosination cycle in important cellular processes, such as mitosis, neuronal function, and muscle contraction. However, indirect side effects associated with these

approaches cannot be excluded. Recently, the identification of tubulin detyrosinating enzymes Vasohibin 1 and 2 (VASH1/2) opened the way for the genetic manipulation of α-tubulin detyrosination. To determine how the detyrosination/tyrosination of α-tubulin impacts mitosis, we challenged human U2OS cells to grow in extreme tubulin detyrosination or tyrosination conditions. This was achieved by ectopic overexpression of GFP-tagged detyrosinated or tyrosinated α-tubulin in cells knockout (KO) for TTL or VASH1/2, respectively. Super-resolution CH-STED microscopy confirmed that TTL KO cells overexpressing detyrosinated α-tubulin showed high levels of this PTM on mitotic spindle microtubules, especially k-Fibers and astral microtubules. In contrast, VASH1/2 KO cells overexpressing tyrosinated α-tubulin showed extremely low detyrosinated α-tubulin in all mitotic spindle microtubule subpopulations. Live-cell imaging revealed that mitotic cells growing under extremely high detyrosinated α-tubulin conditions have enlarged mitotic spindles and show a dramatic increase in chromosome segregation errors. On the other hand, cells growing under extremely low α-tubulin detyrosination showed penetrant chromosome congression defects, including the formation of chronically misaligned chromosomes at the poles. These findings, provide direct genetic evidence for a role of the α-tubulin detyrosination/tyrosination cycle in the regulation of mitotic spindle length, error correction and chromosome congression during human cell division.

B159/P1849

Microtubule stability reinforces stochastic detyrosination to define functional microtubule subsets

Q. Tang[1], C. Bond[1], S. Sensale[2], A. Qiao[2], A. Arab[1], S. Hugelier[1], G. Arya[2], M. Lakadamyali[1]; [1]Physiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, [2]Mechanical Engineering and Materials Science, Duke University, Durham, NC.

Microtubules in cells are segregated into functionally diverse subpopulations carrying distinct post-translational modifications (PTMs). Akin to histone code, the tubulin code regulates myriad microtubule functions ranging from intracellular transport to chromosome segregation. However, how individual PTMs only occur on subsets of microtubules to contribute to microtubule specialization is not well understood. In particular, microtubule detyrosination, which is the removal of the C-terminal tyrosine on α-tubulin subunits, marks the stable population of microtubules and modifies how microtubules interact with other microtubule-associated proteins to regulate a wide range of cellular processes. Previously, we found that only a small subpopulation of microtubules are highly enriched with the detyrosination mark (~30%) and that detyrosination spans most of the length of a microtubule, often adjacent to a completely tyrosinated microtubule. How a cytosolic detyrosinase, Vasohibin (VASH), builds up and maintains only a small subpopulation of highly detyrosinated microtubules is unclear. Here, using quantitative super-resolution microscopy, we visualized nascent microtubule detyrosination events in cells consisting of 1-3 detyrosinated α-tubulin subunits after Nocodazole washout. Microtubule detyrosination accumulates slowly and in a disperse pattern across the microtubule length. By visualizing single molecules of VASH in live cells, we found that VASH engages with microtubules stochastically on a short time scale with no apparent cooperativity, indicating limited removal of tyrosine per interaction, consistent with the super-resolution results. Combining these quantitative imaging results with simulations incorporating parameters from our experiments, we propose a stochastic model for cells to establish a subset of detyrosinated microtubules via a detyrosination-stabilization feedback mechanism.

A novel probe illuminates the chemical logic of microtubule detyrosination

Y. Yue, T. Hotta, K. J. Verhey, R. Ohi; Department of Cell and Developmental Biology, University of Michigan Medical School, Ann Arbor, MI.

Detyrosination is a post-translational modification (PTM) of α-tubulin that is critical for cell function in many physiological contexts. The carboxypeptidases responsible for this modification, VASH/SVBP and MATCAP, have been identified recently. How these enzymes select specific microtubules for detyrosination remains elusive. To study this, we generated an Alexa488-labeled fragment antigen-binding (Fab) protein that specifically recognizes detyrosinated microtubules (ΔY-Fab^{488}). We validate the ΔY-Fab^{488} as a probe by showing that taxol treatment, which is known to increase detyrosination, results in the efficient decoration of microtubules by the ΔY-Fab^{488} probe in living cells and rapid decoration of taxol-stabilized microtubules upon incubation with VASH1/SVBP in *in vitro* assays. Thus, the ΔY-Fab^{488} probe allows us to visualize the process of microtubule detyrosination in living cells and *in vitro* with high spatial and temporal resolution. We then turned to single-molecule imaging assays to examine the mechanism of detyrosination by VASH1/SVBP. We show that VASH1/SVBP undergoes frequent short interactions with taxol-stabilized microtubules regardless of their detyrosination state. These interactions result in rapid detyrosination of the entire microtubule lattice. In contrast, VASH1/SVBP activity is sensitive to the nucleotide state of the microtubules as VASH1/SVBP rapidly detyrosinates GMPCPP-stabilized but not GDP-tyrosinated microtubules. Collectively, our work suggests the underlying mechanism by which VASH1/SVBP detyrosinates microtubules and also provides a novel tool to monitor microtubule PTMs in living cells and *in vitro*.

Physical properties of the cytoplasm tune tubulin post-translational modifications

Y. Shen, K. M. Ori-McKenney; Department of Molecular and Cellular Biology, University of California, Davis, University of California, Davis, CA.

Microtubules tune the physical properties of the cytoplasm; however, it is poorly understood how microtubules could be reshaped by the complex physical environment present in a living cell, which is often crowded, heterogenous and fluctuating. A recent study has demonstrated that the rates of both microtubule polymerization and depolymerization scale linearly and inversely with cytoplasmic crowdedness. Here, we ask how tubulin post-translational modifications (PTMs) and microtubule associated proteins (MAPs) respond to changes in the cytoplasm by applying osmotic challenges to three types of epithelial cells and evaluating the interplay between tubulin PTMs and MAPs and their effects on cargo transport. By using single-particle tracking of genetically encoded multimeric nanoparticles (GEMs), we characterize the spatial heterogeneity of the crowdedness of the cytoplasm and monitor these changes upon osmotic challenges. We find that the α-tubulin C-terminal tail modification, detyrosination, and the α-tubulin luminal modification, acetylation, which both mark stabilized microtubules, respond differently to an osmotic challenge. Increasing cytoplasmic crowdedness gradually increases the acetylation level, whereas decreasing the cytoplasmic crowdedness causes the opposite. However, a sharp increase of detyrosination is only observed upon decreasing crowdedness, whereas α-tubulin tyrosination is insensitive to the osmotic challenge. Interestingly, these changes of PTMs are correlated with changes in the association of MAP7, a major MAP in epithelial cells that is important for kinesin-1 driven transport. MAP7 and acetylated microtubules largely colocalize and

enrich at perinuclear region where the local crowdedness is higher than that of the cell periphery. Upon decreasing cytoplasmic crowdedness, MAP7 drastically disassociates from microtubules. Over-expression of MAP7 does not affect tyrosination, but causes an increase of acetylation and lessens the effects of osmotic challenge to acetylation levels. Taken together, our findings suggest that the physical cue from the cytoplasm may signal deeper to the microtubules than we previously appreciated, which may help explain the spatial heterogeneity of tubulin PTMs and MAPs and their interplay in cells under various physiological and pathological conditions.

Polyglutamylation of microtubules drives motor axon remodeling

A. Gavoci[1], M. Wang[1], N. Marahori[1], C. Janke[2], M. Magiera[3], T. Misgeld[1], **M. S. Brill**[1]; [1]Technical Universtiy Munich, institute of Neuronal Cell Biology, Munich, GERMANY, [2]Institut Curie, PSL Research University, CNRS UMR3348, F-91401 Orsay, France; Université Paris-Saclay, CNRS UMR3348, F-91401 Orsay, France, Orsay, FRANCE, [3]Institut Curie, PSL Research University, CNRS UMR3348, F-91401 Orsay, France; Université Paris-Saclay, CNRS UMR3348, Orsay, FRANCE.

Motor axons undergo activity driven synapse elimination of terminal branches. Loss of microtubules in early phases of axon competition is a critical factor, which is in part mediated by the microtubule severing enzyme spastin recruited to polyglutamylated microtubules. The underlying regulatory mechanisms for these branch-specific cytoskeletal re-arrangements are unknown. Consistent with an instructive role of polyglutamylation, motor neurons ablating the deglutamylases CCP1&6 accelerated axon dismantling, while deleting the chain elongating glutamylase TTLL1, delayed axonal remodeling. Further measurements of polyglutamylation, microtubule mass and dynamics corroborate the predicted branch-specific regulation of microtubule stability, hinting at a rheostatic regulation of spastin-mediated severing and hence axonal remodeling. Surprisingly, deleting TTLL7, which 'seeds' the first glutamate residue, had no effect on polyglutamylation, suggesting several layers of regulation that are ingrained in parallel or consecutive steps of editing the 'tubulin code'. Neurotransmission coordinates glutamylases and deglutamylases function, as blockade of synaptic activity to mimic a dismantling branch, modulated polyglutamylation and reduced tubulin mass. Hence, a specific posttranslational modification of tubulin, polyglutamylation, acts as an instructive signal for spastin-mediated severing, which in turn paces developmental axon pruning. The 'tubulin code' could thus control specific morphogenetic events during nervous system development and could similarly determine axon stability in central neurons and during disease.

