Mutation of the motif, however, does not affect Ska complex assembly. High-speed atomic force microscopy imaging visually demonstrate Ska1 loop mediating contacts with the C-terminal region of EB1 dimer leading to the formation of stable extended structure. NMR analysis showed that the Ska1 SHLP motif interacts with the residues in the EB-homology domain of EB1, which are known to bind to several plus end-associated proteins. Our results demonstrate that the Ska1 loop with its conserved motif regulates EB1-Ska1 interaction and stable kinetochore-microtubule attachment. They also implicate that the SHLP motif-mediated EB1-Ska1 interaction could provide microtubule plus-end attachment specificity for the vertebrate kinetochore.

Towards the Structural Basis for CENP-V Mediated Regulation of Chromosome Segregation

L. Di Pompeo, A. A. Jeyaprakash, W. C. Earnshaw; Wellcome Trust Centre for Cell Biology, Institute of Cell Biology, University of Edinburgh, Edinburgh, UNITED KINGDOM.

Centromere protein V (CENP-V) is an outer kinetochore protein, originally identified in isolated mitotic chromosomes and very well conserved among vertebrates. A previous study using RNAi to deplete canonical CENP-V in HeLa cells suggested that the protein was involved in the compaction of mitotic chromosomes and completion of cell division. More recently, CENP-V was shown to bind microtubules and to maintain spindle integrity during meiosis of mouse oocytes. How CENP-V achieves these diverse functions is still unknown, and is the subject of my Ph.D. studies. Studies of human CENP-V are complicated by the presence of a canonical CENP-V gene plus three paralogs that may or may not encode functional proteins. Analysis of the protein sequence suggested that CENP-V contains a glutathione-dependent formaldehyde-activating (GFA) domain, reported to be involved in formaldehyde metabolism in bacteria. By using a combination of biochemical and structural characterization and cell biology, my research specifically aims to investigate whether CENP-V does have GFA-like enzymatic activity and whether this might be associated with the metabolism of formaldehyde released in nuclear demethylation reactions. My high-resolution crystal structures confirm that CENP-V has a GFA-like domain that binds reduced glutathione (GSH) via a binding pocket stabilised by a zinc ion and the glutathione itself. These observations support the hypothesis of a catalytic activity similar to the bacterial enzyme. I have also confirmed that human CENP-V binds tightly to microtubules *in vitro* mainly via its unstructured N-terminal region that precedes the GFA domain. My ongoing work aims to use structure-based mutants and conditional knock-out to understand how glutathione and microtubule binding activities of CENP-V are linked to its suggested roles in maintaining chromosome structure and/or spindle integrity.

A phosphoproteomic approach to investigate the role of the Bub1 kinase domain in chromosome segregation

A. Bunning[1], J. Walley[2], M. Gupta[1]; [1]Genetics, Development, and Cell Biology, Iowa State University, Ames, IA, [2]Plant Pathology and Microbiology, Iowa State University, Ames, IA.

Accurate chromosome segregation is crucial for cell survival and preventing aneuploidy. A bioriented spindle must be formed where each kinetochore is attached to a microtubule emanating from the opposite spindle pole body. These bioriented attachments are reinforced by microtubule-generated tension at kinetochores that creates the pulling force needed to separate sister chromatids during

anaphase. Both microtubule attachments and tension at kinetochores are vital for forming a bioriented spindle needed for proper chromosome segregation. Bub1 and Bub3 are key proteins in the Spindle Assembly Checkpoint (SAC), a signaling cascade that prevents anaphase onset if one or more kinetochores are unattached. Bub1 and Bub3 are recruited to unattached kinetochores, leading to an anaphase onset delay by preventing activation of the APC/C (anaphase promoting complex). Bub1 and Bub3 have been shown to delay anaphase onset in the presence of attached, low tension kinetochores independent of the canonical SAC. The Bub1 kinase domain is not needed for SAC signaling but localization of Sgo1, a protein implicated in tension sensing and localization of error correction machinery. How the Bub1 kinase domain specifically responds to tensionless kinetochores and promotes chromosome segregation remains unclear. To address this, we used quantitative mass spectrometry in budding yeast cells to investigate differences in phosphorylation between nocodazole-treated bub1-Δkinase and wild type cells. This experimental design isolates tension-specific phosphorylations of the Bub1 kinase domain. We identified over 15,000 phosphorylations, and of the total downregulated phosphorylations in the Bub1-Δkinase cells, roughly 350 sites were significant and enriched. Some of these significant sites were found on proteins implicated in anaphase onset timing (Pds1 and Apc1) and cohesion maintenance and establishment. Using a CRISPR-based mutation method, we generated point mutations in the endogenous locus of Apc1 and Pds1, creating phospho-null and phospho-memetic mutants. Surprisingly, these point mutants were not sensitive to benomyl, suggesting that spindle assembly and the SAC are fully functional. We will perform qualitative chromosome loss assays to further explore chromosome segregation fidelity in these mutants. Further analysis from this data set will help to uncover the importance of understanding how the Bub1 kinase domain ensures chromosome segregation through regulating anaphase onset timing and sister chromatid cohesion.

Kinetochore motor CENP-E drives congression and promotes stepwise end-on conversion of polar chromosomes by opposing Aurora B-mediated phosphorylation at the outer kinetochore

K. Vukusic, I. M. Tolić; Ruder Boskovic Institute, Zagreb, CROATIA.

Congression is a movement of chromosomes toward the spindle equator that, if unsuccessful, results in unaligned polar chromosomes, a phenomenon frequently observed in cancer cells. Interestingly, peripheral polar chromosomes are most susceptible to congression failure, and these chromosomes exclusively require the kinetochore motor CENP-E for congression. Current models state that CENP-E-driven congression is independent of biorientation and involves plus-end-directed activity of the motor domain regulated by Aurora kinases. However, Aurora kinases also oppose stable end-on attachments of the kinetochore to microtubules by phosphorylating other components of the kinetochore, and CENP-E-independent congression of polar chromosomes has been reported. Therefore, it remains unknown why only polar chromosomes require CENP-E-mediated congression and how their congression relates to the activity of Aurora kinases. To systematically explore the relationship between the role of CENP-E during congression and the mechanisms regulating biorientation, we established a library of live-imaged RPE1 cells with unaligned polar chromosomes treated with small-molecule inhibitors of various mitotic regulators. Here, we report that polar chromosomes initiate congression immediately without CENP-E if biorientation is allowed by acute inhibition of Aurora B. Interestingly, initiation of congression required loss of outer kinetochore pool of Aurora B, whereas it did not require loss of centromeric aurora B and chromosome cohesion or activity of chromokinesins and phosphatases. Moreover, congression was not induced by perturbation of activities of Mps1, Aurora A, and dynein. However, by using STED

microscopy, we show that subset of polar kinetochores during CENP-E-independent congression struggled to completely reach metaphase plate due to generation of syntelic or merotelic attachments. Importantly, by tracking markers of kinetochore tension and Mad2 dynamics, we show that a similar type of congression accompanied by biorientation is also observed after restoration of CENP-E activity regardless of aurora B activity, and occasionally in cells without CENP-E, but in both cases without enrichment in erroneous attachments. Lastly, under all conditions, only chromosomes located near the spindle poles required CENP-E to align, whereas the motor was not required for alignment if centrioles were removed from the centrosomes. In conclusion, we unravel the complex coordination between congression and biorientation and propose that CENP-E-mediated opposition to activity of Aurora B kinase close to centrosomes is a crucial first step during the congression of polar chromosomes that promotes their gradual transition from lateral to amphitelic end-on attachments.

Reconstitution of Kinetochore Motility and Microtubule Dynamics Reveals a Role for a Kinesin-8 in Establishing End-on Attachments

J. R. Torvi, J. Wong, D. Serwas, A. Moayed, D. G. Drubin, G. Barnes; University of California, Berkeley, Berkeley, CA

During mitosis, individual microtubules make attachments to chromosomes via a specialized protein complex called the kinetochore to faithfully segregate the chromosomes to daughter cells. Translocation of kinetochores on the lateral surface of the microtubule has been proposed to contribute to high fidelity chromosome capture and alignment at the mitotic midzone, but has been difficult to observe in vivo because of spatial and temporal constraints. To overcome these barriers, we used total internal reflection fluorescence (TIRF) microscopy to track the interactions between microtubules, kinetochore proteins, and other microtubule-associated proteins in lysates from metaphase-arrested *Saccharomyces cerevisiae*. TIRF microscopy and cryo-correlative light microscopy and electron tomography indicated that we successfully reconstituted interactions between intact kinetochores and microtubules. These kinetochores translocate on the lateral microtubule surface toward the microtubule plus end and transition to end-on attachment, whereupon microtubule depolymerization commences. The directional kinetochore movement is dependent on the highly processive kinesin-8, Kip3. We propose that Kip3 facilitates stable kinetochore attachment to microtubule plus ends through its abilities to move the kinetochore laterally on the surface of the microtubule and to regulate microtubule plus end dynamics.

Checkpoint-independent control of rapid embryonic mitoses by PLK1-mediated recruitment of CDC20 to kinetochores

J. M. Houston[1], M. Ohta[2], S. Gomez-Cavazos[3], A. Deep[1], K. Corbett[1], K. Oegema[1], P. Lara-Gonzalez[4], T. Kim[5], A. Desai[1]; [1]University of California, San Diego, San Diego, CA, [2]Okinawa Institute of Science And Technology, Onna, JAPAN, [3]Bristol Myers Squibb, San Diego, CA, [4]University of California, Irvine, Irvine, CA, [5]Pusan National University, Busan, KOREA, REPUBLIC OF.

Early embryogenesis in many species is characterized by rapid cell cycles with fast mitoses. In contrast to somatic cell divisions, the spindle assembly checkpoint is weak in early embryos, and the mechanisms governing mitotic timing are not well understood. Mitotic timing is controlled by Cdc20-mediated activation of the Anaphase Promoting Complex/cyclosome (APC/C). Phosphorylation of Cdc20 by Cdk1/2

prevents it from binding and activating the APC/C. Using the early *C. elegans* embryo, we show that mutation of a key inhibitory phosphorylation site on CDC-20 to either increase the persistence of or prevent phosphorylation correspondingly delays or accelerates anaphase onset; these effects of altering CDC-20 phosphorylation on embryonic mitotic duration are independent of the spindle checkpoint. Notably, accelerating mitosis sensitizes embryos to mitotic perturbations, and delaying mitosis leads to embryonic lethality. Thus, CDC-20 phosphoregulation is a spindle checkpoint-independent mechanism for optimizing mitotic duration in rapidly dividing early embryos. We previously showed that kinetochores accelerate anaphase onset by recruiting CDC-20 to kinetochores where it is dephosphorylated by a localized phosphatase pool (Kim, Lara-Gonzalez et al. 2017, *Genes Dev. 31*:1089-1094). CDC-20 is recruited to kinetochore by interaction with an ABBA motif in BUB-1. Surprisingly, mutation of a conserved docking site on BUB-1 for Polo-like Kinase 1 (PLK-1), ~100 aa distal to the ABBA motif, resulted in a mitotic delay identical to that resulting from mutation of BUB-1's ABBA motif. To identify the target(s) of PLK-1 kinase activity, we conducted a clustered mutagenesis screen focused on BUB-1. This effort identified putative PLK-1 sites within and adjacent to the BUB-1's ABBA motif that were required for CDC-20 kinetochore recruitment. In vitro binding assays with purified components showed that BUB-1 binding to CDC-20 is strongly stimulated by PLK-1 phosphorylation and that the putative target sites in the ABBA motif are essential for this stimulation. Collectively, these data indicate that PLK-1 tethered on BUB-1 controls mitotic progression by phosphorylating sites in the BUB-1 ABBA motif to enhance CDC-20 flux through the kinetochore. This enhanced flux accelerates CDC-20's activation by dephosphorylation and ensures timely mitotic exit during embryogenesis.

B207/P1893

A novel mechanism of Spindle Assembly Checkpoint control through CDK1 regulation of outer-kinetochore assembly

I. Manley, U. Gruneberg; The Sir William Dunn School of Pathology, University of Oxford, Oxford, UNITED KINGDOM.

The Spindle Assembly Checkpoint (SAC) is essential for maintaining genomic stability by monitoring attachment of chromosomes to the mitotic spindle and preventing premature chromosome segregation in mitosis. Checkpoint regulation is coordinated by the opposing activities of kinases and phosphatases. CDK1 is the major mitotic kinase required for mitotic entry and activation of the SAC. In particular, CDK1 regulates recruitment of the principle checkpoint kinase MPS1 to kinetochores, a critical event for downstream checkpoint signalling. Here, we demonstrate that circumventing this requirement for CDK1 is insufficient for SAC signalling when CDK1 is inhibited, therefore revealing a crucial, unknown role of CDK1 in SAC signalling. Using high resolution live and fixed cell imaging, we confirm that outer-kinetochore assembly is CDK1 dependent and disassembly of outer-kinetochore proteins is differentially regulated by the CDK1-opposing phosphatases PP1 and PP2A-B55. Critically, we observe that the outer-kinetochore protein and checkpoint scaffold KNL1 is rapidly lost at the metaphase-to-anaphase transition, before other outer-kinetochore proteins. This occurs through a novel CDK1-mediated interaction between the MIS12 complex and KNL1 that is critical for regulating checkpoint function. Therefore, specific phosphatase-mediated disassembly of the outer-kinetochore supports complete checkpoint shutdown through KNL1 loss while leaving microtubule-kinetochore attachments intact through NDC80, thus safeguarding directionality of the metaphase-to-anaphase transition.