Tubulin arginylation regulates microtubule dynamics via MAP1S

B. MacTaggart, A. Kashina; University of Pennsylvania, Philadelphia, PA.

Arginylation is the post-translational addition of arginine to a protein by arginyl transfer enzyme 1 (ATE1). Previous studies have found that ATE1 targets multiple cytoskeletal proteins, and *Ate1* deletion causes cytoskeletal defects, including reduced cell motility and adhesion. Some of these defects have been linked to actin arginylation, but the role of other arginylated cytoskeletal proteins has not yet been studied. Here, we characterize tubulin arginylation and its role in the microtubule cytoskeleton. Mass spectrometry of Taxol-purified cellular microtubules identified arginylation of α- (E77 of *TUBA1B*) and β-tubulin (D74 of *TUBB*), which is absent in *Ate1*$^{-/-}$ cells. While *Ate1* deletion did not visibly affect the level

or distribution of tubulin, *Ate1*$^{-/-}$ cells showed a reduction in EB1 comet velocity compared to wildtype, indicating reduced microtubule growth. Moreover, when treated with nocodazole, *Ate1*$^{-/-}$ cells showed an increased fraction of depolymerization-resistant microtubules compared to wildtype, indicating increased microtubule stability. These phenotypes were rescued by exogenous ATE1, but not by exogenous arginylated β-actin, supporting a specific role for tubulin arginylation. Comparison of the microtubule associated protein fractions from wildtype and *Ate1*$^{-/-}$ cells showed that *Ate1* knockout results in an increased amount of MAP1S associated with microtubules. Knocking down *Map1s* in *Ate1*$^{-/-}$ cells was able to rescue microtubule growth rate and stability to wildtype levels. These effects are consistent with the previously demonstrated roles of MAP1S in limiting microtubule growth rate and promoting microtubule stability. Furthermore, overexpression of non-arginylatable α-tubulin (E77A) recapitulated the microtubule defects observed in *Ate1*$^{-/-}$ cells, namely decreased microtubule growth rate, increased microtubule stability, and an increased fraction of MAP1S associated with the polymerized tubulin fraction. Together, these results demonstrate a new type of tubulin regulation by post-translational arginylation, which regulates microtubule growth rate and stability through the microtubule associated protein, MAP1S.

B164/P1854

Acetylation regulates multiple functions of the TOG protein Stu2, an XMAP215/CKAP5 homologue.

M. A. Greenlee, B. Witt, J. Sabo, S. C. Morris, R. K. Miller; Department of Biochemistry and Molecular Biology, Oklahoma State University, Stillwater, OK.

Stu2 is the yeast member of the XMAP215/Dis1/CKAP5/chTOG family of microtubule associated proteins. These proteins have multiple functions in controlling microtubules, including microtubule polymerization, microtubule depolymerization, linking chromosomes to the kinetochore, and assembly of γ-TuSCs at the SPB. Whereas phosphorylation has been shown to be critical for Stu2 localization at the kinetochore, other regulatory mechanisms that control Stu2 function are still poorly understood. Here, we report that acetylation is a novel form of Stu2 regulation. Using western blotting and mass spectrometry, we identified three acetylated lysine residues at K252, K469, and K870, located in three distinct domains of Stu2, in TOG1, in TOG2, and in the MAP interacting domains, respectively. Homology alignments showed that lysines 469 and 870 are highly conserved across evolution, from fungi, plants, and vertebrates to humans. To study functional significance, we generated a series of K to Q substitutions in Stu2 that act as acetyl-mimetics, nullifying lysine's positive charge. We also made a similar series of K to R substitution that act as acetyl-blocking mutations. Several combinations of double and triple mutations were also constructed. In extracts prepared from logarithmically growing cultures, these mutants were abundant at levels equivalent to WT Stu2. These acetyl-mimetic and acetyl-blocking mutations did not impact the essential function of Stu2. However, mutational analyses revealed distinct functions associated with the three different sites. Some of these mutations lead to a decrease in chromosome stability. Other mutant combinations lead to increased resistance to the microtubule depolymerization drug, benomyl. Based on published crystallography coordinates from other labs, we developed an *in silico* model that predicted altered interactions between Stu2p mutants and γ-tubulin. In agreement with this model, western blotting showed that several acetylation-mimetic mutants displayed increased interactions with γ-tubulin. Our analysis of the mutants suggests a hierarchy of intragenetic epistatic regulation for Stu2 acetylation at the SPB and kinetochore. Together, these data suggest that acetylation is a previously unappreciated mechanism that governs multiple Stu2 functions, including chromosome stability and interactions at the SPB. Funding by NIH-R15GM119117-01.

B165/P1855

alpha-tubulin H11' is a key site for the intrinsic and extrinsic regulation of microtubule dynamics

K. J. Hoff, J. K. Moore; University of Colorado, Aurora, CO.

Microtubule dynamics in cells are regulated both by extrinsic factors, such as microtubule-associated proteins (MAPs), as well as intrinsic mechanisms from the tubulin heterodimer itself. Free tubulin heterodimer exists in a curved conformation that straightens as it is assembles into the microtubule lattice. This transition between conformational states represents a potentially powerful point of regulation; however, much remains unknown about how this transition might be controlled by different regions of the heterodimer and interactions with MAPs. We previously identified the helix 11' (H11') region of alpha-tubulin as a strong candidate for regulating this transition. Mutations in H11' cause human brain malformations and alter tubulin's intrinsic polymerization activity and interactions with XMAP215/Stu2. In this study, we use an evolutionary approach to further our understanding of the relationship between H11', regulatory MAPs, and tubulin conformation. By aligning alpha-tubulin sequences from over 500 species, we find that H11' is highly conserved, except notably in the mitotic tubulins expressed in *Naegleria fowleri* and *Naegleria gruberi*. These divergent tubulins have unique properties, suggesting that the variants found in H11' may contribute to these distinctions. We hypothesize that H11' plays a key role in the regulation of tubulin conformation, and that the divergent *Naegleria* H11' disrupts normal conformation changes, resulting in a straightened heterodimer. To measure the impact of these H11' variants on tubulin function, and ultimately decipher the regulatory role of H11', we modeled the *Naegleria* H11' by introducing mimetic mutations at the corresponding residues in *Saccharomyces cerevisiae*. Our results reveal that these variants impact cellular fitness, create hyper-stable microtubules, and disrupt normal microtubule regulation, similarly to what we expect from a straightened heterodimer. This work highlights the role of alpha-tubulin H11' in intrinsic heterodimer conformation dynamics, as well as how it impacts conformation-sensing extrinsic MAPs. Both intrinsic and extrinsic factors play crucial roles in microtubule dynamics regulation throughout development and disease, and this work emphasizes how these mechanisms are not separate control points, but rater are intricately linked.

Assembly and Disassembly of Cilia/Flagella

B169/P1856

Testing the ion-current model for *Chlamydomonas* flagellar length sensing

H. Ishikawa[1], J. Moore[2], D. Diener[3], M. Delling[1], W. Marshall[1]; [1]University of California, San Francisco, San Francisco, CA, [2]Yale University, New Heaven, CT, [3]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, GERMANY.

Eukaryotic cilia and flagella are microtubule-based organelles whose relatively simple shape makes them ideal for investigating the mechanisms of fundamental size regulation. Most of the flagellar materials are transported from cell body via an active transport process called intraflagellar transport (IFT) because no protein synthesis occurs in the flagellum. The rate of IFT injection has been shown to negatively correlate with flagellar length. However, it remains unknown how the cell measures the length of its flagella and controls IFT injection. Here we experimentally tested one theoretical model of flagellar length-sensing: the ion-current model. This model posits that there is a uniform distribution of

Ca^{2+} channels along the flagellum and that the Ca^{2+} current from the flagellum into the cell body increases linearly with flagellar length. In this model, the cell uses the Ca^{2+} current to negatively regulate IFT injection. To test this model, we measured and manipulated the levels of Ca^{2+} inside of *Chlamydomonas* flagella and quantified IFT injection. Although level of Ca^{2+} inside of flagella was weakly correlated with the length of flagella, we found that IFT injection was reduced in calcium-deficient flagella, rather than increased as a model predicted, and that variation in IFT injection was uncorrelated with the occurrence of flagellar Ca^{2+} spikes. Thus, Ca^{2+} does not work as a negative regulator of IFT injection, hence it cannot form the basis of a stable length control system.

IFT-A structure reveals carriages for membrane protein transport into cilia

S. J. Hesketh, A. G. Mukhopadhyay, D. Nakamura, K. Toropova, A. J. Roberts; Department of Biological Sciences, Institute of Structural and Molecular Biology, Birkbeck College, London, UNITED KINGDOM.

Intraflagellar transport (IFT) trains are molecular machines that traffic proteins between cilia and the cell body. With a molecular weight over 80 MDa, each IFT train is a dynamic polymer of two large complexes (IFT-A and IFT-B) and motor proteins - posing a formidable challenge to mechanistic understanding. Here, we reconstituted the human IFT-A complex and overcame its conformational flexibility to obtain its structure using cryo-EM. Combined with AlphaFold analysis and genome-edited mammalian cell data, our results illuminate how IFT-A polymerizes; interacts with IFT-B; and uses an array of β-propeller and TPR domains to create “carriages” of the IFT train that engage TULP adaptor proteins. These data establish a structural link between IFT-A’s different functions; provide a blueprint for the IFT-A train; and shed light on how IFT evolved from a proto-coatamer ancestor.

B171/P1858

Role of Sfi1 proteins in *Stentor coeruleus* membranellar band regeneration

C. Yan, P. Sood, R. McGillivary, A. Lin, W. Marshall; University of California, San Francisco, San Francisco, CA.

In response to injury and external perturbations, it is vital for individual cells to be able to heal and re-build complex structures. The giant ciliate *Stentor coeruleus* is a classical model system for studying regeneration, patterning and morphogenesis at a single cell level. At the anterior of the cell is the membranellar band (MB), which consists of organized clusters of cilia. When induced to shed its oral apparatus with an osmotic shock, the cell will generate a new oral structure in a series of defined morphological steps. This raises the question of what molecular signals are involved in building complex cellular structures and re-establishing normal patterning of the cell. A previous transcriptional study and proteomic analysis of *Stentor coeruleus* revealed several Sfi1 proteins involved in MB regeneration. While Sfi1 proteins had not previously been identified in Stentor, Sfi1 in other ciliate systems contain centrin-binding repeat motifs and are implicated in basal body orientation, stability and Ca2+ induced contraction. RNAi knockdown of Sfi1 shows that Sfi1 is involved in the completion of regeneration, with earlier expressed Sfi1 proteins being more critical than those expressed later. Immunofluorescence shows Sfi1 localizes as lateral fibers in between the cortical rows throughout the cell, as well as the cortical rows in the posterior of the cell. Similarly, centrin localizes as a mesh-like network in the anterior of the cell, and only in the cortical rows in the posterior of the cell. Sfi1 and centrin also localize to the developing oral primordium as well as the completed oral apparatus. Interestingly, in

regenerating RNAi knockdown Sfi1 cells, centrin does not appear to localize to the oral primordium. In non-regenerating Sfi1 knockdown cells, the networks of centrin are less dense and more localized to the cortical rows. This indicates that Sfi1 regulates the localization of centrin in static cells, as well as cells during regeneration, and these interactions may play a role in building and organizing the oral primordium. These concepts will shed light on sub-cellular regeneration paradigms in other systems and will give rise to insights to how individual cells are able to recover from external injury.