Checkpoint-independent control of rapid embryonic mitoses by PLK1-mediated recruitment of CDC20 to kinetochores

J. M. Houston[1], M. Ohta[2], S. Gomez-Cavazos[3], A. Deep[1], K. Corbett[1], K. Oegema[1], P. Lara-Gonzalez[4], T. Kim[5], A. Desai[1]; [1]University of California, San Diego, San Diego, CA, [2]Okinawa Institute of Science And Technology, Onna, JAPAN, [3]Bristol Myers Squibb, San Diego, CA, [4]University of California, Irvine, Irvine, CA, [5]Pusan National University, Busan, KOREA, REPUBLIC OF.

Early embryogenesis in many species is characterized by rapid cell cycles with fast mitoses. In contrast to somatic cell divisions, the spindle assembly checkpoint is weak in early embryos, and the mechanisms governing mitotic timing are not well understood. Mitotic timing is controlled by Cdc20-mediated activation of the Anaphase Promoting Complex/cyclosome (APC/C). Phosphorylation of Cdc20 by Cdk1/2 prevents it from binding and activating the APC/C. Using the early *C. elegans* embryo, we show that mutation of a key inhibitory phosphorylation site on CDC-20 to either increase the persistence of or prevent phosphorylation correspondingly delays or accelerates anaphase onset; these effects of altering CDC-20 phosphorylation on embryonic mitotic duration are independent of the spindle checkpoint. Notably, accelerating mitosis sensitizes embryos to mitotic perturbations, and delaying mitosis leads to embryonic lethality. Thus, CDC-20 phosphoregulation is a spindle checkpoint-independent mechanism for optimizing mitotic duration in rapidly dividing early embryos. We previously showed that kinetochores accelerate anaphase onset by recruiting CDC-20 to kinetochores where it is dephosphorylated by a localized phosphatase pool (Kim, Lara-Gonzalez et al. 2017, *Genes Dev. 31*:1089-1094). CDC-20 is recruited to kinetochore by interaction with an ABBA motif in BUB-1. Surprisingly, mutation of a conserved docking site on BUB-1 for Polo-like Kinase 1 (PLK-1), ~100 aa distal to the ABBA motif, resulted in a mitotic delay identical to that resulting from mutation of BUB-1's ABBA motif. To identify the target(s) of PLK-1 kinase activity, we conducted a clustered mutagenesis screen focused on BUB-1. This effort identified putative PLK-1 sites within and adjacent to the BUB-1's ABBA motif that were required for CDC-20 kinetochore recruitment. In vitro binding assays with purified components showed that BUB-1 binding to CDC-20 is strongly stimulated by PLK-1 phosphorylation and that the putative target sites in the ABBA motif are essential for this stimulation. Collectively, these data indicate that PLK-1 tethered on BUB-1 controls mitotic progression by phosphorylating sites in the BUB-1 ABBA motif to enhance CDC-20 flux through the kinetochore. This enhanced flux accelerates CDC-20's activation by dephosphorylation and ensures timely mitotic exit during embryogenesis.

Alignment and segregation of sex trivalents in metaphase I and anaphase I

A. Borseth[1], R. Beebe[1], N. Pedraza-Aguado[1], M. Thomas[1], Z. Zhu[1], T. Müller-Reichert[2], G. Fabig[2], **L. Paliulis**[1]; [1]Bucknell University, Lewisburg, PA, [2]Technische Universität Dresden, Dresden, Germany

Chromosome alignment appears to be critical for proper segregation of a correct quantity of genetic information into daughter cells, yet there are many examples in many taxa of chromosomes that never align prior to segregation. In general, homologous autosomes recombine to form a bivalent in meiosis I. Bivalents then attain bipolar attachments to the spindle by metaphase I, and align in the center of the spindle. Metaphase I alignment precedes separation of homologues to opposite poles in anaphase I. Sex bivalents (e.g. X-Y bivalents) behave like autosomal bivalents, forming bipolar attachments and aligning at the center of the spindle with the autosomal bivalents. The praying mantids *Hierodula membranacea*

and *Tenodera sinensis,* and the cellar spider *Pholcus phalangioides* have X_1, X_2, and Y sex chromosomes, and in males X_1, X_2, and Y chromosomes link together in a sex trivalent. The sex trivalent is placed such that the X_1 and X_2 kinetochores face one spindle pole while the Y kinetochore faces the opposite pole. With one kinetochore-microtubule attachment opposing two kinetochore-microtubule attachments, one might assume that the sex trivalent would not align with the autosomes, but would be closer to the spindle pole associated with the two X chromosomes. We have found that the sex trivalent aligns with all of the autosomes on the metaphase plate in both species of mantids and in the cellar spider. We proposed that one reason for the alignment of the sex trivalent with the autosomes was that the X_1 and X_2 kinetochores are associated with fewer microtubules than the Y kinetochore. We show that the X_1 and X_2 kinetochores were each associated with fewer microtubules than the Y kinetochore, and than any autosomal kinetochore in the cell.

B210/P1896

Kinetochore Structure and Localization is Altered in Yeast Strains with Only 2 Chromosomes

J. Stanton, P. McConnell, K. Bloom, E. Yeh; University of North Carolina - Chapel Hill, NC, CHAPEL HILL, NC

In S. cerevisiae, the haploid genome is distributed into 16 chromosomes. In metaphase, kinetochores cluster into two foci upon biorientation of 16 pairs of sister chromatids.To address the minimal number of kinetochores required to build a network of DNA loops at the pericentromere, essential for the fidelity of chromosome segregation, we examined kinetochores and cohesin in a yeast strain engineered to contain two chromosomes. We tagged kinetochore proteins and cohesin subunits with GFP (Kinetochore Ame1-GFP and Ndc80-GFP, cohesin Scc1-GFP) to visualize their organization. In a 16-chromosome strain, Ndc80 and Ame1 appear as two foci associated with kinetochore microtubule plus-ends. In the 2-chromosome strain, Ame1 appeared as two foci. In contrast Ndc80 was distributed along the spindle axis into ~3-5 foci of varying intensity. Using quantitative intensity measurements to assess protein number, we found Ame1 at 30% the number of Ame1 molecules in the 16-chromosome strain. Based on the number of chromosomes (2 vs. 16) we expected Ame1 to be 12.5% the level of Ame1 in the 16-chromosome strain. Thus, there is about 2.5X more Ame1 than expected based on the number of centromere DNA sequences. The disperse distribution of Ndc80 is further indication of the disruption of kinetochore organization in the engineered yeast strain. Visualization of Scc1-GFP indicates that cohesin is not enriched in the pericentromere in the 2-chromosome strain, as it is in the 16-chromosome strain. These data reveal that the structure of the kinetochore and pericentromere are distinct in the 2-chromosome strain.

Spatial Map of Polo like kinase-1 (Plk1) in prometaphase

R. X. Norman[1], C. L. Carlsen[2], R. F. Lera[1], M. E. Burkard[1]; [1]Medicine, University of Wisconsin-Madison, Madison, WI, [2]Cell and Regenerative Biology, University of Wisconsin-Madison, Madison, WI.

Accurate chromosome segregation during mitosis is essential to prevent aneuploidy. The kinetochore is a proteinaceous complex that plays a major role in ensuring faithful segregation by serving as a hub for various events including microtubule binding, kinase signaling, and Spindle Assembly Checkpoint (SAC). Polo-like kinase-1 (Plk1) is known as the master regulator in mitosis and is one of the kinases orchestrating various signaling events during mitosis. Plk1 regulates processes including mitotic entry,

kinetochore-microtubule binding, SAC, and cytokinesis. The Polo Box Domain (PBD) of Plk1 recruits Plk1 to its substrates. We found that Plk1 is also involved in protecting the centromere integrity during mitosis against the microtubule pulling forces. We found that when Plk1 is chemically inhibited, the centromeres unwind, leading to the removal of kinetochore proteins including CENP-A, C, T, and Hec1. Targeting Plk1 activity to the centromere was able to rescue this phenotype. Using delta analysis, we also found that a major pool of Plk1 exists at the centromere away from CENP-U and Bub1, the two major recruiters of Plk1 as described by other studies. In order to identify the Plk1 recruiter at the centromere, we employed a proximity-based biotin labeling approach. We fused Plk1 WT and Plk1 PBD mutant with TurboID, a biotin ligase to biotinylate the Plk1 neighborhood and identify the proteins using mass spectrometry. We also generated TurboID fused to kinetochore proteins such as CENP-U, Bub1, CENP-L, Dsn1, and Kif2c as controls to ensure the biotinylation is restricted to the targeted site. We found that the biotinylation using this system was restricted to the tagged protein neighborhood. We also found that the Plk1 neighborhood was labeled within 10 minutes allowing us to study Plk1 localization in a specific stage of mitosis. Using mass spectrometry, we found that the Plk1 is localized near INCENP (inner-kinetochore), PICH, HELLS(centromere), CENP-C (CCAN), Bub1, BubR1, CENP-E (outer-kinetochore) in prometaphase. Using a modified Expansion Microscopy method (mExM) developed in the lab, we were also able to visualize a pool of Plk1 at the inner centromere.

Cytokinesis 2

B212/P1898

Nanoscale organization of the midbody revealed by expansion microscopy

N. M. Hümpfer[1], G. Russo[2], T. Brill[1], K. Bruckmann[1], S. Donat[3], J. Schmoranzer[3], M. Krauss[2], H. Ewers[1]; [1]Institute for Chemistry and Biochemistry, Freie Universität Berlin, Berlin, GERMANY, [2]Leibniz Institute for Molecular Pharmacology, Berlin, GERMANY, [3]Advanced Medical BIOimaging Core Facility, Charité Universitätsmedizin Berlin, Berlin, GERMANY.

Septins are GTP-binding proteins originally discovered acting in the cell division cycle of budding yeast. Cell division implies cytokinesis as the last step, which is common to all eukaryotic cells. The role of septins in cytokinesis is conserved from yeast to mammals. Their knock down leads to cytokinetic defects, such as multinucleation. To date, septins are considered the fourth component of the cytoskeleton; owing to their ability to form oligomers that assemble into higher order structures such as filaments and rings. Moreover, septins interact with actin and microtubules, and link the cytoskeleton to the plasma membrane.

Both the plasma membrane and the cytoskeleton undergo remodeling during cytokinesis. First, the membrane is constricted at the cleavage furrow. The two emerging cells are connected by a thin tubular structure called the midbody. This remodeling is mirrored by the changes in septin architecture. During cytokinesis, septins populate the membrane of the cleavage furrow, form rings that flank the midbody, attach to midbody microtubules and are found in membrane blebs extruded from the midbody during constriction.

It is elusive how the different septin structures are composed and what distinguishes them in their biological function. We aim to elucidate the roles of septins during cytokinesis using super-resolution microscopy. However, the midbody is densely packed with proteins and therefore resists conventional immunofluorescence staining.

Here, we employ ultrastructure expansion microscopy (U-ExM) to visualize proteins in the midbody,

taking advantage of the decrowding effect inherent to U-ExM. The approximate fourfold expansion of the sample leads to an increase in resolution to 70 nm on a confocal microscope. In contrast to other super-resolution techniques, U-ExM enables multiplexing of targets and collection of volumetric information in a short time. We generate a dataset of unique spatial resolution and cellular context depicting the evolution of septins in cytokinesis.
Our results shed light on the diversity of structures formed by septins during cytokinesis and their tight temporal and functional appearance. In addition, we can show septins in concert with cytokinetic partners, such as anillin and the endosomal sorting complex required for transport (ESCRT). Moreover, we complement our data with lattice light sheet imaging. Live cell recordings of genome-edited cells undergoing cytokinesis allow us to set the U-ExM data in a temporal context. Altogether, we generate a spatio-temporal map of septin reorganization in concert with their partners during cytokinesis, providing the basis for future functional studies.

Molecular Dynamics Simulations Suggest Anillin-related Mid1 is Adaptive and Multimodal Contractile Ring Anchoring Protein

A. R. Hall, Y. K. Choi, W. Im, D. Vavylonis; Lehigh University, Bethlehem, PA.

The positioning of the cytokinetic ring at the cell equator in animals and fungi depends crucially on the anillin scaffold proteins. During fission yeast interphase and early mitosis, anillin-related Mid1 binds to the plasma membrane and helps establish a broad band of cytokinetic nodes near the cell center. Mid1 consists of a C-terminal globular domain with two potential regions for membrane binding, the PH and C2 domains, both of which prefer PIP2 lipids, and an N-terminal intrinsically disordered region that is strongly regulated by phosphorylation. The PH and C2 domains are joined by a connector domain and the C2 domain contains a predicted flexible region (L3 loop) that is important for membrane binding. Previous studies have shown that both PH and C2 domains can associate with the membrane. However, it's unclear if they can simultaneously bind to the membrane in a way that allows dimerization or oligomerization of Mid1, and if one domain plays a dominant role. In order to elucidate Mid1's membrane binding mechanism, we used the available structural information of the PH, C2, and connector domains in all-atom molecular dynamics simulations of Mid1 near membrane compositionally based on experimental measurements (including PIP2 lipids.) To avoid bias due to initial conditions, we simulated 10 systems starting from different Mid1 orientations with respect to the membrane. We also performed control simulations of a known membrane binding-defective mutant. The results indicate that Mid1 initially binds through the C2's L3 loop, and can further bind through the PH domain and C2's L1 loop. These multiple modes of binding may reflect Mid1's multiple interactions with membranes and other node proteins, and ability to sustain mechanical forces.