B172/P1859

High Temporal Resolution Mapping of the Phosphorylation Footsteps of Ciliogenesis

R. E. Turn[1], M. Aziz-Zanjani[1], T. Kanie[2], J. Demeter[1], P. K. Jackson[1]; [1]Stanford University, Stanford, CA, [2]University of Oklahoma Health Sciences Center, Oklahoma City, OK.

The primary cilium serves as a pivotal signaling hub to drive essential life functions, ranging from development, metabolism, neural transmission, vision, olfaction, and more. This small, specialized organelle is highly organized, and failure to coordinate the generation of a functional cilium leads to severe pathologies, ranging from developmental disorders, diabetes, blindness, and even cancer. To date, though, the cilium is largely understudied in part because of its size (~3µm long, ~250nm diameter) and limited tools to study it. By deciphering the stages of ciliogenesis, we will lay the groundwork for much needed insight into the mechanisms that are disrupted in the context of disease. The field has made great strides in defining key steps driving ciliogenesis. Yet, little is known concerning the dynamics of these early events, much less the post-translational modifications (notably phosphorylation events) that drive many of these protein-protein interactions and their function. This is in large part due to 1) the failure to induce synchronized ciliogenesis in cell culture, and 2) under-developed approaches for performing high-sensitivity phosphoproteomics. To address this gap, our lab has monitored ciliogenesis after releasing RPE cells from mitosis, therein systematically synchronizing ciliogenesis in a single, ~2-hr long wave. Key signaling steps are monitored by detailed immunofluorescence microscopy and by data dependent-parallel accumulation-serial fragmentation DDA-PASEF mass spectrometry. So far, we have captured critical signaling events, including the final stages of abscission, the recruitment of early factors to prime ciliary vesicle recruitment and basal body docking, and axonemogenesis. We have identified ~30,000 phosphopeptides and have correlated kinase activities to specific linked substrates to critical stages of ciliogenesis. We further validated these candidates in ciliogenesis-synchronized RPE cells via immunofluorescence in combination with pharmacological and genetic approaches. For instance, we discovered that autophosphorylation of critical ciliogenesis kinase TTBK2 is pivotal for removing CP110 and licensing early ciliogenesis. Together, our work will lay the foundation for future studies studying the temporal and spatial mechanisms driving ciliary assembly.

B173/P1860

Towards a unifying mechanism for trafficking of proteins to the primary cilium membrane.

V. Palicharla[1], S. Hwang[1], K. Liem[2], S. Mukhopadhyay[1]; [1]Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX, [2]Pediatrics, Yale University School of Medicine, New Haven, CT.

The membrane of the primary cilium has a distinct protein and lipid composition, despite being contiguous with the plasma membrane. To understand the role of cilium-generated signaling in homeostasis, it is necessary to decipher the mechanisms that drive such unique compartmentalization. The tubby family protein, TULP3, transports integral membrane proteins into cilia through binding with

the intraflagellar transport complex-A (IFT-A) and phosphoinositides. These transmembrane cargoes have short motifs that are necessary and sufficient for TULP3-mediated trafficking. However, mechanisms of ciliary compartmentalization of non-integral, membrane-associated proteins are poorly understood. In addition, the mechanism by which such diverse cargos are trafficked to cilia by TULP3 is not well understood. ARL13B is a palmitoylated atypical GTPase, that is highly enriched in cilia. We recently reported that cilia in kidney tubular epithelia deleted for *Tulp3* lacked ARL13B preceding renal cystogenesis. Here, using *Tulp3* knockout mouse embryonic fibroblasts and cell lines, we show that TULP3 is required for ciliary transport of ARL13B. By promoting ARL13B trafficking, TULP3 also determines ciliary enrichment of ARL13B-dependent lipidated cargos, including farnesylated INPP5E, and myristoylated NPHP3 and CYS1. Trafficking of transmembrane cargoes, such as G-protein coupled receptors, by TULP3 requires both IFT-A and phosphoinositide binding. In contrast, we found that lipidated protein trafficking to cilia required TULP3 binding to IFT-A but not to phosphoinositides, reflective of increased affinity of interactions between TULP3 and ARL13B, compared to transmembrane cargoes. Furthermore, we identified that an N-terminal amphipathic helix in ARL13B preceding the GTPase domain and including the palmitoylation site mediated direct ARL13B binding to TULP3. This helix was required for ciliary trafficking of ARL13B irrespective of palmitoylation and RVxP sorting motifs previously implicated in ciliary trafficking. We also identified critical residues in the β-barrel of TULP3's tubby domain that mediated direct ARL13B binding and promoted ciliary trafficking of both lipidated and transmembrane cargoes. Some of these residues are mutated in human subjects with renal and liver cystogenesis and have been implicated in causing renal cystogenesis in mouse models. These findings indicate an expanded role of a shared tubby domain surface in TULP3 that captures short sequences of diverse cargoes to directly mediate their transport into cilia in concert with IFT-A. Targeting the TULP3-cargo interactions could provide therapeutics in ciliary trafficking-regulated diseases such as polycystic kidney disease and obesity.

B174/P1861

Molecular and anatomical transformations in cilia and centrosomes underlie ciliary deconstruction during cerebellar granule cell differentiation

C. Ott[1], S. Constable[2], A. Lemire[1], A. Lim[3], J. Lippincott-Schwartz[1], S. Mukhopadhyay[4]; [1]Janelia Research Campus, Ashburn, VA, [2]Adelaide Centre for Epigenetics, Adelaide, AUSTRALIA, [3]Wellesley College, Wellesley, MA, [4]UT Southwestern Medical Center, Dallas, TX.

Granule cells (GCs) in the cerebellum are the most abundant neurons and abnormal GC proliferation causes sonic hedgehog (Shh)-subtype medulloblastoma. GC progenitors divide in response to cilia transduced Shh signals prior to differentiating and migrating. Reduced ciliation in post-mitotic GCs has been described, however how cilia change as GCs mature is not well understood. The migration-induced separation of GCs during neurogenesis enabled us to explore the mechanism of cilia deconstruction using parallel analysis of ultrastructure, transcript levels and protein localization in the developing cerebellar tissue. Analysis of ciliary structure in a large-scale 3D electron microscopy volume revealed that cilia in GC progenitors formed through an intracellular biogenesis pathway during which many were concealed from external signaling. As GCs differentiated, most cilia remained internal and gradually reduced in length and frequency. Intermediate structures suggested active recovery of the cilia-related membranes as well as internal components. To identify molecular candidates contributing to the observed anatomical changes, we queried single cell transcriptomic data from developing cerebella for expression changes in centrosome and cilia related genes. Several genes important for cell cycle

dependent cilia resorption, including Aurka, were diminished in differentiating and mature cells, suggesting that alternative pathways likely regulated ciliary deconstruction during neurogenesis. We investigated gene expression changes and found that maturing GC progenitors had reductions in genes coding for pericentriolar material, centriolar satellite components, and intraflagellar transport proteins. We then used immunofluorescence imaging and found that changes in protein levels of these components accompanied decreased transcription. Immunostaining revealed that Shh signaling competent cilia-centrosomal complexes persisted in proliferative GC nests prior to tumorigenesis. These results indicated that ciliogenesis initiates early in differentiation and then cilia were deconstructed as a programmed part of neurogenesis using a pathway that includes diminution of proteins required for cilia maintenance. The regulated abatement of cilia mediated signaling is likely important for GC maturation and is dysregulated during medulloblastoma pathogenesis.

B175/P1862

Three-dimensional ultrastructural analysis reveals stepwise asymmetric initiation of ciliogenesis

Q. Lu, H. Zhao, Z. Khan, I. Saha, K. Narayan, C. Westlake; NCI/NIH, Frederick, MD.

Ciliogenesis requires a highly complex yet poorly understood sequence of membrane and cytoskeletal assembly processes. In cells that build the cilium partially in the cytoplasm, the earliest steps of ciliogenesis involve the docking of pre-ciliary membrane vesicles (PCV) to distal appendages on the mother centriole. PCVs are fused to form a larger ciliary vesicle (CV) that covers the distal end of the mother centriole. The CV subsequently seeds the ciliary membrane, that surrounds the axoneme, and the ciliary pocket membrane, which connects the cilium to the plasma membrane. The formation of the CV is associated with the removal of CP110/CEP97 (MC cap) from the distal end of the MC which is essential for axoneme elongation and transition zone (TZ) formation. How the CV and TZ formation is coordinated at the early stage of ciliogenesis is not clear. We investigated these ciliogenesis events using super-resolution live-cell imaging and volume-based electron microscopy. The 3-D ultrastructural analysis reveals that the mother centriole is surrounded by a large number of vesicles before CV formation. Distribution correlation analysis suggests that these vesicles are associated with the adjacent Golgi apparatus. Surprisingly, we found that vesicles docked on the distal appendages of the mother centriole asymmetrically fused to form a novel “C”-shaped vesicle. The “C”-shaped vesicle then fuses its ends into a toroidal ciliary vesicle before the CV is formed. Next, we correlative TZ formation to vesicle fusion and found that TZ proteins are recruited to the “C” and toroidal vesicles, which would create a link between the early vesicles and the microtubule doublets of the basal body. Remarkably, we show the removal of the MC cap correlates with this asymmetric ciliary membrane assembly process. Moreover, we find that membrane shaping and fusion directed by EHD1 functions in CP110 removal from the. MC. Together our work provides new insight into how the ciliary membrane assembles and directs ciliogenesis events on the centriole.

B176/P1863

Cell-specific α-tubulin TBA-6 and pan-ciliary IFT cargo RAB-28 generate a non-canonical transition zone

J. Akella[1], M. S. Silva[2], K. C. Q. Nguyen[3], D. H. Hall[3], M. M. Barr[1]; [1]Rutgers University, Piscataway, NJ, [2]Human Technopole, Milan, ITALY, [3]Albert Einstein College of Medicine, Bronx, NY.

Identifying mechanisms of ciliary specialization is crucial to understanding tissue-specific phenotypes of ciliopathic mutations. In *C. elegans* inner labial type 2 (IL2) neurons, the ciliary transition zone (TZ)

reorganizes from a canonical 9 microtubule (MT) arrangement to a non-canonical arrangement with 7 or fewer MTs. Here, we examined the mechanism and potential function of IL2 TZ reorganization. IL2 TZ reorganization involves the termination and disassembly of ciliary MTs and requires cell-specific α-tubulin TBA-6. Pan-ciliary IFT cargo and EV regulator RAB-28 controls IL2 TZ reorganization after axoneme assembly. IL2 TZ reorganization is important to properly localize the cell-specific motor KLP-6 but is not required for ciliary EV shedding and release. Our results identify a novel role for tubulin isotypes in generating TZ diversity. We also extend previous findings identifying a relationship between TZ and IFT. Our results highlight differences in the requirements for EV shedding and release from ciliated cells and suggest that cell-specific effects of ciliary gene mutations on EVs could contribute to differences in phenotypic severity in ciliopathies. Our simple *C. elegans* model allows us to uncover the molecular mechanisms that govern cilia specialization and plasticity. This developmental plasticity suggests that some ciliary defects (ciliopathies) may be corrected at later times, and that this represents a point of therapeutic intervention.

B177/P1864

Transcriptional regulation of flagella-specific genes during flagellar assembly in Chlamydomonas

K. Perlaza, **W. Marshall**; University of California, San Francisco, San Francisco, CA.

Length regulation of cilia and flagella represents a tractable model for investigating the general question of organelle size control. In Chlamydomonas, flagellar length results from a balance of assembly and disassembly, leading to the question of how these processes are coordinated. Most studies of flagellar assembly and length regulation have focused on the transport of proteins to the flagellar tip, but it is known that transcription and new protein synthesis are required for flagella to grow to full length. Most genes encoding flagellar proteins are upregulated during flagellar assembly, but the mechanism of this regulation is not known. Using quantitative measurements of mRNA levels by qPCR and Nanostring detection, we find that flagellar gene upregulation is partially triggered by the loss of flagella, but that full expression requires the active regrowth of flagella. We propose that flagellar genes are regulated by a repressor molecular that is sequestered into the growing flagellum, such that when flagella grow rapidly, repressor is depleted from the cell body, leading to gene induction. Because induction of flagellar genes should stimulate further flagellar growth, this scheme represents a positive feedback loop with the potential for instability. However, computational analysis indicates that in fact the system is stable and robust.

B178/P1865

Assembly of FAP93 at the proximal end of *Chlamydomonas reinhardtii* cilia depends on total ciliary length

S. Gordon[1], J. Hwang[2], H. Yanagisawa[3], E. L. Hunter[2,4], L. A. Fox[2], A. R. Jimenez[1], R. E. Goodwin[1], C. D. E. Stuart[1], K. C. Davis[5], R. Bower[6], M. E. Porter[6], S. K. Dutcher[4], W. S. Sale[2], L. M. Alford[1]; [1]Oglethorpe University, Atlanta, GA, [2]Emory University, Atlanta, GA, [3]University of Tokyo, Tokyo, JAPAN, [4]Washington University in St. Louis, St. Louis, MO, [5]Clayton State University, Morrow, GA, [6]University of Minnesota, Minneapolis, MN.

Cilia are highly-conserved, threadlike organelles required for cell motility and sensation, found on the surfaces of nearly all human cells. Defects in ciliary structures can lead to a wide array of ciliary related diseases, termed ciliopathies. Cilia are composed of over 700 proteins that are highly organized into

complex structures, but not symmetrically (Dutcher, 2019). FAP93 is a novel ciliary protein located at the proximal end of the cilium, where the bend for movement is initiated. To learn more about the function of FAP93, we are investigating its localization via immunofluorescence microscopy. FAP93 assembles at the proximal 1.10 ± 0.1µm of wild-type cilia, but is significantly shorter in the short flagella mutants *shf1* (0.69 ± 0.2µm, $p < 0.01$) and *shf2* (0.72 ± 0.2µm, $p < 0.01$), where the total ciliary length is nearly half that of wild-type. Additionally, because FAP93 is a proximally located ciliary protein and the *fap93* mutant phenotype is not overt, it is possible that its function is redundant or associated with other proximally located ciliary proteins, such as ODA10 and VFL3 (Dean & Mitchell, 2013 & Ochi et al., 2020). To assess whether there is a relationship between FAP93 and these proximal proteins, we localized FAP93 via immunofluorescence microscopy in *oda10* and *vfl3* mutants. The prediction is that FAP93 will be mis-localized, reduced, or absent if the defective protein is required for FAP93 assembly at the proximal end of the axoneme. FAP93 localization does not appear to be affected in *vfl3* mutants, but does appear to be reduced in *oda10*. To further investigate FAP93 in *oda10*, axonemes will be isolated from wild-type and *oda10* mutant cell types for FAP93 quantification via immunoblot. These results indicate the length of FAP93 assembly correlates with ciliary length, demonstrating ciliary length-dependent assembly of FAP93. Moreover, FAP93 may interact with ODA10 and play a role in proximal axoneme assembly.

Axonemal dynein light intermediate polypeptide 1 (DNALI1) plays a role in MEIG1/PACRG Manchette association and sperm differentiation in mammalian spermatogenesis

Y. Yap[1], W. Li[1], Q. Huang[2], D. Zhang[3], L. Mladenovic-Lucas[1], J. Granneman[1], D. Williams[4], R. Hess[5], A. Toure[6], Z. Zhang[1]; [1]Wayne State University, Detroit, MI, [2]Wuhan University of Science and Technology, Wuhan, CHINA, [3]College of William and Mary, Williamsburg, VA, [4]University of North Carolina, Chapel Hill, NC, [5]University of Illinois, Urbana, IL, [6]Université Grenoble Alpes, Grenoble, FRANCE.

Axonemal dynein light intermediate polypeptide 1 (DNALI1) was originally cloned from *Chlamydomonas reinhardtii* in an effort to find motor proteins essential for flagellar motility. We discovered that DNALI1 is a binding partner of parkin co-regulated gene 1 (PACRG), which forms a complex with meiosis expressed gene 1 (MEIG1) in the manchette, a transient and unique structure only present in elongating spermatids and required for normal male germ cell differentiation. DNALI1 recruits the PACRG protein in transfected CHO cells, and also stabilizes PACRG in bacteria and transfected mammalian cells. The untagged DNALI1 could also be co-purified with His-tagged PACRG when the two proteins were co-expressed in bacteria. Immunofluorescence staining on isolated male germ cells revealed that DNALI1 was present in the manchette of elongating spermatids, and colocalized with PACRG in this structure. In *Pacrg* mutant mice, localization of DNALI1 in the manchette was not changed, suggesting that DNALI1 and PACRG form a complex in the manchette, with DNALI1 being an upstream molecule. Mice deficiency in DNALI1 specifically in male germ cells showed dramatically reduced sperm numbers, immotile sperm and were infertile. In addition, majority of the sperm exhibited abnormal morphology including misshapen heads, bent tails and enlarged midpiece, discontinuous accessory structure, and loss of sperm individualization, emphasizing the importance of DNALI1 in sperm development. Examination of testis histology revealed impaired spermiogenesis in the conditional *Dnali1* knockout mice. Electron microscopy revealed disrupted ultrastructure in sperm of the *Dnali1* mutant mice. Testicular levels of MEIG1, PACRG and SPAG16L proteins were not changed in the *Dnali1* mutant mice. However, MEIG1 and SPAG16L were no longer present in the manchette in the absence of DNALI1. These findings

demonstrate that DNALI1 is involved in the connection of the MEIG1/PACRG complex to the manchette microtubules for sperm flagella formation. Given that *Dnali1* mutant mice showed impaired sperm individualization that was not observed in the MEIG1 nor PACRG-deficient mice, DNALI1 might fulfill multiple roles in sperm cell differentiation and function.

Galectin-8 induces primary cilia loss by calcium influx and Aurka/HDAC6 activation impacting on leptin signaling in POMC hypothalamic cell lines.

C. Herrera-Cid[1], B. Kerr[1], A. Soza[1,2,3], A. González[1,2,3]; [1]Centro de Biología Celular y Biomedicina (CEBICEM), Facultad de Medicina y Ciencia, Universidad San Sebastián, Santiago, CHILE, [2]Centro de Envejecimiento y Regeneración (CARE), P. Universidad Católica de Chile, Santiago, CHILE, [3]Fundación Ciencia y Vida, Santiago, CHILE.

Introduction. Primary cilium is a cell surface antenna-like organelle where several transduction systems are located and is lost when cells enter the cell cycle and proliferate, mostly involving activation of aurora kinase A (Aurka)/HDAC6 and Ca^{2+} signaling, among other regulators. However, whether and how the primary cilium structure is regulated during physiological processes beyond cell proliferation remains little known. POMC neurons control satiety and energy balance in the hypothalamus, triggering anorexigenic signals in response to leptin, which activates the Leptin Receptor B (LepR-B) and downstream STAT3 present in the primary cilium. The loss of cilium in these neurons leads to leptin resistance, metabolic syndrome and obesity in mice models. Galectin-8 (Gal-8) is a carbohydrate binding protein that interacts with beta-galactosides present in cell surface glycoproteins, through which it can modulate a variety of cellular processes. In the brain, Gal-8 has neuroprotective properties and its expression regions include thalamus, hypothalamus and choroid plexus. Proinflammatory conditions similar to those described in obesity, diabetes and metabolic syndrome can upregulate Gal-8 expression. Here we study the role of Gal-8 on primary cilia and leptin signaling in POMC neurons. **Material and Methods.** POMC cell line Clu-177 treated with human recombinant Gal-8 was analyzed by confocal immunofluorescence for acetylated α-tubulin for cilium, FURA-2 signals for intracellular calcium changes and immunoblot for phosphorylated HDAC6 and pSTAT3. **Results.** Independently of cell proliferation, Gal-8 treatment decreased the ciliated cells by 20% and reduced cilia length by 25%, diminished leptin signaling associated with increased HDAC6 activation and calcium influx, while Aurka inhibition and extracellular calcium chelation prevented cilia loss. Cilium resorption seemed to be the main mechanism of deciliation induced by Gal-8, as shown by live-cell imaging and conditioned media analysis. **Discussion.** Gal-8 has the potential to regulate the primary cilum impacting on leptin receptor signaling, which in the brain may contribute to energy balance modulation and its alterations.