Probing Mechanical and Functional Contributions of F-actin to Microtubule Aster Organization in Cycling *Xenopus* Egg Extract

L. Bai, C. M. Field, T. J. Mitchison; Department of Systems Biology, Harvard Medical School, Boston, MA.

As cells exit mitosis during anaphase, correct positioning of the cleavage plane depends on asters organized by microtubules. In small somatic cells, anaphase asters are positioned by cortical dynein, but in large egg cells where microtubules do not reach the cortex for most of anaphase, the forces are less

understood. A related question is the physical nature of asters. Do they behave as a rigid array of discrete microtubules or a deformable gel? Actomyosin also plays a central role in cell division. In small cells, cortical actomyosin likely dominates cytomechanics, but in large frog eggs, bulk cytoplasmic networks may also be important. To probe microtubule, actin and keratin mechanics in frog eggs, we developed a *Xenopus laevis* egg extract system in which actin-intact, cycling extract was spread under oil. This system allows live imaging over multiple cell cycles and access to mechanical and biochemical perturbation. F-actin was a dominant mechanical player in our extract system. When F-actin was intact, forces exerted by a needle propagated for hundreds of microns and asters behaved as a deformable gel. When F-actin was depolymerized, forces did not propagate over long distances and the aster was easily fragmented by the needle. In the actin-intact system, the interior region of asters was more deformable than the periphery, with implications for force transmission from the periphery to centrosomes during aster movement and centrosome positioning. Functionally, we found that leaving F-actin intact improved segregation of chromosomes and daughter compartments compared to published work where cyclin extract was prepared with actin depolymerized. CPC-enriched zones between sister asters, which determine cleavage planes in intact cells, also formed more robustly when F-actin was intact. The main intermediate filament protein in eggs is keratin. We found that keratin filaments depended on both aster microtubules and F-actin for normal organization. By studying all three cytoskeletal networks in the cell-free system, we are generating novel insights into egg cytomechanics, in particular revealing central roles of bulk cytoplasmic F-actin.

B215/P1901

Dynamics at the nanoscale within the constricting contractile ring in fission yeast

B. Levesque, K. Bellingham-Johnstun, G. Mathew, J. Belmonte, C. Laplante; North Carolina State University, Raleigh, NC.

The contractile ring is a highly complex and dynamic structure. To understand how the contractile ring works, we must determine its molecular organization and the motions of its components. The motions of protein complexes within the contractile ring are governed by their molecular environment and the forces applied to them and therefore contain a wealth of information regarding the function of the contractile ring. Single molecule localization microscopy (SMLM) can resolve protein complexes in dense protein arrays and data acquired in live cells contains dynamic information of their motions at the nanoscale. We developed NanoTrax, an algorithm that tracks clusters of single molecules at the nanoscale, to measure the dynamics of protein complexes within dense cellular structures in data acquired by SMLM in live cells. NanoTrax fits the center of clusters of single molecule emitters over time. NanoTrax ends the tracking when the number of localizations per cluster falls below a minimum threshold of emitters or when an influx of emitters is detected, indicating a collision with another object. In fission yeast, the contractile ring assembles by the coalescence of a band of nodes, complexes of cytokinesis proteins, through actin and myosin interactions. We applied NanoTrax to determine the motions of cytokinesis nodes inside the constricting contractile ring of fission yeast cells. The motions of nodes both in the band and the contractile ring were either diffusive or directed. In both the band and the ring, the majority (~65%) of node motions were diffusive. The high proportion of diffusive nodes within the contractile ring suggests that nodes spend most of their time unbound from the actin filament network. Diffusive nodes had no movement bias within the ring and diffused in all directions while directed nodes primarily moved around the circumference of the ring presumably following the organization of the actin filaments. Interestingly, diffusive nodes never escaped the width of the ring

suggesting the presence of a mechanism that keeps nodes constrained. Our work establishes a new method to examine the dynamics of protein complexes at the nanometer scales and determine how the molecular environment within the contractile ring influences its function.

B216/P1902

Neighbor cells restrain furrowing during epithelial cytokinesis

J. Landino, E. Misterovich, S. Chumki, B. Adhikary, A. L. Miller; University of Michigan, Ann Arbor, MI.

During epithelial cytokinesis, contractile ring ingression challenges tissue homeostasis by generating mechanical force that pulls on neighboring cells *via* cell-cell junctions. How epithelial neighbor cells respond to and regulate cytokinesis is not well understood. Previous work in our lab has shown that apical cell-cell junctions at the furrow are specifically reinforced through the recruitment of the force-sensing protein, Vinculin, and overexpression of a dominant-negative Vinculin mutant increases the rate of furrow closure. This suggests that the cytokinetic contractile array in epithelial cells is subject to resistive forces from non-dividing neighbor cells which regulate furrow closure. To investigate neighbor cell function in epithelial cytokinesis, we examined the localization of contractility factors (active Rho, F-actin, and Myosin II) in neighbor cells of gastrula-stage *Xenopus laevis* embryos and found these factors accumulate specifically at and near junctions neighboring the cytokinetic furrow, indicating that non-dividing neighbors assemble a contractile array in response to furrow ingression. We next asked whether neighbor cell actomyosin could modulate cytokinesis and predicted that increased stiffness or contractility in neighbor cells would slow the rate of furrow ingression. We first tested this by overexpressing the actin cross-linking protein α-actinin in neighbor cells and found that high level α-actinin overexpression in neighbors slowed furrowing. We also activated Rho-mediated contractility in neighbor cells with high spatiotemporal precision using the TULIP optogenetic system. Optogenetic activation of Rho-mediated contractility in neighbors paused furrowing for the duration of optogenetic stimulation. Notably, for cells with two different neighbors (one control and one with increased contractility), the rate of furrowing was only changed on the side of the cell with a contractile neighbor. Additionally, preliminary experiments show that optogenetic stimulation of Rho-mediated contractility in both neighbor cells blocks successful furrow ingression and induces cytokinetic failure. These findings indicate that neighbor cell actomyosin contractility regulates the speed and success of epithelial cytokinesis.

Post-anaphase microtubule networks and interphase microtubules cooperate to re-center the nucleus after spindle breakdown

K. Bellingham-Johnstun, A. Thorn, J. Belmonte, C. Laplante; NCSU, Raleigh, NC

Centering the nucleus is critical for symmetrical cell division in fission yeast. During mitosis, the spindle pushes the daughter nuclei to the cell tips and the nucleus must reposition to the cell center. We measured that the nucleus remains off center after the disassembly of the spindle until ~40 minutes after septation. Depolymerization of microtubules in cells that recently completed anaphase prevented nuclear repositioning. The presence of the mitotic spindle pole body (mSPB) and post-anaphase array (PAA) microtubules coincided with the timing of nuclear repositioning before septation. We leveraged known mutations in the *mto1* gene, encoding a component of the gamma-tubulin complex, to determine the specific role of the mSPB and PAA microtubules during nuclear repositioning. The mSPB

microtubules are connected to the nuclear envelope at the SPB and their plus ends grew toward the end of the cell. In *mto1(1-1085)* cells, where mSPB microtubules are absent, the daughter nuclei remained at the cell tips. The PAA microtubule network assembled in the plane of the contractile ring with microtubules extending away from the ring toward the nucleus. In *mto1-427* cells, which lack PAA microtubules, the daughter nuclei traveled closer to the division plane. These results suggest that the mSPB microtubules push the nucleus away from the end of the cell while the PAA microtubules limit its movement toward the contractile ring. This push-push mechanism positioned the nucleus at ~1/3 of the distance between the end of the cell and the contractile ring by the end of cytokinesis. In the newborn cell, the nucleus reached the cell center at a velocity of 0.03 µm/min, slower than the repositioning of an artificially displaced nucleus in interphase cells. We used Cytosim simulations constrained by experimentally measured microtubule dynamics to determine the mechanism that influences nuclear displacement velocity. We found that the ratio of the distance between the nucleus and the old cell end (l) and the nucleus and the new cell end (L) governs nuclear displacement velocity. Smaller l/L ratios resulted in faster displacements. This relationship recapitulated our experimentally measured displacement velocities in wild-type, *mto1-427* and *mto1(1-1085)* cells. Together, these microtubule-dependent mechanisms ensure the centering of the nucleus ahead of cytokinesis.

CUL3 E3 Ligase-Dependent Contractile Ring Ubiquitination Underlies Unilateral Cytokinesis in *Caenorhabditis elegans* Zygotes

C. Hsu[1,2], W. Fan[1,2], K. Sugioka[1,2]; [1]Zoology, University of British Columbia, Vancouver, BC, CANADA, [2]Life Sciences Institute, Vancouver, BC, CANADA.

Cytokinesis is the last step of cell division during which a mother cell is physically separated into two daughter cells via the contractile ring. Eccentric closure of the contractile ring, called unilateral cytokinesis, plays crucial roles in animal morphogenesis. Although previous studies revealed several unilateral cytokinesis regulators such as anillin and adherens junction, the molecular mechanisms regulating asymmetric contractile ring constriction remain elusive. Here we show that CUL-3 E3 ubiquitin ligase regulates asymmetric contractile ring closure. By performing 4D live-imaging, we found that *cul-3(RNAi)* resulted in concentric ring closure. Immunostaining of dividing cells using an anti-poly-ubiquitin antibody revealed that the contractile ring is asymmetrically ubiquitinated. Furthermore, this asymmetric contractile ring ubiquitination is lost in *cul-3(RNAi),* suggesting that ring ubiquitination is CUL-3-dependent. To identify the potential substrate of CUL-3-dependent ubiquitination, we have tested several actomyosin regulators required for unilateral cytokinesis. We found that CYK-1/formin and ANI-1/anillin are not required for contractile ring ubiquitination. However, contractile ring ubiquitination was lost after the knockdown of POD-1/coronin. A previous study reports the physical interaction between POD-1 and an adaptor protein of CUL-3 E3 ligase MEL-26 (Luke-Glaser et al., 2005). Although the study concluded that POD-1 is not the target of ubiquitination based on Western blotting, the subcellular concentration of POD-1 may be controlled by the CUL-3 E3-ubiquitin ligase-dependent degradation. To test this hypothesis, we will quantify POD-1 protein levels with and without CUL-3 activity. Our study will reveal the intricate mechanism of actomyosin regulation during cytokinesis.

Anillin forms linear structures and facilitates furrow ingression after septin and formin depletion

M. Lebedev[1], **E. Zanin**[1], F. Chan[2], J. Bellessem[3], D. Osório[2], E. Rackles[3], T. Mikeladze-Dvali[3], A. X. Carvalho[2]; [1]Department Biologie, FAU Erlangen, Erlangen, GERMANY, [2]Instituto de Investigação e Inovação em Saúde (i3S), Porto, PORTUGAL, [3]Department Biologie, Ludwig-Maximilians University, München, GERMANY.

In animal cells a contractile ring consisting of formin-nucleated filamentous actin and myosin II assembles at the cell equator at the end of cell division. Contractile ring constriction deforms the plasma membrane and thereby forms the two daughter cells. In the absence of formin activity no unbranched F-actin is generated, no cleavage furrow forms and cell division fails. Surprisingly it was shown that a temperature-sensitive formin (CYK-1) mutant can ingress a cleavage furrow when septins are co-depleted (Jordan et al., 2016). To understand how those embryos ingress a cleavage furrow in the absence of CYK-1-nucleated F-actin, we investigated the dynamics of the contractile ring components anillin (ANI-1) and myosin II (NMY-2) in CYK-1-depleted C. elegans embryos. We found that ANI-1 forms linear structures after CYK-1 depletion, which are decorated by NMY-2. The linear ANI-1 structures circumferentially align around the cell equator similar to F-actin in control embryos. Therefore we tested whether ANI-1 is required for furrow ingression in CYK-1 and septin co-depleted embryos. Indeed we observed that ANI-1 is essential for cleavage furrow ingression in CYK-1 and septin co-depleted embryos. To tests, which region of ANI-1 is responsible for the formation of linear structures, we split ANI-1 into two parts. The N-terminal part comprises the putative myosin II binding domain, actin-binding domain and a large unstructured linker region. The C- terminal part contains the RhoA, membrane (C2) and septin (PH) binding domains. We find that the N-terminal ANI-1 part forms linear and the C-terminal part circular structures. Further, the N-terminal part partially rescues furrow ingression in CYK-1 and septin co-depleted embryos whereas the C- terminal one does not. Together, our results reveal that the N-terminal part of ANI-1 forms linear structures and assists furrow ingression in the absence of septins and formins. Since the N-terminal part is highly disordered and such regions frequently undergo liquid-liquid phase separation, we speculate that a condensation-based mechanism mediates the contraction of the ANI-1 network. Together, we uncover a novel ANI-1 dependent and unbranched F-actin independent mechanism of furrow ingression during cell division.

Two-Color Super-Resolution Imaging Reveals the Spatial Organization of Two Type II Myosins within Contractile Ring in Fission Yeast

C. Bi[1], D. Ma[1], W. Sayyad[2], T. D. Pollard[2], F. Huang[1]; [1]Purdue University, West Lafayette, IN, [2]Yale University, New Haven, CT.

During cytokinesis, myosin-II constricts the contractile ring that separates one cell into two daughter cells. The fission yeast cytokinetic contractile ring contains two types of myosin II, Myo2 and Myp2, which join the ring at different times but confocal imaging and genetics studies showed that both contribute to the constriction and integrity of the ring. Previously, using 2D live cell single molecule localization microscopy, we showed that cytokinetic nodes, the basic building blocks of the ring, persist

after ring assembly and throughout constriction. Confocal and super resolution microscopy suggested the Myp2 is located further from the plasma membrane than Myo2. However, the precise ultrastructural arrangement of the two type II myosins remains in question. Here, we investigated the relative spatial arrangement of Myo2p and Myp2p within contractile ring using two-color super-resolution microscopy based on salvaged fluorescence imaging. Our aim is to determine how the spatial distributions of the two myosin II proteins evolve during contractile ring constriction. We established a robust protocol for fixing and staining fission yeast with nanobodies. We used the *cdc25-22* temperature sensitive strain to synchronize the cells in mitosis. By radiometric detection of spectrally overlapped fluorescence tags, Alexa Fluor 647 and CF660C, we obtained two-color super-resolution images of nanobody labeled Myo2p and Myp2p with minimized wavelength induced misalignment. Quantitative analysis of the nanoscale images should provide useful information for modeling contractile ring assembly and constriction.