A Novel Cby1-like/ciBAR1 Complex Mediates Precise Positioning of the Annulus, a Septin-based Fibrous Ring, Along the Flagellum in Sperm Tail Segmentation

M. Hoque[1], J. Chen[1], Y. Fuchs[2], F.-Q. Li[1], K.-i. Takemaru[1]; [1]Stony Brook University, Stony Brook, NY, [2]Technion – Israel Institute of Technology, Haifa, Israel

The sperm flagellum is a specialized motile cilium divided into three regions: midpiece (MP), principal piece (PP), and end piece. The annulus, a septin-based ring structure, is positioned at the MP/PP boundary, where it acts as a structural support and a diffusion barrier, analogous to the transition zone of the cilium. Failure to form an annulus leads to male fertility defects. However, its components and assembly and migration mechanisms are poorly understood. The annulus is initially formed at the flagellar base and physically migrates distally to the MP/PP junction as spermatids mature. We previously reported that Chibby 1 (Cby1) localizes to the base of cilia and interacts with the membrane-binding ciBAR1 and 2 (Cby1-interacting BAR domain-containing 1 and 2; formerly known as FAM92A and B) to facilitate ciliogenesis. Cby1-like (Cby1L) is the closest family member to Cby1, but Cby1L's biological function remains unknown. We found that Cby1L is abundantly and exclusively expressed in mammalian testes, suggesting its important role in spermatogenesis. In differentiating spermatids, Cby1L localizes to the annulus at the base of the flagellum and then co-migrates to the MP/PP junction. To investigate the role of Cby1L in male germ cell differentiation, we generated a $Cby1L^{-/-}$ mouse model and found that $Cby1L^{-/-}$ males are completely infertile with markedly reduced sperm counts and kinked tails, strikingly similar to sperm from mice lacking septins. Interestingly, the annulus is present in $Cby1L^{-/-}$ sperm but fails to stop at the MP/PP junction and progresses into the PP. $Cby1L^{-/-}$ sperm also show defective membrane diffusion barrier. In addition, TEM analyses revealed that, although the annulus is firmly attached to flagellar membranes in WT spermatids, $Cby1L^{-/-}$ spermatids exhibit signs of impaired annulus-membrane attachment. Furthermore, we found that, like Cby1, Cby1L binds to ciBAR1, and ciBAR1 colocalizes with Cby1L at the annulus. Consistent with these findings, $ciBAR1^{-/-}$ male mice show fertility defects with kinked sperm morphology and annulus displacement into the PP. Moreover, the annulus localization of Cby1L and ciBAR1 is mutually dependent. Collectively, our findings suggest a working model in which a membrane-binding Cby1L/ciBAR1 complex localizes to the annulus to ensure stable annulus-membrane attachment and precisely position the annulus at the MP/PP junction, thereby contributing to proper sperm tail segmentation.

Mechanisms of centrosome positioning and cilia formation during Left-Right Organizer development

F. Ononiwu, N. Krishnan, C. Taveras, J. Manikas, E. Ingram, N. Hall, J. Freshour, H. Hehnly; Syracuse University, Syracuse, NY.

An essential process for cilia formation during epithelialization is for the centrosome to move and dock with the cell's forming apical membrane. Our study examined centrosome positioning using *Danio rerio's* left-right organizer (Kupffer's Vesicle, KV) as a model. We found that when KV mesenchymal-like cells transition into epithelial cells that are organizing into a rosette-like structure, KV cells move their centrosomes from random intracellular positions to the forming apical membrane. During this process, these cells' centrosomes were constructing cilia intracellularly and were surrounded by Rab11-associated membranes containing MyoVa while the centrosome was repositioning towards the rosette center. Once the centrosome with associated cilia reaches the rosette center, the intracellular cilia

recruits Arl13b and waits to extend into the forming lumen until the lumen reaches an area of approximately 300 μm^2. Using optogenetic strategies we identified that the small GTPase, Rab11 and its associated membranes, regulates not only cilia formation, but centrosome movement towards the forming apical membrane, whereas Rab8 was primarily involved in cilia elongation once cilia extends into the KV lumen. These studies present both conserved and unique roles for Rab11 and Rab8 function in cilia formation during KV lumenogenesis.

Vertebrate model to study cilia assembly and repair

V. G. Rao[1], V. Subramanianbalachandar[1], M. M. Magaj[2], S. Redemann[3], S. Kulkarni[4]; [1]Department of Cell Biology, University of Virginia, Charlottesville, VA, [2]Ctr for Membrane & Cell Phys, Dept of Molecular Phys & Biological Physics, Dept of Cell Biology, University of Virginia, Charlottesville, VA, [3]Center for Membrane & Cell Physiology, Department of Molecular Physiology and Biological Physics Dep, University of Virginia, Charlottesville, VA, [4]Department of Cell biology, Department of Biology, University of Virginia, Charlottesville, VA.

Motile cilia beating is critical for the mucociliary barrier to function as the first line of defense in the lungs. Due to exposure to several factors (such as acid reflux, infection, and inflammation), these cilia can undergo damage, that can be repaired by regenerating cilia. Though cilia regeneration mechanisms are well studied in unicellular models such as *Chlamydomonas* and *Tetrahymena*, however our understanding of cilia regeneration remains poor in vertebrate models. We use *Xenopus tropicalis* embryos as a model to study motile cilia regeneration of the mucociliary epithelium. We induce deciliation by calcium shock and show that the motile cilia completely regenerate within 6 hours. Using live imaging we demonstrate that multiciliated cells (MCCs) grow their cilia rather than undergo stem cell-based renewal. To understand if cilia regeneration depends on the preexisting pool of unassembled ciliary proteins or requires translational/transcriptional upregulation, we exposed deciliated MCCs to cycloheximide to block new protein synthesis. Our results showed that the precursor pool of ciliary proteins can drive the initial regeneration of all cilia, however, in the absence of new protein synthesis, MCCs prioritize fewer but longer cilia. MCCs do that by accumulating IFT proteins only at the few basal bodies to build longer cilia. We further studied the site of deciliation and observed that the deciliation does not affect the apical actin lattice and the basal body number, organization, or polarity in the MCCs. Unlike *Chlamydomonas*, we observe that the transition zone (TZ) is lost along with cilia during deciliation. We studied the transition zone assembly during cilia regeneration using electron tomography and by observing the dynamics of known TZ protein B9D1 during regeneration. While all ciliogenesis models predict that TZ is assembled first followed by before the assembly of axoneme assembly, we observed that these cilia begin to regenerate in the absence of TZ. Moreover, we show that B9D1 is not a part of the ciliary precursor pool in the cytoplasm during the initial stages of regeneration. The current work opens possibilities to pose new questions such as what the spatial and temporal sequence of transition zone assembly during cilia regeneration is. In conclusion, our work provides novel insights into cilia repair mechanisms in MCCs using a vertebrate model organism.

The WAVE complex drives the morphogenesis of the photoreceptor outer segment cilium

W. J. Spencer[1], N. F. Schneider[2], N. P. Skiba[2], V. Y. Arshavsky[2]; [1]Upstate Medical University, Syracuse, NY, [2]Duke University, Durham, NC

The photoreceptor outer segment is a modified cilium filled with hundreds of flattened "disc" membranes responsible for efficient light capture. To maintain photoreceptor health and functionality, outer segments are continuously renewed through the addition of new discs at their base. This process is driven by branched actin polymerization nucleated by the Arp2/3 complex. To induce actin polymerization, Arp2/3 requires a nucleation promoting factor. Here, we show that the nucleation promoting factor driving disc morphogenesis is the pentameric WAVE complex and identify all protein subunits of this complex. We further demonstrate that the knockout of one of them, WASF3, abolishes actin polymerization at the site of disc morphogenesis leading to formation of disorganized membrane lamellae emanating from the photoreceptor cilium instead of an outer segment. These data establish that, despite the intrinsic ability of photoreceptor ciliary membranes to form lamellar structures, WAVE-dependent actin polymerization is essential for organizing these membranes into a proper outer segment.

B185/P1872

Uncovering principles of rod photoreceptor outer segment size control by genetically increasing growth

A. Jensen, L. Gilliam, J. Willoughby; University of Massachusetts, Amherst, MA

The sensory compartment of rod photoreceptors, the rod outer segment (ROS), is a highly modified primary cilium where photons of light are captured by the Rhodopsin protein and transduced into changes in membrane potential that alter synaptic neurotransmitter release. The ROS has the typical ciliary microtubular axoneme but additionally holds hundreds of densely packed, stacked, discrete intramembranous discs containing the phototransduction machinery (1300-1500 discs in a human ROS, Krstic, 1997). Further, compared to a typical mammalian primary nonmotile cilium, the ROS length is about 10 times longer, volume about 250-300 times greater, and membrane area nearly 1000 times greater (Marshall et al., 1979; Praetorius and Spring, 2005). Another major difference between photoreceptor outer segments and primary cilia is that the ROS is continuously regenerated or renewed through the combined processes of proximal growth and distal shedding (Young, 1967; Young and Droz, 1968; Young and Bok, 1969; Young, 1971; LaVail, 1973). It is postulated that photoreceptors renew their outer segments because the very narrow connecting cilium cannot accommodate the retrieval of worn outer segment disc membrane and associated proteins for disposal and recycling in the inner segment compartment. Since its discovery, progress in understanding the renewal process and principles of ROS size control has been slow. To accelerate progress, we developed multiple genetic tools in zebrafish that allow us to temporally manipulate transgene expression specifically in rods and also quantitatively measure both ROS growth and shedding rates (Willoughby and Jensen, 2012). To better understand how mature homeostatic ROS length is controlled, we used the TetOn rod system we created (Campbell et al., 2012) to overexpress Rheb, an effector of the central cellular mTOR growth pathway (review, Laplante and Sabatini, 2012). We find that following 14 days of doxycycline (DOX), Rheb-overexpressing ROS grow faster by about 26% (Wt growth = 11.11um; Rheb growth = 14.03um), while the ROS shedding rates are similar. We examined the ROS ciliary axoneme, the microtubule-based structure that extends

about 63% of the length of the ROS. The axoneme is a good candidate to control ROS homeostatic length by serving to deliver material/molecules to support ROS structure, function and integrity. We measured axoneme length in Wt and Rheb-overexpressing ROS and find no significant difference (Wt, 12.64um sem 0.86; Rheb, 13.67um sem 0.79). These results suggest that ROS homeostatic length is not controlled by the number of discs, distance from the inner segment or axoneme length.

B186/P1873

JNK is a novel ciliogenesis regulator controlling actin driven processes

M. Chatzifrangkeskou, P. Skourides; University of Cyprus, Nicosia, Cyprus

c-Jun N-terminal kinases (JNKs) are a family of protein kinases that play a central role instress signaling pathways and are involved in the development of a number of diseases, such as diabetes, neurodegeneration and liver disease. They have been implicated in various cellular processes including gene expression, neuronal plasticity, regeneration, cell death, and regulation of cellular senescence. We show that JNK is closely associated with the basal bodies of both primary and motile cilia. Using super-resolution imaging, we demonstrate that JNK is localized at the transition zone and is specifically associated with the transition fibers. We further show a critical role of JNK in the development and function of motile multiciliated cells (MCCs) in Xenopus laevis. Loss of JNK prevents the association of IFT52 with the basal bodies and leads to deregulation of the actin cytoskeleton. This in turn inhibits basal body migration and docking leading to severe ciliogenesis defects. JNK inhibition in mature MCCs leads to the disorganization of the apical and subapical actin networks and elicits defects in basal body spacing and cilia driven flow generation. In summary, our work uncovers a novel kinase dependent role of JNK in ciliogenesis and ciliary function.

B187/P1874

EHD1 controls centriolar satellite delivery of HERC2 to the mother centriole to promote CP110 ubiquitination and degradation

S. Xie, N. Naslavsky, S. Caplan; University of Nebraska Medical Ctr, Omaha, NE

Primary cilia are sensory organelles that coordinate diverse signaling pathways, controlling development and homeostasis. Progression beyond the early steps of ciliogenesis requires removal of a distal end protein, CP110, from the mother centriole, a process mediated by Eps15 Homology Domain protein 1 (EHD1). However, it remains unclear how CP110 is removed from the mother centriole. In this study, we show that EHD1 regulates CP110 ubiquitination during ciliogenesis, and identify two E3 ubiquitin ligases, HECT domain and RCC1-like domain 2 (HERC2) and mindbomb homolog 1 (MIB1), that interact with and ubiquitinate CP110. We determined that HERC2 is required for ciliogenesis and localizes to centriolar satellites, which are peripheral aggregates of centriolar proteins known to regulate ciliogenesis. We reveal a role for EHD1 in the transport of centriolar satellites and HERC2 to the mother centriole during ciliogenesis. Taken together, our work showcases a mechanism whereby EHD1 controls centriolar satellite movement to the mother centriole, thus delivering the E3 ubiquitin ligase HERC2 to promote CP110 ubiquitination and degradation.

B188/P1875

Understanding IFT train location in ciliated eukaryotic cells by structural studies

A. Marteil[1], T. Blisnick[2], A. Araujo Alves[2], P. Bastin*[2], A. Mallet*[1]; [1]Ultrastructural BioImaging Core Facility (UBI), C2RT, Institut Pasteur, Paris, FRANCE, [2]Trypanosome Cell Biology Unit, University of Paris, INSERM U1201, Institut Pasteur, Paris, FRANCE.

Cilia are cytoplasmic extensions found in almost all eukaryotic cell types. Defects in these structures can cause diseases termed ciliopathy, whose etiology is little understood. Cilia are constructed by the action of IntraFlagellar Transport (IFT) trains of protein complexes which allow the delivery of structural proteins thanks to kinesin and dynein molecular motors. Here, we are using protists of the Kinetoplastid order as model organisms to study IFT. They possess a flagellum composed of a canonical axoneme constituted of 9 doublet microtubules and a central pair, and a paraflagellar rod (PFR), a lattice-like structure attached to the axoneme via doublets 4 to 7. In *Trypanosoma brucei,* IFT trains are always localized next to doublets 3-4 and 7-8 of the axoneme, whereas they are found on at least 7 doublets in *Chlamydomonas,* an organism that lacks PFR. What could explain the restricted location of IFT trains in trypanosomes ? Is it related to the presence of the PFR that occupies a large volume in the flagellum and could generate intraflagellar congestion, hence restricting the location of IFTs to doublets 3-4 and 7-8. To address this question, IFT train location will be studied in presence and absence of a PFR thanks to different kinetoplastid models. First, we will produce a *T. brucei* strain genetically modified by RNAi to artificially delete the PFR and then observe if there is a repositioning of IFT trains. Second, we will investigate species which either lack the PFR such as *Strigomonas oncopelti* or where the PFR is extremely reduced in length and thickness such as *Angomonas deanei*. Control species will be *T. brucei* wild-type and *Crithidia fasciculata* that possess a fully developed PFR. Data will be obtained by the use of 2D light and electron microscopy techniques which will allow cell observation at different levels. The first results obtained with Scanning Electron Microscopy have shown the global morphology and size of each species, as well as the cytoskeleton and the PFR after membrane stripping. Results obtained by Transmission Electron Microscopy have confirmed the ultrastructural organization of the intraflagellar components : PFR, IFT trains and axoneme. Moreover, first fluorescence light microscopy results have shown different protein locations between each species and confirm the presence and the absence of the PFR based on detection (or not) of signal with the primary antibody L13D6 that recognizes two major PFR proteins.Other techniques can be used to complete data, like 3D electron microscopy (FIB-SEM) to visualize the volume and the spatial organization of IFT trains.

Kinetochore Assembly and Functions

B190/P1876

Investigating the role of dynein in eviction of distinct kinetochore populations of spindle assembly checkpoint proteins

A. H. Ide[1], L. Allan[2], A. Saurin[2], S. M. Markus[1], **J. G. DeLuca**[1]; [1]Biochemistry, Colorado State University, Fort Collins, CO, [2]Division of Cellular Medicine, School of Medicine, University of Dundee, Dundee, UNITED KINGDOM.

Kinetochore-microtubule attachment status is monitored by the spindle assembly checkpoint, a molecular surveillance system that generates a “wait anaphase” signal at unattached kinetochores. In metazoa, the minus end-directed motor protein cytoplasmic dynein-1 localizes to kinetochores at high

levels in early mitosis, and to progressively lower levels as mitosis proceeds. Upon stable microtubule attachment, kinetochore localized dynein has been proposed to transport checkpoint proteins away from the kinetochore and toward the spindle poles using its microtubule-dependent motor activity, thus contributing checkpoint silencing, and progression into anaphase. Given the minus end-directed motility of this motor protein, the prevailing model posits that dynein actively evicts checkpoint proteins (e.g., Mad1, Mad2, etc.) away from properly attached kinetochores by transporting them as cargoes. In this study, we set out to more carefully assess the role of dynein in the eviction of spindle assembly checkpoint effectors from kinetochores. In addition to determining the relative contribution of dynein to checkpoint protein eviction, we find that lateral attachments are indeed sufficient to initiate kinetochore dynein activity, and that checkpoint effectors within the fibrous corona are capable of signaling a checkpoint arrest from a small number of unaligned chromosomes. Our results indicate that the role of kinetochore-associated dynein in the eviction of checkpoint proteins and in checkpoint silencing is markedly reduced in cells in which checkpoint effectors can no longer accumulate at the corona. Thus, dynein's role in checkpoint silencing is likely restricted to evicting checkpoint proteins from the corona rather than from the outer kinetochore.
This work is supported through a grant from the National Science Foundation, NSF1518083SMM and JGD contributed equally to this project*

B191/P1877

Understanding chromosome segregation by drug-mediated tension responses

V. Todi, M. Gupta; Iowa State University, Ames, IA.

Improper chromosome segregation during cell division can be deleterious by causing birth defects and aneuploidy, or even resulting in the development of tumors. Chromosome biorientation is crucial to ensure faithful segregation, wherein kinetochore-microtubule attachment as well as microtubule-generated tension across the attachments of sister chromatids is required to satisfy the Spindle Activation Checkpoint (SAC) and progress into anaphase. It is therefore, essential to understand the pathways leading to activation of the SAC and associated mechanisms that promote chromosome biorientation prior to anaphase. Toward this goal, we developed a novel Taxol-sensitive yeast strain with which we isolated the tension-specific and attachment-mediated responses at kinetochores, which both induce delay in anaphase onset. This revealed discrete functions for SAC proteins; whereas Bub1, Bub3, Mad1, Mad2 and Mad3 are all required for SAC signaling due to unattached kinetochores, Bub1 and Bub3 specifically facilitate a transient delay in response to low tension at attached kinetochores. When microtubule-kinetochore attachments lack sufficient tension, Aurora B kinase (Ipl1 in yeast) phosphorylates kinetochore-associated proteins to promote detachment and subsequent SAC activation. Our Taxol-sensitive yeast model offers a unique opportunity to investigate the functions of microtubule-generated tension and associated proteins in tension-mediated error correction and anaphase onset delay mechanisms which help promote the high-fidelity of chromosome segregation. It will also help elucidate the mode of highly successful cancer therapeutics. Our overall goal is to understand how microtubule-generated tension at kinetochores regulates key aspects of bipolar attachment and chromosome separation. The inclusive impact of the tension- and attachment-based responses will significantly advance our knowledge of how healthy cells ensure genome stability and support the development of therapeutic strategies for states such as cancer and developmental disabilities.