B221/P1907

Disruption of Cell Division by P34R Mutated RAC1

E. McBeath[1], L. Cruz[2], A. Herrera Montejano[2], R. Yarmand[1], M. Hofmann[1]; [1]University of Texas MD Anderson Cancer Center, Houston, TX, [2]Monterrey Institute of Technology School of Medicine and Health Sciences, Monterrey Nuevo León, MEXICO.

Background: While investigating the cause of resistance to the drug dabrafenib in PDX.008.CL, an anaplastic thyroid cancer cell line with a dabrafenib sensitive BRAF mutation, we discovered that these cells had a combined amplification and P34R mutation of the *RAC1* gene. RAC1 is a small GTPase involved in cell motility and cytoskeletal reorganization. It is known to shuttle between the cytoplasm (inactive state) and the plasma membrane (active state). RAC1 overexpression and hyperactivity are common in many cancers. However, the mechanisms by which altered RAC1 drives tumor progression are unknown. We hypothesize that the P34R RAC1 mutation drives hyperactivity, in turn dysregulating chromosome segregation and/or cytokinesis during cell division. This leads to an increased level of cell death, random mutations and altered protein expression from which a stable metastatic cell can rapidly arise.
Methods: mNeonGreen-tagged $RAC1^{WT}$ and $RAC1^{P34R}$ proteins were transiently expressed in the papillary thyroid cancer (PTC) cell line MDA-T85, which in addition to the $BRAF^{V600E}$ mutation, contains the normal two copies of $RAC1^{WT}$. Stable transfectants were selected by cell sorting. Cells were visualized by phase contrast, confocal, and time-lapse fluorescence microscopy.
Results and discussion: PDX.008.CL cells were 10x more resistant to dabrafenib compared to several $BRAF^{V600E}$-mutated PTC cell lines. Treatment of PDX.008.CL cells with the RAC1 activity inhibitor EHop-016 restored sensitivity to dabrafenib. This implies that excess RAC1 activity due to the P34R mutation and/or gene amplification is directly involved in resistance to dabrafenib. When transiently transfected with fluorescent $RAC1^{P34R}$ and compared with $RAC1^{WT}$, the PTC cell line MDA-T85 had reduced levels of $RAC1^{P34R}$ in the cytoplasm, distinct cell membrane and nuclear envelope fluorescence, increased cell death, and frequently a clear disruption of cytokinesis and disorganized nuclear structures. This may have led to the polyploidy observed in the metastatic patient sample and derived PDX.008.CL cell line. MDA-T85 cells stably expressing $RAC1^{P34R}$ showed shape and cytoskeletal changes identical to that seen in PDX.008.CL, indicating dedifferentiation. This suggests that eventually, further changes occurred that overcame the cell death caused by the effect of overactive $RAC1^{P34R}$ on cell division.

Cytoplasmic divisions without nuclei

A. Bakshi, F. Echegaray Iturra, A. Alamban, M. Rosas-Salvans, S. Dumont, **M. G. Aydogan**; University of California, San Francisco, San Francisco, CA.

Cytoplasmic divisions have been commonly considered a sequel to nuclear divisions, even in the absence of DNA replication. Here we found in fruit flies that the cytoplasm can compartmentalize and divide without nuclei. Our targeted screen for potential necessary and sufficient conditions revealed that, although the cytoplasmic compartments are tightly associated with centrosomes, they can form without astral microtubules and divide without centrioles. Although a focal pool of microtubules is *necessary* for maintaining cytoplasmic compartments, this is not sufficient for their initial formation. Actin filaments are similarly an essential component of cytoplasmic compartments; however, their myosin II-based contractility is unexpectedly dispensable for divisions. We show that the myosin II-based contractility is instead involved in regulating the *pace* of cytoplasmic divisions. Importantly, our results revealed that the cytoplasmic divisions without nuclei can occur in a periodic manner autonomously of the Cdk-Cyclin oscillator that normally drives the cell cycle. We demonstrate that such autonomy of cytoplasmic divisions is preserved even in normal development, where it is leveraged to extrude mitotically delayed nuclei from the blastoderm, safeguarding embryos against local delays in mitotic entry prior to morphogenesis. We propose that an active coordination between otherwise autonomous cycles of cytoplasmic and nuclear divisions act as a quality control mechanism for genome integrity and partitioning in development.

Midbody reorganization precedes ring canal formation during gametogenesis

K. L. Price, L. Cooley; Yale University School of Medicine, New Haven, CT

Animal gametes typically develop through some or all of gametogenesis as syncytia of cells attached by stable intercellular bridges called ring canals. However, how canonical cytokinesis is altered during germ cell division to produce ring canals is poorly understood. Using time-lapse imaging of cytokinesis proteins in dividing germ cells in the Drosophila male germline, we observe that ring canal formation occurs via reorganization of the germline midbody, a structure classically associated with its function in recruiting abscission-regulating proteins in complete cytokinesis. Centralspindlin complex components Pav (MKLP1) and Tum (MgcRacGAP), while initially localized to the central spindle and cleavage furrow, accumulate in a dense focus resembling a canonical midbody core. The midbody-like focus is compositionally similar to the midbodies formed during complete cytokinesis; the centralspindlin-containing midbody core is encircled by a ring of Septin-2, Anillin, and Citron kinase/Sticky proteins, all known components of the midbody ring. However, the germline midbody is short-lived, and rapidly reorganizes to join the proteins in the midbody ring resulting in a ring canal with an open lumen. This reorganization from midbody-to-ring canal is accompanied by a ~5-fold decrease in centralspindlin fluorescence intensity suggesting that degradation or relocalization of centralspindlin protein is required for ring canal formation. We found a remarkably similar midbody-to-ring canal transformation in mouse and Hydra testes, suggesting it is an intrinsic feature of gamete formation. Interestingly, we find a role for Sticky in the midbody-to-ring canal transition. Germ cell-specific knockdown of Sticky in the testis results in the formation of ectopic midbodies, decreased ring canal diameter (as shown by Naim et al., 2004), as well as a decrease in the average fluorescence of Pav in ring canals. Live imaging of Pav in

nos>sti RNAi testes reveals that Sticky is necessary for the timely midbody-to-ring canal transition. Of the ring canals that form, the timing from formation of the central spindle to nascent ring canal is delayed in contrast to controls and some midbodies never reorganize to form ring canals. Furthermore, we find a reduction in fecundity in *nos>sti RNAi* males suggesting an important role for Sticky during incomplete cytokinesis in spermatogenesis.

B224/P1910

Bridging the [CYK-4] GAP: The CYK-4 GAP Domain Activates ECT-2 and Inactivates Rac to Promote Cytokinetic Furrow Ingression

A. Schlientz[1], S. Gómez-Cavazos[1,2], K.-Y. Lee[2], P. Lara-González[3,2], A. Desai[1,2,1], K. Oegema[1,2,1]; [1]University of California, San Diego, La Jolla, CA, [2]Ludwig Institute for Cancer Research, La Jolla, CA, [3]University of California, Irvine, Irvine, CA

During cytokinesis, contractile ring assembly is controlled by the Rho family small GTPase RhoA, whose key activator, the Rho guanine nucleotide exchange factor (GEF) ECT2, is held in an autoinhibited state. Thus, a central question in cytokinesis is understanding how ECT2 autoinhibition is relieved to enable contractile ring assembly. ECT2 is activated by centralspindlin, which is comprised of two molecules of the microtubule motor kinesin-6 and two molecules of CYK-4. Centralspindlin is required for assembly of the central spindle, and the CYK-4 subunit is important to recruit centralspindlin to the equatorial plasma membrane where it interacts with and activates ECT2. CYK-4 has two regions implicated in furrow ingression: an N-terminal region that is phosphorylated by Polo-like Kinase 1 to enhance its binding to the BRCT repeat region of ECT2, and a C-terminal GTPase-activating protein (GAP) domain. Whether the CYK-4 GAP domain directly activates ECT2 or acts indirectly by inactivating the competing Rho family GTPase Rac has been controversial. Here, we address how the GAP domain of CYK-4 promotes furrow ingression in the *C. elegans* embryo. In support of the model that the CYK-4 GAP domain promotes cytokinesis by inactivating Rac, Rac depletion rescued the furrow ingression defect of a CYK-4 GAP domain mutant but not of an N-terminal phosphosite region mutant. To determine if the CYK-4 GAP domain also directly activates ECT-2, we analyzed furrow ingression in embryos lacking the nematode-specific ECT-2 activator NOP-1. Under this condition, simultaneous mutation of the CYK-4 N-terminal phosphosite region and of the C-terminal GAP domain's interface with Rho GTPases prevented furrow ingression. In contrast, CYK-4 constructs in which only the N-terminal phosphosite region or only the C-terminal GAP domain were mutated supported furrow ingression. Essentially identical results were obtained in Rac-depleted embryos. These findings indicate that the C-terminal GAP domain of CYK-4 promotes furrow ingression independently of regulation of Rac and are consistent with a model in which the N-terminal phosphosite and C-terminal GAP domains of CYK-4 act coordinately to fully relieve ECT-2 autoinhibition.

B225/P1911

A similar two-domain strategy is used by IQGAPs to regulate cytokinesis in budding yeast, fission yeast, and mammalian cells

K. Wang[1], H. Okada[1], C. Wloka[1,2], E. Bi[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]University of Groningen, Groningen, Netherlands

IQGAP is a multi-domain protein known to regulate cytokinesis in eukaryotes from yeast to human. However, how the predicted domains function in cytokinesis and whether the sequences between the

domains have evolved during speciation to accommodate organism-specific features of cytokinesis have largely remained a mystery. Here, by making precise deletions of any specific regions at the chromosomal locus of *IQG1*, which encodes the IQGAP in budding yeast, coupled with GFP tagging and quantitative live-cell imaging, we have defined the boundary of the calponin homology domain (CHD) and discovered an unexpected domain, which we designate Myosin Tail Associated domain (MTA). The CHD domain localizes to actin cables and the MTA domain localizes to the division site in a myosin-II dependent manner. The CHD and MTA domains together target to the division site more efficiently and more specifically than either domain alone. We further demonstrated that these two domains function together to enable efficient actomyosin ring (AMR) assembly, constriction, and removal. Next, we tested the corresponding regions of the budding yeast Iqg1's CHD and MTA in Rng2, the IQGAP in fission yeast, and found that the MTA-corresponding region localizes to the division site by binding to both myosin-IIs and the F-BAR protein Cdc15. For this reason, we named the MTA-corresponding region "Cytokinesis Factor (CykF) binding domain". Similar to budding yeast, the CHD-CykF module in Rng2 localizes to the division site during cytokinesis and regulates the AMR assembly and constriction. Finally, we examined this module-like design in IQGAP3 in Hela cells. We found that the CHD does not localize to the division site by itself whereas the MTA-corresponding region in IQGAP3, i.e., IQGAP-specific repeats (IR) domain, localizes to the division site only during late stage of furrowing. Strikingly, the CHD and IR together, localize to the division site robustly and during the entire furrowing process, and this localization depends on anillin. Anillin is known to interact with actin and myosin-II and play an important role in cytokinesis. Taken together, these analyses uncover a novel two-domain strategy used by IQGAPs to control cytokinesis from yeast to human, which reflects the principle of evolution - conservation (indicated by the CHD) and speciation (indicated by the MTA/CykF/IR).

B226/P1912

Bni5 interacts with septins and non-muscle myosin-II via distinct domains to carry out its roles in actin retrograde flow and cytokinesis

H. Okada, K. Wang, J. Marquardt, E. Bi; University of Pennsylvania, Philadelphia, PA

Myo1, the sole non-muscle myosin-II (NM-II) in the budding yeast *Saccharomyces cerevisiae*, is recruited to the septins, a family of cytoskeletal proteins that are organized into a cortical ring at the future division site (i.e., the bud neck), at the beginning of the cell cycle, and then interacts with actin filaments in anaphase to form an actomyosin ring (AMR) to drive cytokinesis. While its role in cytokinesis is similar to that of NM-IIs in other organisms, the mechanism underlying its early recruitment and function at the bud neck remain poorly understood. To address this question, we focused our analysis on Bni5, the sole linker between the Myo1 and the septins before cytokinesis. First, we constructed and found a striking difference between an N-terminally and a C-terminally GFP-tagged Bni5 strains by quantitative live-cell imaging analysis. The C-terminally tagged Bni5 showed ~10 min delay in the initial recruitment due to disruption of a direct association to the septins. Next, we performed a structure-function analysis of Bni5, which is predicted to contain three coiled-coiled (CC1-3) regions and a long-disordered region between CC1 and CC2. We examined the in vivo behaviors of ~30 different fragments of Bni5 by time-lapse microscopy in wild-type and various mutant strains. These analyses have led to the identification of the N-terminal CC1 region as the Myo1-binding domain, the C-terminal CC2 and its immediate upstream ~30 amino-acid extension as the septin-binding domain, and the CC2 + CC3 region as the Elm1 kinase (a septin stabilizer)-binding domain. We also found that deletion of *BNI5* slowed down actin retrograde flow, which maintains yeast longevity before cytokinesis. Furthermore, we observed that

deletion of *BNI5* reduced the amount of Myo1 at the division site by half at the onset of cytokinesis. Importantly, this reduction was sufficient to drive cytokinesis under normal conditions but failed to do so when cells were exposed to various stresses (e.g., actin filament perturbation). Taken together, Bni5 promotes Myo1 recruitment to the division site via distinct interactions to ensure efficient execution of two different but consecutive processes during the cell cycle: (1) actin retrograde flow to maintain longevity before cytokinesis, and (2) AMR assembly for the robustness of cytokinesis against environmental insults.