B192/P1878

Special phase separation regulates kinetochore-microtubule attachments

J. McGory; University of Massachusetts, Amherst, MA.

Kinetochores connect chromosomes and spindle microtubules to ensure proper segregation during cell division. Crosstalk between the motor protein dynein and kinetochore-microtubule attachment factors promotes accurate chromosome segregation through a poorly understood pathway. Here we identify a functional linkage between the intrinsically disordered protein (IDP) Spc105 (*Dm*KNL1) and dynein using an opto-genetic assay. Using this assay, we determined that Spc105 has a propensity to phase separate in living cells. We uncovered a minimal phase separating region that is sufficient to link Spc105 to dynein and is necessary for accurate chromosome segregation. Additionally, our work demonstrates that recruitment of dynein targeting factors to Spc105 requires both protein binding motifs and phase separation. Our results identify a previously undiscovered molecular link between an IDP and dynein, and also implicate phase separation in the regulation of microtubule attachment stability.

B193/P1879

Interactions between the central spindle microtubules and the kinetochores promotes homologous chromosome bi-orientation in meiosis.

S. Wu, J. K. Jang, N. Changela, J. Shapiro, J. Joshi, **K. McKim**; Rutgers University, Piscataway, NJ.

The reason for pairing and crossing over between homologous chromosomes is so that they will segregate from each other in the first meiotic division. The two chromosomes of a bivalent, which are connected by at least one chiasma, bi-orient by attaching to microtubules from opposite spindle poles. This process involves a mechanism that regulates the interactions between kinetochores and the microtubules to prevent homologous chromosomes attaching to the same pole. How the error correction/avoidance mechanisms operate in meiosis I is poorly understood. Our previous work has shown that a central spindle Kinesin 6 (Subito) and the chromosome passenger complex (CPC), which includes the Aurora B kinase, are required for meiotic spindle assembly. The CPC is first recruited to the chromosomes, where it promotes recruitment of microtubules. The CPC then promotes spindle assembly, and then moves to the central spindle microtubules in a process that depends on Subito. Within the central spindle, the CPC and Subito are required for accurate bi-orientation of the homologous chromosomes. We are currently investigating how the central spindle complex interacts with the kinetochores to regulate microtubule attachments. Our results support a model in which Aurora B kinase associated with the central spindle microtubules regulates kinetochore-microtubule attachments. One of the targets is SPC105R/ KNL1, which is a hub that integrates several activities at the kinetochore. We have developed a system to study the functions of SPC105R and found It has several separable domains including domains for recruiting most kinetochore components including MIS12 and NDC80, checkpoint proteins such as Mad1 and Mad2, and bi-orientation proteins required for bi-orientation such as MPS1, the RZZ complex, and the CPC. These results show that SPC105R integrates several important genetically separable meiotic functions such as the SAC and error avoidance.

B194/P1880

Control of Chromosome Segregation in *Arabidopsis* Meiosis

F. Böwer[1], K. Lampou[1], S. Komaki[2], Y. Hamamura[1], C. Yang[3], A. Schnittger[1]; [1]Universität Hamburg, Hamburg, GERMANY, [2]Nara Institute of Science and Technology, Ikoma, JAPAN, [3]Huazhong Agricultural University, Wuhan, CHINA.

The spindle assembly checkpoint (SAC) is a safeguarding mechanism preventing anaphase onset (AO) until all kinetochores are properly attached to spindle microtubules. The importance of the SAC in sustaining the vegetative growth and development of *Arabidopsis thaliana* becomes apparent when the microtubule cytoskeleton is challenged. However, not much is known about the function of the SAC in meiosis in plants. Thus, we set out to study chromosome segregation during male meiosis in *Arabidopsis* by utilizing our recently published live cell imaging protocol of *Arabidopsis* anthers. This work led to a cytological framework of SAC action in meiosis in which we could monitor with great temporal resolution the order of SAC assembly and disassembly. Importantly, we find that the SAC is active in meiosis but cannot block meiotic progression for more than 6 hours indicating a weak and permissive SAC. In addition, we find evidence for a striking diversification of the SAC with some core components known from yeast and animals having an adapted function in *Arabidopsis*. Looking then into the regulation of the meiotic SAC, we find that SHUGOSHIN 1 (SGO1) interacts with central players of the SAC. Conversely, SGO1 promotes the timely AO in a SAC-dependent manner. We found that SGO1 in turn is required to assure the correct localization of the phosphatase PP2A, and in *pp2a* mutants, anaphase onset is also significantly delayed in a SAC-dependent manner. Interestingly, we also found with a functional reporter a previously unrecognized dynamic localization pattern of SGO1: the majority of SGO1 was associated with microtubules prior to nuclear envelope breakdown (NEB), followed by a rapid transport to the centromeric regions of chromosomes. Intriguingly, bypassing the microtubule association of SGO1 with a nuclear localization signal also resulted in prolongation of metaphase I. This gives rise to a complex network of highly ordered events of assembly and disassembly of the SAC with an important participation of phospho-control in regulating kinetochore-microtubule attachments.

Chromosome size affects alignment efficiency in mammalian mitosis

M. K. Chong, S. Dumont; University of California, San Francisco, San Francisco, CA

The kinetochore connects chromosomes to spindle microtubules during cell division. Accurate chromosome segregation requires sister kinetochores to biorient, attaching to opposite spindle poles. To achieve biorientation, the kinetochore destabilizes incorrect attachments and stabilizes correct ones. How it discriminates correct from incorrect attachments is not clear. Here, we test the model that tension serves as the stabilizing cue at correct attachments and how that model affects chromosomes of different sizes. Live imaging of mitotic PtK2 cells reveals long chromosomes align at the metaphase plate more slowly than short chromosomes. Using laser ablation to shorten long chromosome arms—reducing polar ejection forces on them—we show that chromosomes align faster after ablation, indicating chromosome size affects alignment efficiency. Finally, artificially enriching for incorrect attachments using STLC washouts and imaging error correction live, we show that long chromosomes exhibit a delay in correcting errors, rather than simply in attachment formation. We propose a model where increased polar ejection forces on long chromosomes stabilize not only correct but also incorrect

attachments, delaying their biorientation and alignment. As such, long chromosomes may experience more challenges correcting errors and, as a result, higher missegregation rates.

Inhibitor-2 promotes Protein Phosphatase 1 activity and mitotic progression in the *C. elegans* embryo

N. Varshney, K. Oegema, A. Desai; University of California San Diego, San Diego, CA.

The catalytic subunit of Protein phosphatase 1 (PP1c) is responsible for a major fraction of Ser/Thr dephosphorylation events in the cell. PP1's catalytic activity and specificity is tightly regulated by a conserved group of regulatory/biogenesis factors, including Inhibitor-2 (I2), a widely conserved protein that was discovered based on its binding and inhibition of PP1's catalytic activity. Using the early *Caenorhabditis elegans* embryo as an *in vivo* model system to investigate PP1c and its regulatory network, we find that the two PP1c isoforms, GSP-1 and GSP-2, act redundantly prior to anaphase onset, with their double depletion leading to severe defects. By contrast, the effect of I2 (named SZY-2 in *C. elegans*) inhibition is significantly milder, with the primary defect being delayed anaphase onset. Anaphase onset is controlled by the Anaphase Promoting Complex/Cyclosome (APC/C) activated by its substrate adapter CDC-20. Cdk1/2 phosphorylation of CDC-20 inhibits its binding to and activation of the APC/C; removal of inhibitory phosphorylation on CDC-20 is catalyzed by PP1c docked on the kinetochore scaffold protein KNL-1 as CDC-20 fluxes through the kinetochore. The anaphase onset delay observed in the I2 depletion is similar to the PP1c docking mutant of KNL-1 and is rescued by a non-phosphorylatable form of CDC-20. Depletion of I2 in the PP1c docking mutant of KNL-1 further delayed anaphase onset, suggesting that I2 promotes PP1c-mediated dephosphorylation of CDC-20 in the cytoplasm. Analysis of *in situ* tagged GFP fusions of the two PP1c isoforms revealed a reduction in overall PP1c levels and in kinetochore-localized PP1c following I2 depletion. Collectively, these data indicate that I2 is important for normal levels and activity of PP1c and its loss negatively affects PP1c activity at kinetochores and in the cytoplasm that promotes mitotic progression via CDC-20 dephosphorylation. Thus, unlike its name, I2 acts as a promoter of specific PP1c functions *in vivo*. Using transgene-based replacement of endogenous I2 with engineered mutants, we are currently addressing the contribution of distinct conserved I2 interfaces with PP1c to elucidate the mechanism by which it contributes to PP1c function in mitotic progression.

Human Artificial Chromosomes as a Tool to Discover New Human CIN Genes

M. Liskovykh[1], E. Chiang[2], K. Cheng[2], H. Masumoto[3], W. Earnshaw[4], N. Kouprina[1], V. Larionov[1]; [1]National Cancer Institute, Bethesda, MD, [2]NCATS, Rockville, MD, [3]Kazusa DNA Research Institute, Chiba, JAPAN, [4]Wellcome Centre for Cell Biology, Edinburgh, UNITED KINGDOM.