B227/P1913

An anillin-CIN85 complex regulates the re-organization of septin filaments of distinct compositions to drive intercellular bridge maturation

A. Wilde, T. Panagiotou; University of Toronto, Toronto, ON, Canada

Cytokinesis, the last stage of cell division, orchestrates the physical separation of newly forming daughter cells. After the cleavage furrow ingresses between the segregated chromosomes, the intercellular bridge (ICB) is established that serves as the final connection between daughter cells. This dynamic structure undergoes an ordered maturation process: extending, thinning, and tubulating membrane before it is ultimately abscised. Disruption of any of these intermediates restricts cytokinetic efficiency and success, promoting tumorigenesis among other pathologies. The cytokinetic scaffold anillin and the family of filamentous septins have been identified as key players in ICB establishment and development, where the interaction between anillin's C-terminal PH domain and septins is required to mature the ICB. Septins exist in cells as membrane-associated filaments composed of hexameric and octameric units that are differentiated by the hexamer's omission of septin monomers from the SEPT3-subgroup, where the sole member expressed in HeLa cells is SEPT9. While it is unclear if hexameric and octameric units construct homo- or hetero-typic filaments in vivo, the cellular functions of septins appear invariably attributed to octamers. Intriguingly, while other septins are required to complete early cytokinetic events, SEPT9 is the sole septin required for ICB abscission, indicating that septin hexamers and octamers may perform different functions during cytokinesis. How septin hexamers and octamers function to establish the ICB, and their relation to anillin during this process, remains unclear. Here we report that the novel cytokinetic factor CIN85 is required for ICB assembly and maturation, by simultaneously binding both anillin and septin octamers. CIN85 directly interacts with SEPT9 and the N-terminus of anillin, while the C-terminus of anillin interacts with SEPT11-positive septin units. Strikingly, these SEPT11-positive units lack SEPT9, indicating they are septin hexamers. We find that this network of interactions is required to stabilize septin octamers on the ICB membrane. We propose that octameric and hexameric homotypic septin filaments are connected and reorganized through anillin-CIN85 complexes to actively form and mature the ICB for successful cell division.

G0, G1, S-phase and Cell Proliferation Control

Revealing b-TrCP activity dynamics in live-cells with a genetically encoded biosensor

D. Paul[1,2], S. C. Kales[1], J. A. Cornwell[1], M. M. Afifi[1], G. Rai[1], A. Zakharov[1], A. Simeonov[1], S. D. Cappell[1]; [1]NIH, Bethesda, MD, [2]Lcbg, NCI, Bethesda, MD.

The F-box protein beta-transducin repeat containing protein (β-TrCP) acts as a substrate adapter for the SCF E3 ubiquitin ligase complex, plays a crucial role in cell physiology, and is often deregulated in many types of cancers. Here, we developed a fluorescent biosensor to quantitatively measure β-TrCP activity in live, single cells in real-time. We found β-TrCP remains constitutively active throughout the cell cycle and functions to maintain discreet steady-state levels of its substrates. We found no correlation between expression levels of β-TrCP and β-TrCP activity, indicating post-transcriptional regulation. A high throughput screen of small-molecules using our reporter identified receptor-tyrosine kinase signaling as a key axis for regulating β-TrCP activity by inhibiting binding between β-TrCP and the core SCF complex. Our study introduces a method to monitor β-TrCP activity in live cells and identified a key signaling network that regulates β-TrCP activity throughout the cell cycle.

B229/P1915

Regulation of cell size and Wee1 by elevated levels of Cdr2

R. A. Berg, J. B. Moseley; Dartmouth College, Hanover, NH.

Many cell cycle regulatory proteins catalyze cell cycle progression in a concentration-dependent manner. In fission yeast *S. pombe*, the protein kinase Cdr2 promotes mitotic entry by organizing cortical oligomeric nodes that lead to inhibition of Wee1, which itself inhibits Cdk1. *cdr2Δ* cells lack nodes and divide at increased size due to overactive Wee1, but it has not been known how increased Cdr2 levels might impact Wee1 and cell size. Using a Tetracycline-inducible expression system, we found that a 6X increase in Cdr2 expression caused hyperphosphorylation of Wee1 and reduction in cell size. This overexpressed Cdr2 formed clusters that sequestered Wee1 adjacent to the nuclear envelope. Cdr2 mutants that disrupt either kinase activity or clustering ability failed to sequester Wee1 and to reduce cell size. We propose that Cdr2 acts as a dosage-dependent regulator of cell size by sequestering its substrate Wee1 away from Cdk1 in the nucleus. This mechanism has implications for other clustered kinases, which may act similarly by sequestering substrates.

B230/P1916

Mechanisms determining where DNA replication initiates in the human genome

T. Noble[1,2], C. G. Sansam[2], B. Majchrzycka[2], K. Wittig[1,2], C. Xu[3], C. L. Sansam[2,1]; [1]Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK, [2]Cell Cycle and Cancer Biology, Oklahoma Medical Research Foundation, Oklahoma City, OK, [3]Biostatistics and Epidemiology, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

The selection of replication origins is a defining characteristic of DNA replication in higher eukaryotes, yet its mechanism in humans has not been well-defined. In yeast, origin selection involves replication initiation factor (Sld3-Sld7) recruitment to origins during G1. In this study, we use Cut&Run to examine genomic binding locations for TICRR and MTBP, the Sld3 and Sld7 orthologs. We have constructed two

HCT116 human colorectal cancer cell lines in which the endogenous TICRR or MTBP loci were tagged at their carboxy-termini with mClover. Using these cell lines, we have shown that TICRR and MTBP genomic binding sites can be mapped using Cut&Run with anti-GFP antibody. We mapped TICRR and MTBP binding throughout the cell cycle by performing experiments in asynchronous, G1, or G2-arrested cells. Peaks of TICRR and MTBP binding frequently overlap at Ini-seq replication origins. Additionally, our results show HCT116 TICRR and MTBP peaks overlap with MTBP peaks previously defined (Kumagai et al. Cell Rep. 2020) in a DLD-1 cell line. Interestingly, our data show that TICRR and MTBP binding patterns are less defined in asynchronous cells than G1, possibly due to cell cycle phase-specific recruitment of TICRR-MTBP to replication origins in human cells.

B231/P1917

Fission yeast cells integrate multiple pathways for geometry-based cell size control

K. E. Miller[1], C. A. Vargas-Garcia[2], A. Singh[3], J. B. Moseley[1]; [1]Geisel School of Medicine at Dartmouth, Hanover, NH, [2]Colombian Agricultural Research Institute, Bogotá, COLOMBIA, [3]University of Delaware, Newark, DE.

The size of a cell is critical to its function and physiology. Many studies have established that eukaryotic cells delay cell cycle transitions until a threshold cell size is reached. However, the specific aspect of cell size that is monitored is less well understood in most cases. Fission yeast cells enter mitosis and divide at a specific cell surface area due to regulated activation of Cdk1, in part through surface area-dependent accumulation of the protein kinase Cdr2. Using a panel of genetic mutations that alter cell size, we find that fission yeast cells only divide by surface area under a certain size threshold but shift to volume-based divisions at a larger size. The threshold for changing from surface area to volume-based size control is set by ploidy, consistent with longstanding connections between ploidy and cell size. These results led us to investigate the molecular nature of size control beyond surface area and Cdr2. We tested how the concentration of mitotic activators Cdc13/cyclin and Cdc25, which accumulate with increasing cell size, scale with different parameters of cell geometry. We find that Cdc25 concentration increases specifically with cell volume, as opposed to other aspects of size. In contrast, the concentration of mitotic cyclin Cdc13 does not scale with cell size, but rather accumulates with time regardless of cell size or growth. We combined these molecular pathways measuring volume, surface area, and time into a mathematical model for fission yeast cell cycle progression. Our results lead to an integrated model for cell size control based on multiple signaling pathways that report on distinct aspects of cell size and growth, including cell surface area (Cdr2), cell volume (Cdc25), and time (Cdc13). Such an integrated system provides robust and dynamic properties for size control upon changes to individual pathways or size parameters.

Phosphorylation of p27 at T197 promotes cell cycle progression through transcriptional coregulation of cJun and STAT3 action

A. Bagheri, S. Razavipour, J. Slingerland; Oncology, Georgetown University, Washington, DC.

p27 is a cyclin dependent kinase (CDK) inhibitor that binds cyclin-CDKs to arrest the cell cycle. p27 undergoes PI3K/AKT-mediated C-terminal phosphorylation that alters its protein-protein interactions and function. Our lab showed C-terminally phosphorylated p27 (p27pT157pT198) promotes its association with cJun. Genomic profiling showed p27 is co-recruited with cJun to over half of cJun

chromatin binding sites to either activate or repress target genes. p27/cJun activated gene targets include TGFB2, and are associated with EMT, and programs that upregulate stem cells and alter cell adhesion and migration. We pursue the novel hypothesis that cyclic changes in C-terminally phosphorylated p27 abundance govern p27-regulated transcriptional activity across the cell cycle, switching p27 from a corepressor of target genes in G0, to a transactivator upon PI3K/AKT activation in mid-G1. In synchronized NIH3T3 cells, we made the novel observation that cJun, phospho-activated cJunpS63, and phosphorylated STAT3 (STAT3pY705) levels periodic across the cell cycle. cJun is minimally expressed in quiescence, and is strongly upregulated in early G1. Phosphorylated cJun demonstrates a different pattern of expression than total cJun. While total cJun expression level remains constant at all time points after T=3 hours, cJunpS63 rises sharply in G1 and then declines with cell cycle progression. Total STAT3 levels are constant across G0 to S phase. The expression pattern for phosphorylated STAT3pY705 is similar to that of cJun pS63, minimal in quiescence, then increases as the cells enter cell cycle.To investigate the binding of p27pT197 to both c-Jun and STAT3 in NIH3T3 cells, we used a phospho-specific antibody against p27pT197 to perform Co-IP. p27pT197 not only co-precipitates with each of c-Jun and STAT3, but also this co-precipitation is periodic during cell cycle progression. The greater co-precipitation of p27pT197 with c-Jun and STAT3 in mid-G1-to S phase of the cell cycle suggests that complex formation is actively regulated. These data raise the intriguing possibility that p27 co-regulation of cJun and STAT3 transcription might be critical for cell cycle progression from quiescence to mid-G1. This is currently under investigation. Ongoing work investigating cell cycle-regulated profiles of p27-STAT3-cJun driven gene expression is underway and will be presented.The potential role of p27-regulated gene expression in the coordination of cell cycle progression has not been explored to date. A better understanding of how p27/cJun/STAT3 transcriptional complexes are regulated in normal tissue and in development might identify new therapeutic targets to be exploited for tissue regeneration and cancer therapy.

Tissue confinement regulates cell growth and size in epithelia

J. Devany[1], M. J. Falk[1], L. J. Holt[2], A. Murugan[1], M. L. Gardel[1]; [1]Department of Physics, University of Chicago, Chicago, IL, [2]Institute for Systems Genetic, New York University, New York, NY.

Cell proliferation is a central process in tissue development, homeostasis and disease. Yet how proliferation is regulated in the tissue context remains poorly understood. Here, we introduce a quantitative framework to elucidate how tissue growth dynamics regulate cell proliferation. We show that tissue growth causes confinement that suppresses cell growth; however, this confinement does not directly affect the cell cycle. This leads to uncoupling between rates of cell growth and division in epithelia and, thereby, reduces cell size. Division becomes arrested at a minimal cell size, which is consistent across diverse epithelia in vivo. Here, the nucleus approaches a volume limit set by the compacted genome. The loss of Cyclin D1-dependent cell size regulation results in an abnormally high nuclear-to-cytoplasmic volume ratio and DNA damage. Overall, we demonstrate how epithelial proliferation is regulated by the interplay between tissue confinement and cell size regulation.

B234/P1920

Differential APC/C^{Cdh1} activity controls two independent S phase entry pathways

S. Upadhya[1], N. Ratnayeke[2], T. Meyer[1]; [1]Cell & Developmental Biology, Weill Medical College/Cornell University, New York, NY, [2]Chemical & Systems Biology, Stanford University School of Medicine, Stanford, CA.

Cells make the fundamental decision to proliferate in G1 phase by inactivating the E3 ubiquitin ligase APC/C^{Cdh1} and activating the cyclin-dependent kinases CDK2 and CDK1, as well as the kinase CDC7 that promotes DNA replication. APC/C^{Cdh1} degrades numerous proteins that promote cell-cycle progression, and its inactivation allows for the buildup of these proteins. Recent work has shown that CDK1 alone is sufficient to start S phase without CDK2 and CDC7 activity. However, other studies suggested that cells can start S phase without requiring CDK1 activity. We hypothesize that cells utilize two mechanisms to enter S phase, with or without CDK1 activity. Our study makes use of a live-cell reporter system that we developed for non-transformed human MCF10A epithelial cells to measure the inactivation of APC/C^{Cdh1}, activation of CDK2/1, and precise time of S phase entry, all in the same cell. Earlier work shows that premature APC/C^{Cdh1} inactivation accelerates S phase entry and that DBF4 is degraded during G1, thereby suppressing G1 DBF4-CDC7 kinase activity. Surprisingly, we now found that (i) DBF4 is only weakly degraded by APC/C^{Cdh1} and CDC7 kinase is already active in G1, and (ii) cells frequently start S phase before they inactivate APC/C^{Cdh1}. However, Cdh1 knockdown also causes increased proliferation. Together with measurements using selective kinase inhibitors and genetic manipulations of critical regulators, our initial data suggests that APC/C^{Cdh1} regulation is pivotal to control which path cells take to proliferate: To enter S phase, cells either require (1) increased activity of both CDK2 and CDC7, which does not require cells to inactivate APC/C^{Cdh1} and also does not require CDK1 activity, or (2) increased activity of CDK1, which requires that cells first inactivate APC/C^{Cdh1} but does not require CDC7 and CDK2 activity. Thus, our work provides evidence that mammalian cells can use two independent paths to start S phase with one path requiring APC/C^{Cdh1} inactivation and the other not. Our goal is to understand how cells can control these two paths with the ultimate goal of identifying optimal drug combinations that could be used as therapies to regenerate tissues or treat cancer.

B235/P1921

Temperature modulates the period of *in vitro* cell cycle oscillations

F. Tavella[1], E. Flores[2], Q. Yang[1]; [1]Biophysics, University of Michigan, Ann Arbor, MI, [2]University of Texas at San Antonio, San Antonio, TX.

Temperature is known to affect the cell cycle duration in vivo. However, it remains elusive how temperature affects the core signaling network driving cell cycle oscillations and what components are essential for this response. Theoretical studies suggest that positive feedback regulates the period and amplitude tunability of biological oscillators. To this end, we analyze how the period and amplitude of a cell cycle oscillator centered around cyclin-dependent kinase (Cdk1) responds to changes in temperature. We encapsulate Xenopus Laevis cycling egg extract in cell-sized microfluidic droplets and study cell cycle oscillations at different temperatures using a Cdk1 FRET sensor. We study the system between 15 °C and 45 °C and analyze the role positive feedback plays in the response by using Wee1 and Cdc25 inhibitors--two of the core components of Cdk1's positive feedback loop. Both low and high temperatures are shown to increase the oscillator's period with the fastest oscillations occurring between 22 °C and 24 °C. A custom device for the generation of a temperature gradient was generated

for this project and is discussed in detail, as well as the techniques used for droplet formation and long-term imaging. This study opens the door for understanding the connection between the network connectivity of an oscillator and its robustness in response to temperature.

B236/P1922

Uncovering the post-transcriptional regulation of cyclin B in *S. pombe*

J. M. Rogers, **S. G. Chethan**, X. Yao, J. Chen, S. Hauf; Virginia Tech, Blacksburg, VA.

Cyclins are the "engine" of the cell cycle. They derive this name from their cyclic protein abundance, oscillating with the cell cycle. Cyclins activate cyclin-dependent kinases (CDKs), which then phosphorylate a multitude of substrates to execute cell cycle events. Understanding the patterns of cyclin abundance is important to elucidate how cells orchestrate these cell cycle events at the appropriate time and in the proper order. In fission yeast (*Schizosaccharomyces pombe*), the entire cell cycle can be driven by a single cyclin (Cdc13/cyclin B) and a single CDK (CDK1). Cdc13, as its orthologs across other eukaryotes, begins accumulating during DNA replication and peaks in mitosis, when it is targeted for rapid degradation. Using live cell imaging to analyze Cdc13 dynamics in single cells, we show that Cdc13 concentration increases during interphase in a strikingly linear fashion. Such linearity could theoretically be explained if Cdc13 had a long protein half-life so that its steady-state concentration is not reached within one cell cycle. However, our measurements suggest that the Cdc13 half-life is too short to explain this linear pattern. Because we find that the cdc13 mRNA concentration stays constant throughout interphase, we propose that additional post-transcriptional regulation influences Cdc13 abundance. Interestingly, cdc13 and other CDK regulators have some of the longest 5'UTRs in the *S. pombe* genome, raising the possibility that this unique linear pattern is influenced by cell cycle-dependent translational regulation. Our current experiments focus on testing the role of the 5'UTR and other factors which may contribute to this post-transcriptional regulation. Revealing the mechanisms that control Cdc13's accumulation may illuminate new facets of cell cycle regulation and will allow us to determine the importance of Cdc13 accumulation in coordinating cell cycle events.

B237/P1923

Modes of intracellular amino acid sensing in budding yeast

A. Jalihal, J. Palme, M. Springer; Systems Biololgy, Harvard Medical School, Boston, MA.

Unicellular organisms must tightly coordinate nutrient availability with cellular growth. It is known that major regulators of cellular growth perceive intracellular nutrient cues (Conrad, 2014). This design of nutrient concentration sensing is expected to produce an unstable response, as the delay between perception and cellular growth response might occur on different timescales. Furthermore, concentration sensing is sensitive to the sensor levels. We have recently described a novel, alternative hypothesis regarding the mode of nutrient sensing, namely flux sensing (Palme, 2022, In Preparation). Flux sensing can be achieved by a bi-functional enzyme that also possesses signaling activity; such an enzyme can convey information related to the flux through the reaction that it is catalyzing. We explore a potential flux sensing mode of nutrient perception by the growth regulatory kinase TORC1. We hypothesize that the glutamine sensor Pib2 functions as a concentration sensor, and the leucine tRNA synthetase Cdc60 functions as a flux sensor. Our model of flux sensing in nutrient perception provides insight into an important question of cellular growth control.

B238/P1924

Characterization of the nuclear envelope/ER protein Msc1 in budding yeast

P. Gholami Tilko, L. Carson, H. Yu; Florida State University - Tallahassee, FL, tallahassee, FL.

A landmark of cell division in higher eukaryotes is the breakdown of the nuclear envelope, which reforms upon the completion of mitosis. In contrast, in lower eukaryotes such as the budding yeast *S. cerevisiae*, the nuclear envelope remains intact during cell division, a process known as closed mitosis. Although cell division has been studied extensively in yeast, the mechanism by which the nuclear envelope separates during anaphase is not entirely clear. Recently, it has been shown that a localized nuclear envelope breakdown occurs at anaphase in the fission yeast *S. pombe*. This localized nuclear envelope breakdown is regulated by the inner nuclear membrane protein Les1, which constricts nuclear envelope breakdown to the anaphase bridge. In *S. cerevisiae*, the homolog of Les1 is the meiotic sister-chromatid recombination protein Msc1. Using a bimolecular fluorescence complementation assay, we have found that Msc1 localizes to the lumen of the nuclear envelope and ER. Through domain analysis, we show that the N-terminus of Msc1 is both necessary and sufficient for its localization to the ER lumen. To determine Msc1 interacting factors, we performed a targeted genetic screen, which revealed that Msc1 genetically interacts with the Doa10 branch of the ERAD pathway. We speculate that like Les1, Msc1 functions in nuclear envelope remodeling. Uncovering the function of Msc1 will provide insight into the conserved mechanisms between closed and open mitosis.

B239/P1925

YAP and TAZ regulation of the cell cycle controls the number of fat cells produced during adipogenesis

H. Berger[1], S. Sharma[2], M. N. Teruel[2]; [1]1Department of Biochemistry, Drukier Institute of Children's Health, & Weill Center for Metabolic He, Weill Medical College/Cornell University, New York City, NY, [2]Department of Biochemistry, Drukier Institute of Children's Health, & Weill Center for Metabolic He, Weill Medical College/Cornell University, New York City, NY.

Overexpression of YAP in mice leads to a 3-fold increase in fat mass (PMID: 30309656), suggesting that YAP activity strongly promotes adipogenesis. YAP overexpression downregulates TAZ, which is known to inhibit adipogenic gene expression in mature fat cells, leading the authors to conclude that loss of TAZ in these mice leads to increased adipogenesis. However, this conclusion does not take into consideration the well-established role of YAP in most other cell systems which is to promote proliferation. Adipogenesis occurs through a competition between proliferation and differentiation processes (PMID: 32553172). In response to an adipogenic stimulus, progenitor cells first enter a clonal expansion period during which they undergo a variable number of cell divisions, followed by a differentiation period in which they increase expression of PPARγ. If the level of PPARγ reaches a critical threshold, the progenitor cell will exit the cell cycle and commit to terminal differentiation. Here we test whether YAP and TAZ have similar proliferation-promoting roles as in other cell systems and that YAP and TAZ promote proliferation during the clonal expansion phase to increase adipogenesis.
We use single-cell timelapse microscopy to track cell cycle progression, differentiation timing and cell lineage simultaneously, together with dox-auxin constructs which allow us to rapidly increase and decrease the levels of YAP and TAZ in cells. We show that loss of TAZ has no effect on the fraction of differentiating cells, and that overexpression of YAP and TAZ both strongly drive proliferation and increase the fraction of actively proliferating progenitor cells. YAP overexpression leads to increased Cyclin D1, suggesting that YAP activity regulates CDK4/6 activity. Furthermore, loss of both YAP and TAZ

leads to cell cycle exit and early differentiation, suggesting that YAP and TAZ activity regulates the duration clonal expansion of pre-adipocytes. Finally, we show that differentiation stimulus strongly downregulates total TEAD expression levels, while total YAP and TAZ levels do not significantly change. These results can explain why adipocytes can remain post-mitotic, even though TAZ levels increase strongly late in adipogenesis. TEADs, which are well-established transcriptional targets of YAP and TAZ, regulate expression of many cell cycle genes. Downregulation of TEADs likely blocks a cell-cycle role for YAP or TAZ late in adipogenesis.The results of this study will likely enable control of the clonal expansion period during adipogenesis, and thereby enable control of the number of fat cells generated in response to feeding and other adipogenic stimuli.

Stem cell size homeostasis in mammalian epithelia

S. Xie[1], G. Q. G. de Medeiros[2], P. Liberali[2], J. M. Skotheim[1]; [1]Stanford University, Stanford, CA, [2]Friedrich Miescher Institute for Biomedical Research, Basel, SWITZERLAND.

Cell size impacts cellular biosynthesis and stem cell fitness. How cell size is controlled, especially in a crowded multicellular context, is poorly understood. We analyzed the growth of single epidermal stem cells during in vivo homeostatic turnover. We find the G1/S transition is cell size-dependent, where smaller-born stem cells spend longer and grow more during their G1 phase. We find that in agreement with previous models, the dilution of RB1 (retinoblastoma protein) by cell growth may couple G1/S transition rate to stem cell size. We further find that in intestinal organoids, as intestinal stem cells commit to differentiation, the size-dependence of G1/S transition remains invariant despite faster cell growth rates. Our results point to cell size a major predictor of the timing of stem cell divisions during mammalian tissue homeostasis.

B241/P1927

A nuclear mechano-sensing mechanism activates the aneuploidy response following centromere crisis

S. Herve*[1,2], A. Scelfo*[2], Y. Miroshnikova[1], G. Bersano-Marchisio[2], M. Deygas[2], G. Nader[2], A. Mace[2], M. Gentili[2], N. Manel[2], M. Piel[2], S. Wickstrom[3], D. Fachinetti[2]; [1]NIH/NIDDK, Bethesda, MD, [2]Institut Curie, Paris, FRANCE, [3]Max Planck Institute for Biology of Ageing, Munster, GERMANY.

Errors during cell division lead to an unbalanced karyotype (aneuploidy) that is associated with cellular inflammation and transformation. In response to aneuploidy, cells elicit a surveillance mechanism that stops proliferation and promotes senescence, however the molecular mechanisms that sense aneuploidy are still a matter of debate. Centromeres, unique chromosomal loci built on long tandem DNA repeats and specialized proteins, are critical players of chromosome separation and prevent aneuploidy. By inducing tunable levels of chromosome missegregation with rapid (< 2 hr) removal of key centromeric proteins in multiple human cell models, we identify a novel causal link between centromere crisis and cell cycle arrest, using a combination of imaging and cell mechanical measurements. We find that cells activate a G1 arrest following centromere dysfunction via a mechano-sensing mechanism that responds to nucleus deformation and epigenetic changes, but independently of prolonged mitosis, the DNA damage response or presence of micronuclei. This novel link between changes in the mechanical properties of the nucleus following mitotic errors and the promotion of the aneuploidy response provides a transformative view on the molecular mechanisms behind the genesis of genome instability.

B242/P1928

G2/M synchronization with CDK1 inhibitor suppresses genome-wide mutations and genome rearrangements during genome editing

K. Kondo, N. Fukuda, K. Soga, S. Yoshiba, J. Narushima, N. Shibata, C. Taguchi, K. Sakata, R. Kato; National Institute of Health Sciences, Kawasaki, Japan

(Background) CRISPR-Cas9 is a promising technique and has great potential for medical applications, such as correcting disease-causing mutations. Extensive studies to mitigate off-target effects in the genome have been performed because the off-target activity of the CRISPR-Cas9 system is a potential concern for therapeutic genome editing applications. There are now methods to reduce the off-target effect to some extent. On the other hand, CRISPR-Cas9 system has been reported to induce large deletions and mega-scale truncations using a single gRNA. The mechanism by which small indels occur is well known, however, little is known about the mechanism underlying the development of large deletions. In general, NHEJ can act immediately as the first player in DNA repair and inhibit large deletions. These recent reports raise the question: could cells with such large deletions be the result of escaping proper DNA repair machinery? If so, the cells may have many different types of mutations throughout their genome. (Methods) To answer this significant question, we applied the Thymidine Kinase (TK) assay to reveal the potential activity of CRISPR-Cas9 system. Genome engineered TK6 ($TK^{+/-}$)-derived TSCE5 cells, where the gRNA and I-*Sce*I recognition sequences were introduced into the intron 4 of *TK*1 locus on one allele, were used to detect large deletions (>80 bp) on the *TK1* locus as the on-target site. The cells can survive in the presence of trifluorothymidine due to the TK1-deficient phenotype ($TK^{-/-}$). Using the assay system, genome-wide small and large indels and structural variants initiated by CRISPR-Cas9 or I-*Sce*I were investigated throughout the genome in the normal and G2/M-synchronized conditions using next-generation sequencing. Mutation signatures were also investigated using SigProfilerMatrixGenerator (signature & transition/transversion ratio). (Results) The large deletion (>80 bp) at the *TK1* locus was detected at frequencies of 1×10^{-4}. This was 500 times lower than small deletion in TSCE5. Next, A greater number of genome-wide mutations occurred in the normal conditions, and single gRNA induced large deletions over 25 kb at the on-target sites and complex genome rearrangements. G2/M synchronization using the CDK1 inhibitor RO3306 during genome editing, after double thymidine block/Colcemid treatment, dramatically attenuates the number of genome-wide mutations (total variants, 5 in G2/M vs 859 in normal conditions). Ts/Tr was 1.0 in G2/M, whereas it was 0.05 in normal conditions. Our findings highlight that the cell conditions induced by G2/M synchronization may prevent the development of genome-wide mutations and rearrangements, possibly due to the suppression of replication machinery.