Mitosis is a fundamental biological process that still holds many secrets. Among these are the mechanisms preventing chromosome instability (CIN). CIN is a phenomenon driven by problems with chromosome segregation during cell division. Errors in chromosome segregation can cause cell death or lead to the production of abnormal daughter cells that can be dangerous to the organism, e.g., by predisposing cells to cancer progression or being a cause for problems in early neurodevelopment. A comprehensive list of all the genes whose misfunction leads to CIN (CIN genes) would be an important step toward a deeper understanding of mitotic regulation. To date, the study of CIN genes in humans has been fragmented, with genes generally discovered by chance or in screens for abnormal cell cycle,

cell size, and proliferation rate. The incompleteness of the list is demonstrated by the fact that new CIN genes are found every year. There was no systematic search for human CIN genes because of the lack of a suitable experimental approach. Given this need, we decided to build a test-system to check as many human genes as possible for their role in chromosome segregation (i.e., loss of function causes CIN). And we tried to answer the key scientific question - which genes are responsible for precise chromosome segregation during mitosis?To identify CIN genes, we developed a novel high-throughput imaging assay that is based on the use of a synthetic human artificial chromosome (HAC), carrying a dual cassette simultaneously expressing two destabilized versions of the GFP. The HAC, which was assembled from normal and synthetic alpha-satellite repeats, contains a functional centromere that allows its stable inheritance as a nonessential chromosome. The HAC loss rate is roughly 10-fold higher than the native chromosomes. Thus, it is relatively stable, but nonetheless sensitized. This makes the assay more manageable, allowing me to observe a statistically significant number of events in realistic sample size when studying the CIN phenotype in human cells. We successfully applied this HAC-based system, establishing reproducible and sensitive assay performance when testing human protein kinases for their role in proper chromosome transmission. Using this system, we identified a novel set of genes whose knockdown results in increased CIN.After the success of using HAC for the identification of new kinases involved in CIN progression. We applied the same approach even on a bigger scale. Recently we conducted genome-wide siRNA screening of 19000 genes to check their role in CIN. Here we would like to share our recent findings in the attempt to find a comprehensive list of human CIN genes.

POLO/PLK1 regulates PP1 to ensure timely Spindle Assembly Checkpoint and genome stability

M. Moura[1,2], J. Barbosa[1], S. Cunha-Silva[1,2], M. Silva[1], M. Oswald[1], S. Lemaire[3], J. Nilsson[4], A. Saurin[5], M. Bollen[3], C. Conde[1]; [1]i3S - Institute for Research and Innovation in Health, University of Porto, Porto, Portugal, [2]ICBAS - Institute of Biomedical Sciences Abel Salazar, University of Porto, Porto, Portugal, [3]Department of Cellular and Molecular Medicine, KU Leuven, Leuven, Belgium, [4]The Novo Nordisk Foundation Center for Protein Research, University of Copenhagen, Copenhagen, Denmark, [5]School of Medicine, University of Dundee, Dundee, United Kingdom

Protein phosphatase 1 (PP1) is a major orchestrator of mitotic exit. PP1 dephosphorylates KNL1 and MPS1 to inactivate the Spindle Assembly Checkpoint (SAC) and ensure timely anaphase onset. However, the mechanisms that prevent PP1 from prematurely driving these events remain ill-defined. Here, we report Polo/PLK1 as a downregulator of PP1 activity in early mitosis. We found that Polo/PLK1 phosphorylates PP1 in its RVxF-binding pocket *in vitro* and in *Drosophila* S2 cells. The phosphorylation is readily detected at unattached/tensionless kinetochores and decreases as chromosomes congress to the metaphase plate. Replacing endogenous PP1 with a phosphomimetic version prevents the inactivation of MPS1 causing a SAC-dependent metaphase delay. Conversely, expression of unphosphorylatable PP1 significantly weakens the SAC response of S2 cells in the presence of colchicine. Notably, tethering phosphomimetic PP1 to kinetochores fails to restore timely SAC inactivation and anaphase onset in asynchronous cultured cells or accelerate mitotic exit when incubated with spindle poisons. These observations suggest that PLK1-mediated phosphorylation of PP1 exerts its inhibitory effect independently of PP1 kinetochore localization. Moreover, biochemical assays indicate that the catalytic efficiency of recombinant PP1 remains unaltered by PLK1 phosphorylation. We are now testing the non-mutually exclusive hypothesis that phosphorylation of PP1 hinders its interaction with SAC substrates (MPS1, KNL1) and/or enhances its binding to inhibitory RIPPOs. Regardless of the underlying

mechanism, the fine-tuning of PP1 activity by PLK1 during mitosis assumes critical relevance in proliferative tissues. *In vivo* analysis shows that, unlike for the wild-type phosphatase, expression of phosphomimetic PP1 transgene fails to restore the fidelity of chromosome segregation and genome stability in larval neuroblasts of *pp1-87b* mutants. These results uncover a new strategy to regulate PP1 activity in order to ensure a timely SAC and avert aneuploidy.

Clustering of the scaffolding protein CENP-T activates recruitment of Ndc80 complexes to assemble a functionally active outer kinetochore

E. V. Tarasovetc[1], G. B. Sissoko[2,3], A. Maiorov[1], I. M. Cheeseman[2,3], E. L. Grishchuk[1]; [1]Department of Physiology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, [2]Department of Biology, Massachusetts Institute of Technology, Cambridge, MA, [3]Whitehead Institute for Biomedical Research, Cambridge, MA.

Proper kinetochore assembly requires binding of multiple copies of different proteins in an ordered and localized manner. In particular, the human kinetochore scaffolding protein CENP-T recruits two Ndc80 molecules, which are required for stable interaction with spindle microtubules. However, when the CENP-T-kinetochore localization domain is removed, individual CENP-T molecules do not associate robustly with Ndc80 when present in the cytoplasm, highlighting the importance of the centromere localization of CENP-T. We hypothesized that clustering of CENP-T molecules at centromeres plays a role in Ndc80 recruitment. To test this, we created genetically-encoded 60-subunit clusters of CENP-T's outer kinetochore recruitment domain and expressed them in human cells. Clustered CENP-T, but not monomeric CENP-T^{1-242}, robustly recruited Ndc80 and other outer kinetochore proteins. Moreover, complexes formed by CENP-T clusters and outer kinetochore components isolated from cells bind to microtubules and move processively with dynamic microtubule tips. To investigate the mechanism that leads to assembly of a functionally active outer kinetochore on clustered CENP-T, we tested whether this phenomenon can be recapitulated using recombinant components. We used a real time TIRF fluorescence assay to monitor interactions between GFP-tagged Ndc80 and CENP-T^{1-242} present in either clustered or monomeric forms. Both forms of CENP-T bind to two Ndc80 complexes, but we found that Ndc80 molecules dissociate significantly faster from monomeric compared to clustered CENP-T. In addition, the stability of CENP-T-Ndc80 binding increases over time, indicating a "maturation" process of Ndc80 binding sites on CENP-T. Such maturation was concurrent with the presence of multiple weakly-bound Ndc80 molecules around CENP-T clusters. The formation of such molecular clouds was not observed with monomeric CENP-T molecules, which experienced much slower maturation compared to clustered CENP-T. Thus, the enhancement of Ndc80 recruitment and stabilization of its binding to CENP-T is an intrinsic feature of CENP-T clusters and is associated with different kinetics of Ndc80 binding and maturation. We propose that, in cells, these molecular mechanisms promote efficient and stable binding of Ndc80 and other outer kinetochore components specifically at the centromere loci, while avoiding interactions between the soluble components in the cytoplasm.

The Astrin-SKAP Complex Lubricates the Kinetochore-Microtubule Attachment

M. Rosas Salvans[1], R. Sutanto[1], p. suresh[2], S. Dumont[1]; [1]University of California, San Francisco, san francisco, CA, [2]Massachusetts Institute of Technology, cambridge, MA.

The kinetochore links chromosomes to spindle microtubules to drive chromosome segregation at cell division. While we know nearly all mammalian kinetochore proteins, how these give rise to the strong yet dynamic microtubule attachments required for function remains poorly understood. Here, we focus on the Astrin-SKAP complex, which localizes to bioriented kinetochores and is essential for chromosome segregation, but whose mechanical role is unclear. Live imaging reveals that SKAP depletion dampens movement and decreases coordination of metaphase sister kinetochores, and increases tension between them. Using laser ablation to isolate kinetochores bound to polymerizing vs depolymerizing microtubules, we show that without SKAP kinetochores move slower on both polymerizing and depolymerizing microtubules, and that more force is needed to rescue microtubules to polymerize. Thus, in contrast to previously described kinetochore proteins that increase grip on microtubules under force, Astrin-SKAP reduces grip, increasing attachment dynamics and force responsiveness and reducing friction. Together, our findings suggest a model where the Astrin-SKAP complex effectively “lubricates” correct, bioriented attachments to help preserve them.

Microtubule plus end targeting motif of Ska1 regulates kinetochore-microtubule attachment and chromosome alignment in human cells.

R. M. RADHAKRISHNAN[1], S. T. Kizhakkeduth[2], V. M. Nair[1], S. Ayyappan[2], B. R[1], N. Babu[1], A. Prasannajith[1], K. Umeda[3], V. vijayan[2], N. Kodera[3], T. K. Manna[1]; [1]Biology, Indian Inst Science Ed/Res (IISER) - Keral IISER TVM - 20122196, Thiruvananthapuram, INDIA, [2]Chemistry, Indian Inst Science Ed/Res (IISER) - Keral IISER TVM - 20122196, Thiruvananthapuram, INDIA, [3]Bio-AFM Frontier Research Center, Kanazawa University, Kanazawa, JAPAN.

Attachment of the dynamic plus ends of microtubules attachment with the kinetochores of chromosomes is essential for the segregation of chromosomes during mitosis. The mechanisms of how kinetochore attachment is stabilized and its movement are coupled with the dynamic plus ends are poorly understood. In budding yeast, ring structures formed by Dam1 complex proteins on the microtubules are implicated to couple kinetochores to the depolymerizing microtubule by dynamically moving/sliding along the microtubule lattice following microtubule depolymerization. The mechanisms of kinetochore coupling and the organization of the molecular factors involved in the process in metazoans have not been completely identified. The absence of Dam1 complex components in higher eukaryotes necessitates the importance of identifying the regulators in higher eukaryotes for this function. Vertebrate Spindle and kinetochore-associated (Ska 1,2,3) complex proteins have been proposed to have an analogous role to Dam1. Microtubule plus end-binding protein, EB1, plays a critical role in coupling microtubule plus ends to the kinetochore by mediating interaction with the Ska in human cells. However, the mechanism underlying EB1 interaction with Ska is incompletely understood. Here, we show that the interaction of Ska1 N-terminal loop region with microtubule plus end protein EB1 through a conserved motif regulates Ska complex recruitment to the kinetochore and metaphase chromosome alignment. Deletion or mutation of Ska1 motif, SHLP disrupts EB1-Ska1 interaction and delocalizes Ska complex proteins from kinetochores, and induces chromosome alignment defects.