B243/P1929

Cyclin B isoforms coordinate mitotic entry and exit events to ensure the normal pace of embryonic divisions

P. Lara-Gonzalez[1], S. Variyar[2,3], J. Budrewicz[4], A. Schlientz[3,2], J. Houston[3,2], K. Oegema[2,3], A. Desai[2,3]; [1]Developmental and Cell Biology, University of California Irvine, Irvine, CA, [2]Ludwig Institute for Cancer Research, La Jolla, CA, [3]Cellular and Molecular Medicine, University of California San Diego, La Jolla, CA, [4]Oregon Health & Science University, Portland, OR.

Entry into mitosis is promoted by Cdk1, a kinase whose activity depends on its binding partner cyclin B. The cdk1-cyclin B complex phosphorylates multiple cellular targets to promote processes such as spindle

assembly, chromosome segregation, and cytokinesis. How mitotic entry is coordinated with embryonic development and how different cdk1-dependent mitotic events are propely orchestrated are both important open questions. Here we focus on cyclin B, which has three evolutionarily conserved isoforms: B1, B2 and B3. Using *C. elegans*, we found that individual depletion of cyclin B1 or B3, while resulting in embryonic lethality, did not prevent mitotic entry in early embryos. By contrast, co-depletion of cyclin B1 and B3 blocked mitotic entry. Thus, these two cyclin B isoforms function redundantly to activate cdk1 for mitotic entry in early embryos, enabling us to characterize in detail the effects of loss of cyclin B1 versus B3-associated cdk1 kinase activities. This analysis revealed remarkably opposite phenotypes of cyclin B1 and B3 inhibitions. Cyclin B1 depletion led to premature chromosome segregation, while cyclin B3 depletion caused a significant delay in mitotic events such as spindle assembly, chromosome alignment and chromosome segregation. These observations indicate that cyclin B3 is an accelerator of mitotic progression in rapidly dividing early embryos. Strikingly, in cyclin B3-depleted embryos, two key events of mitotic exit are reversed: cytokinesis, the process of partitioning the cell, initiates prior to chromosome segregation. To understand the origin of this reversal, we developed fluorescent biosensors for two enzymes central to mitotic exit: the anaphase-promoting complex/cyclosome (APC/C), a ubiquitin ligase that triggers mitotic exit, and separase, the protease whose activity is specifically required for chromosome segregation. This analysis revealed a delay in separase activation relative to APC/C activation following cyclin B3 depletion, explaining the reversed order of mitotic exit events. Thus, in addition to accelerating mitotic progression, cyclin B3 plays a specific role in ordering mitotic exit events by promoting separase activation. Overall, this work reveals remarkable differences between cyclin B isoforms in controlling cdk1 in the early embryo and identifies cyclin B3 as a promoter of rapid and properly ordered mitotic divisions, a key feature of embryonic development where rapid increase in cell number must be coordinated with processes such as cell fate determination and morphogenesis.

B247/P1930

YAP Promotes an Enhanced Mitogen Signaling State that Supports Cell Proliferation under Quiescence-promoting Cues

K. Ferrick[1], T. Meyer[2]; [1]Stanford University, Stanford, CA, [2]Weill Cornell Medical College, New York, NY

Inactivation of the Hippo kinase cascade promotes YAP/TAZ activation and TEAD-dependent transcription of pro-proliferative and pro-survival genes. The Hippo pathway is critical for regulating periods of organogenesis and wound healing yet can also be disrupted for tumorigenesis and metastatic behavior. Merlin (NF2) is a tumor suppressor that functions as a scaffold protein and is an upstream regulator of the Hippo pathway. However, Merlin has putative Hippo-independent roles in mitogen and migration signaling pathways that may further contribute to its potent tumor suppressor activity. We set out to determine how loss of Merlin maintains cell proliferation following mitogen withdrawal and high cell density, conditions that normally promote quiescence. We used live-cell reporters of ERK and AKT activity and quantitative immunofluorescence to assess changes in single-cell signaling dynamics and protein regulators of cell-cycle progression. In addition to Merlin's anticipated role in classic YAP target gene regulation, we observed that Merlin KO cells gained sensitivity to several mitogens. Inhibition of LATS1/2 kinases with a recently published inhibitor or overexpression of YAP phenocopied this novel and generalized mitogen response. We also observed prolonged ERK signaling in response to mitogen stimulation as well as higher basal AKT activity, suggesting that aberrant YAP activity reprograms the proliferative signaling architecture of cells. Transcriptional analysis of quiescent cells induced with YAP

further supports that pathways sustaining mitogen signaling were rapidly up-regulated. We propose that prolonged YAP activity in Merlin KO cells increases the proliferative signaling potential of cells, even in restrictive, low-growth factor conditions.

B248/P1931

Cdt1 inhibits CMG helicase in early S phase to separate origin licensing from DNA synthesis

N. Ratnayeke[1], Y. Baris[2], M. Chung[1], J. T. P. Yeeles[3], T. Meyer[4]; [1]Stanford University, Stanford, CA, [2]MRC Laboratory of Molecular Biology, Cambridge, United Kingdom, [3]MRC Laboratory of Molecular, Stanford, CA, [4]Weill Cornell Medicine, New York, NY

Human cells license tens of thousands of origins of replication in G1 and then must stop all licensing before DNA synthesis in S phase to prevent re-replication and genome instability that ensue when an origin is licensed on replicated DNA. However, the E3 ubiquitin ligase $CRL4^{Cdt2}$ only starts to degrade the licensing factor Cdt1 after origin firing, raising the question of how cells prevent re-replication before Cdt1 is fully degraded. Here, using quantitative microscopy and in vitro reconstituted human DNA replication, we show that Cdt1 inhibits DNA synthesis during an overlap period when Cdt1 is still present after origin firing. Cdt1 inhibits DNA synthesis by suppressing CMG helicase progression at replication forks, and DNA synthesis commences once Cdt1 is degraded. Thus, in contrast to the prevailing model that human cells prevent re-replication by strictly separating licensing from firing, licensing and firing overlap, and cells instead separate licensing from DNA synthesis.

B249/P1932

Cell Division-Enabled Leaf System (CDELS), a transiently induced mitotic model for testing cell cycle-dependent protein expression in tobacco leaves

Y.-R. Lee, C. H. Huang, B. Liu; University of California, Davis, Davis, CA

Plant growth is brought about by mitotic cell division. Successful cell division harnesses the input of proteins that function in cell cycle-dependent manners in order to regulate intracellular motility of cytoskeletal reorganization and chromosome segregation. Fluorescence microscopic assays of mitotically active proteins have been dependent on time-consuming and sometimes technically challenging transformation experiments. To facilitate the discovery and observation of cell cycle-dependent localization and dynamics of plant mitotic proteins, we developed a transiently induced cell division system in tobacco (*Nicotiana benthamiana*), namely Cell Division Enabled Leaf System (CDELS). Plasmid constructs that expressed the D-type cyclin and protein(s) of interest tagged with a fluorescent fusion were delivered into the leaves of *N. benthamiana* by agrobacterial infiltration. Ectopic expression of cyclin D induced differentiated leaf epidermal cells to re-enter mitosis and subsequently cytokinesis, resembling what took place in meristematic cells. The dynamic localization of fluorescent fusion protein(s) was observed throughout the course of mitotic cell division by live-cell fluorescence microscopy. This CDELS allows us to not only discover novel mitotically active proteins but also promptly capture their dynamics and relationship with other known and unknown factors during cell division.

B250/P1933

Cell Cycle Dependent Degradation of RB1 Protein is Controlled by Hyperphosphorylation

S. ZHANG, E. Zatulovskiy, L. F. Valenzuela, J. Skotheim; Stanford University, Stanford, CA

RB1 is a key cell cycle regulator that controls cell cycle progression and contributes to controlling cell size. The amount of RB1 protein remains constant during G1 phase and accumulates during S/G2 phase. This results in a declining concentration of RB1 that reflects cell size so that the G1/S transition is size-dependent. However, the mechanism that regulates RB1 protein amounts during cell cycle progression is still unclear. We found that the RB1 mRNA remained at approximately constant concentration across the cell cycle, and its translational efficiency (TE) did not change significantly in different cell cycle phases, suggesting that RB1 protein is post-translationally regulated. By performing live imaging on reporter cell lines, we found that the protein half-life of RB1 was significantly different between G1 and S/G2 phases. RB1 was stabilized following the G1/S transition. Examination of RB1 phospho-site mutants suggested that the hyperphosphorylation of RB1 mediated the stabilization of RB1 protein in S/G2 phases. Mathematical modeling provided further insights into how the cell cycle dependent half-life of RB1 can give rise to its differential scaling behaviors during cell cycle progression. Taken together, our work supports a protein degradation-based mechanism controlling the dynamics of RB1 protein amounts through the cell division cycle.

B251/P1934

Heterogeneity of RNA-Binding Protein DND1 in G0 male germ cells may provide a selection process for spermatogonial stem cell development

K. Friedman[1], T. Hatkevich[2], B. Capel[2]; [1]University of Richmond, Richmond, VA, [2]Duke University, Durham, NC

The ability to reproduce is dependent upon proper development of the germline. In male *Mus musculus*, germline development involves male germ cells (MGCs) differentiating into spermatogonial stem cells (SSCs), the precursors for male gametes. During this differentiation period, MGCs enter a quiescent phase (G0), an essential stage for SSC development. This G0 phase accompanies changes in transcription as well as chromatin accessibility and re-methylation of DNA. Dead-End 1 (DND1) is an RNA binding protein whose expression has been shown to be essential for the entry and maintenance of G0. During G0, MGCs heterogeneously express DND1, resulting in two MGC populations: “DND1-hi” cells (those which highly express DND1) and “DND1-lo” cells. Bulk RNA-seq studies from our lab show that DND1-hi cells have a distinct transcriptome as compared to DND1-lo cells and highly express transcripts that encode for proteins involved in SSC development. Despite two distinct DND1-expressing MGC populations present in G0, the biological significance of DND1 heterogeneous expression on SSC development remains unknown. Considering only a fraction of G0 MGCs differentiate into SSCs, we hypothesize that the G0 DND1-hi cells develop into SSCs, while the DND1-lo cells undergo apoptosis. To investigate if G0 DND1-lo cells are set to apoptose we used whole-mount immunofluorescence to examine expression of cellular and apoptotic markers throughout G0. We observed the presence of LEFTY, a marker for pre-G0 MGCs that undergo apoptosis, in E12.5 (just prior to G0) and E14.5 (the start of G0); however, LEFTY was absent in a later G0 time point (E16.5). Presence of LEFTY expression at E12.5 and E14.5 did not correlate with the DND1-lo or DND1-hi populations. Instead, LEFTY was present in all early G0 MGCs, despite the level of DND1 expression. We also examined the presence of ɣ-H2Ax, a marker for double-strand DNA breaks that marks cells undergoing apoptosis. We saw ɣ-H2Ax in E14.5

and E16.5 MGCs, indicating that apoptosis occurs in these stages but expression of ɣ-H2Ax was anti-correlated with DND1 expression, suggesting that by the time ɣ-H2Ax is detected, MGCs have stopped expressing DND1. We conclude that this marker is too late in the cell death pathway to test the hypothesis that apoptosis is more likely in DND1-lo cells. We will continue to test our hypothesis by looking at additional apoptotic markers, such as AnnexinV, examining if DND1-hi cells are less likely to undergo apoptosis during G0 compared to DND1-lo cells.

Cancer Therapy - Inhibitor Activity 2

Investigation of Ceramidase Inhibitor Effect in BALB/c Mice with Breast Cancer

M. KUTLU; Eskisehir Technical University, ESKİŞEHİR, TURKEY.

Abstract In recent years, many studies have been carried out to determine the cancer or anticancer effects of drugs that have an effect on sphingolipid metabolism. Thanks to studies with ceramides, new dimensions are added to cancer research. Ceramides are structural molecules found in the membranes of cells and involved in very important metabolic processes such as growth, differentiation and apoptosis. Inhibition of ceramidases is an alternative way to increase apoptosis and ceramide accumulation in cancer cells. The key molecule in this metabolism for cancer treatment is ceramide. Depending on the level of ceramide in the cells, the cells are directed to death or survival can be sustained. Ceramidase enzymes are enzymes that break down the intracellular ceramide, lower the ceramide level in the cells and cause the cells to escape from death. Cancer is a disease that occurs with the uncontrolled division and proliferation of cells and is under the influence of genetic and environmental conditions. There are more than 100 known types of cancer. Breast cancer is a type of cancer that occurs in both men and women. Breast cancer is the most common type of cancer in women after lung cancer and is the second leading cause of cancer-related deaths. With a rate of 24.1%, breast cancer ranks at the top of all cancer cases in women in our country. Developing innovative treatment strategies and understanding the biology of this type of cancer are essential to reduce the death rate from breast cancer. Suppression of ceramidase enzymes as new targets for cancer therapy is shown in the literature. In this study, a breast cancer model was created in BALB/c mice, and then the mice were treated with ceramidase inhibitors D-erythro-MAPP and D-erythro-MAPP KLN. Apoptotic effects of D-erythro-MAPP and D-erythro-MAPP KLN formulation in lung tissue of mice were determined by immunohistochemical marking. It was determined that the staining results of caspase-3 and PARP1 antigens gave statistically significant results according to the H-score values obtained. **Keywords:** D-erythro-MAPP, Breast cancer, Ceramide, Apoptosis.

Identification of Synergistic Therapeutics for Basal-like Breast Cancer Brain Metastases

A. D. Valentine[1], T. H. Turner[2], N. S. Rashid[3], N. S. Hairr[4], T. J. Leftwich[4], J. C. Harrell[4]; [1]Biochemistry, Pathology, Virginia Commonwealth University, Richmond, VA, [2]Internal Medicine/Neurology, Mayo Clinic, Jacksonville, FL, [3]Biology, University of Richmond, Richmond, VA, [4]Pathology, Virginia Commonwealth University, Richmond, VA.

Each year over 280,000 people in the United States will be diagnosed with invasive breast cancer and over 40,000 people will die from metastatic disease. The most difficult subtype to treat is basal-like

triple negative breast cancer (TNBC), as this subtype is highly metastatic and can become chemotherapy resistant. TNBC lacks estrogen and progesterone receptors, as well as HER2, which are actionable drug targets - making it difficult to treat. Furthermore, most chemotherapeutics designed to target TNBC are unable to treat brain metastases due to their inability to permeate the blood-brain barrier (BBB). Therefore, it is crucial to develop novel BBB-permeable treatments for brain-metastatic TNBCs. A selective inhibitor for nuclear export (SINE) was chosen as the prime chemotherapy candidate due to its indication for inhibiting a nuclear export protein which is highly expressed in basal-like TNBC and is negatively associated with brain metastasis-free survival. To identify BBB-permeable drug candidates for synergism studies with this SINE, 34 BBB-permeable drugs were screened in vitro in four basal-like TNBC patient-derived xenograft (PDX) suspension culture models. Based on observed supra-additive trends, 4 drugs were selected for in vitro testing in combination with our SINE of interest; these drugs target dihydropyridine calcium channels, histone deacetylases, neurotrophic tyrosine receptor kinases, and malaria. Synergism was identified with the 4 BBB-permeable drugs and favorable dose reductions were observed in all four PDX models. Based on these results, ongoing studies are now determining the efficacy of these drugs as single agents or combinations on mammary tumors and brain metastases with luciferase-labeled PDXs.

Tocotrienol exerts on-target malignant activity against leukemia

M. L. P. Bueno[1], M. Foglio[2], S. T. O. Saad[1], **F. Marconi Roversi**[1]; [1]Hematology and Transfusion Medicine Center-University of Campinas / Hemocentro-UNICAMP, Campinas, São Paulo, Brasil, Campinas, BRAZIL, [2]Faculty of Pharmaceutical Sciences-University of Campinas / Faculdade de Ciência Farmacêutica-UNICAMP, Campinas, São Paulo, Brasil, Campinas, BRAZIL.

Acute Leukemias comprise a group of hematopoietic malignancies with uncontrolled proliferation of immature blood cells that lost the capability of differentiation. Nowadays, the advance on understanding and improving treatment strategies depends on identifying and developing novel potential compounds that are more effective and less toxic than the currently available chemotherapeutics. Tocotrienol, a vitamin E isoform, was reported to be a potential anti-cancerous agent due to its antimetastatic activity in solid neoplasms and anti-inflammatory effects on the immune system. Hence, our aim was to investigate the role and effects of tocotrienol compound (provided by New Max Industrial) in leukemia. A panel of acute leukemia cell lines (U937, OCI-AML3, RS4;11, Jurkat) were treated with tocotrienol in a time -concentration manner. Viability was evaluated by MTT assay, apoptosis by flow cytometry, and protein levels by Western Blot. To mimetize some microenvironment participation in the leukemia biology, a coculture with monocyte and leukemia cells was done. Tocotrienol treatment resulted in a potent antineoplastic activity in a concentration-dependent manner (1.4-14.0μM): reducing 50% cell growth (U937: 9.5μM, OCI-AML3: 4.4μM, RS4;11: 12.8μM, Jurkat: 14.1μM) associated with increased cell death (fold-increase (FI) U937: 0.9-5.8, OCI-AML3: 1.4-8.6, RS4;11: 1.1-5.0, Jurkat: 0.9-5.1). Tocotrienol also increased leukemia cell death cocultured with tocotrienol-programmed monocytes (FI: 32.9; P<.0001). Tocotrienol was able to reduce ROS production (fold decrease (FD) U937: 1.1-6.9, OCI-AML3: 1.0-7.3, RS4;11: 1.1-5.9, Jurkat: 1.0-5.7) in a concentration-dependent manner (1.4-14.0μM) (all P<.05). Tocotrienol reduced AKT and ERK protein phosphorylation, important overexpressed molecules in leukemia and modulated caspase 3 and 9. On the other hand, tocotrienol treatment of primary cells isolated from healthy donors did not modulate cells survival or apoptosis. In conclusion, tocotrienol arises as an effective cytotoxic and antineoplasm agent for

leukemia treatment without altering apoptosis and survival of normal cells (on-target malignant cell killing activity), probably by blocking ROS production and, consequently, interrupting PI3K and MAPK signaling.Funding: FAPESP grants #2017/21801-2, #2019/25247-5, #2021/05320-0

Effects of ZnO and CuO NPs on Human Thyroid Cancer Cells (ML-1) vs Rat Medullary Thyroid Carcinoma (CA77)

A. Peters, K. Kim, K. Monahan, N. Weaver; Missouri State, Springfeild, MO.

Effects of ZnO and CuO NPs on Human Thyroid Cancer Cells (ML-1) vs Rat Medullary Thyroid Carcinoma (CA77) *Authors: Alyse Peters, Katelyn Monahan, Nakaja Weaver, and Kyoungtae Kim* Nanoparticles (NPs) contribute to the technologies in agriculture and food development, but there is little understanding of how nanoparticles impact human health. To further understand the effects of NPs, this study investigates metal nanoparticles (Me-Nps) on ML-1, CA77 and non-cancerous fibroblast cells to discover their impact. The cytotoxicity of the selected NPs was explored through an XTT viability assay, an superoxide and an apoptosis analysis on cells. XTT results conveyed ZnO and CuO having the greatest decreased viability, therefore CuO and ZnO were selected for a further gene expression study. Similar to the ML-1 cells, CA77 cells also showed a decrease in cell viability quantified by an XTT assay. The production of superoxide in the ML-1 cells when treated with CuO and ZnO was found to be not significantly altered during 24-hour incubation with both nanoparticles; Ca77 cells illustrated a similar trend, but these nanoparticles had a slight decrease in superoxide. The apoptosis assay revealed that ZnO and CuO increased cell death which led to the conclusion that the cause of decreased cell viability comes more from apoptosis rather than superoxide. Ca77 cells show a slightly increased trend though not statistically significant. Consistently, our RNAseq studies illustrated upregulated apoptotic, inflammation, DNA damage response (p53), and xenobiotic metabolism genes with the ZnO treatment. Downregulated genes in ZnO-treated experiments include Golgin family and cytochrome p450 family genes. When treated with CuO NPs, DNA regulation, apoptotic process, cell migration, abiotic stimulus, and DNA repair genes are all upregulated. Cell-cell adhesion, synapse organization and cell proliferation are all downregulated. RNAseq studies were repeated for Ca77 cells. The major pathways upregulated when treated with CuO include inflammation mediated by cytokine and chemokine, interleukin signaling pathway and TGF beta signaling pathway. The major downregulated pathways include angiogenesis, Wnt signaling, and VEGF signaling with CuO treatment. ZnO treatment on Ca77 cells upregulates thyrotropin-releasing hormone signaling receptor pathway, Wnt signaling pathway, integrin signaling pathway, and inflammation mediated by cytokine and chemokines. Downregulated pathways include endothelin signaling pathway, blood coagulation, and angiogenesis. These experiments give powerful insight on potential Me-Nps effects on the human body and animal models. Future experiments include proteomic studies to evaluate the affected proteins in both cell lines when treated with ZnO and CuO.

B257/P1939

Role of the nuclear export protein CRM1 in DNA repair pathway.

Y. Yang, R. Kumar, J. Mendonca, L. Wilson, D. Topiwala, K. Boyapati, N. Thomas, I. Sharma, M. Carducci, S. Kachhap; Johns Hopkins University School of Medicine, Baltimore, MD.

PARP inhibitors have recently been shown to be very successful in treating prostate cancer (PCa) that harbor mutations in DNA repair genes. Since only 20% of prostate cancer patients carry mutation in DNA

repair genes, innovative strategies are needed to expand the clinical usage of PARP inhibitors beyond DNA repair mutant tumors. An innovative strategy would be to create conditions that mimic repair mutants in prostate tumors and then treat them with PARP inhibitors. We found that CRM1, a nuclear export protein that is upregulated in PCa and amplified in neuroendocrine PCa, takes an active part in DNA repair. Our data demonstrates that treatment of PCa cells with Selinexor, a highly selective CRM1 inhibitor with reduced toxicities undergoing several clinical trials, results in BRCA1 and RAD51 downregulation and decreased DNA repair; creating conditions analogous to cells harboring DNA repair mutation. These findings manifest that CRM1 impacts DNA repair and its inhibition results in a defect of DNA repair capacity. We further demonstrate that combination of PARP inhibitor or DNA repair pathway inhibitor and Selinexor significantly decreases growth of PCa cells.

Co-treatment of gallic acid and cisplatin suppresses LPS-induced cancer properties in MDA-MB 231 breast cancer cells

A. R. Aikins, P. Pasgo, J. T. Quarshie, S. M. Baffoe, P. A. Birikorang, Y. Bediako, W. S. K. Gbewonyo; Biochemistry, Cell & Molecular Biology/West African Centre for Cell Biology of Infectious Pathogens, University of Ghana, Accra, GHANA.

Breast cancer remains the most frequently diagnosed cancer in women worldwide. The presence of lipopolysaccharide (LPS) on the cell wall of Gram-negative bacteria identified in some breast cancer tissues have been implicated in inflammatory responses via the TLR4/NF-κB signaling cascade. Inflammation is associated with chemoresistance, which could be suppressed through combination therapy. This study sought to investigate the anticancer effect of combining the phenolic compound, gallic acid (GA) - which has anti-inflammatory properties - with cisplatin on LPS-induced breast cancer progression. Using MDA-MB-231 cells as experimental models, we found that both GA and GA-cisplatin co-treatment reduced cell proliferation in a dose- and time-dependent manner. RT-qPCR analysis and ELISA showed that the GA-cisplatin co-treatment downregulated TLR4 as well as LPS-induced IL-8 expression. Furthermore, GA and GA-cisplatin suppressed LPS-induced cell migration. Inhibiting TLR4 repressed cell proliferation, suggesting a proliferative role for TLR4 in breast cancer and supporting its potential as a therapeutic target. Altogether, we show that GA-cisplatin co-treatment suppresses breast cancer proliferation, LPS-induced inflammation and cell migration via inhibition of TLR4 expression. These findings provide a rationale for the consideration of GA in combination therapy with cisplatin for improved chemotherapy.

Targeting CYP11A1 as a potential therapeutic approach for renal cell carcinoma

H. T. M. Ong[1], T. H. Kim[2], E. Ates[1], J. C. Pyun[2], M. J. Kang[3]; [1]KIST School, University of Science and Technology, Seoul, Korea, Republic of, [2]Yonsei University, Seoul, Korea, Republic of, [3]Korea Institute of Science and Technology, Seoul, Korea, Republic of

Clear cell renal carcinoma (RCC) is commonly known for its metastasis propensity to outspread to other organs and does not exhibit symptoms in the early stage. Recent studies have shown that deficiencies in CYP11A1 expression can lead to fatal adrenal failure if left untreated and are associated with downstream regulation in various cancer types. However, the molecular mechanisms of CYP11A1 and kidney cancer proliferation remain unclear. In this context, normal and renal carcinoma cell lines

(Hek293 and Caki-1) were transfected with CYP11A1 to stimulate overexpression and examined by immunocytochemistry staining. Levels of oxidative stress were determined by absorbance assay and cell cycle distribution was investigated by flow cytometry. The role of related signaling pathways in the activation of CYP11A1 was tested by western blot. Results observed that CYP11A1 defeated the migration of the cancer cell line along with epithelial-intermediate metastatic (EMT) markers. A significant decrease in the expression of cyclin B1 and phosphorylation of Cdc2 was detected whereas the cyclin-dependent kinases (Cdk2 and Cdk4) were not altered. In addition, CYP11A1 overexpressed resulting in the up-regulation of ATM/ATR while phosphorylation of upstream signals related to G2/M phase arrest and blockaded of C-Raf/ERK pathway. Consistently with these data, CYP11A1 overexpression reversed the EMT process, induced G2 phase arrest, generated ROS, and promoted apoptosis in RCC. This study reveals a promising therapeutic target to suppress kidney cancer proliferation without affecting normal cells, thus improving the survival rate of cancer patients.

Enhanced the antitumor effects of chimeric antigen receptor T cells in glioblastoma

E. A. Ogunnaike[1], A. Valdivia[1], M. Yazdimamaghani[1], E. Leon[1], H. Du[1], S. Khagi[1], Z. Gu[2], B. Savoldo[1], F. S. Ligler[3], S. Hingtgen[1], G. Dotti[1]; [1]University of North Carolina - Chapel Hill, NC, Chapel Hill, NC, [2]Zhejiang University, Chapel Hill, NC, [3]North Carolina State University and University of North Carolina at Chapel Hill, Raleigh, NC

Limitations in the delivery of biotherapies to treat glioblastoma (GBM), a lethal and hard to- treat cancer of the brain, includes antigen targets, therapeutic delivery, and invasive tumor microenvironment. Failure to sustain the delivery to address T cell exhaustion and proliferation while considering the GBM-tumor microenvironment (TME) adversely affects therapeutic antitumor efficacy in both animal models and humans. We develop a physiological biomaterial, a fibrin-based hydrogel (FBH) encapsulating chimeric antigen receptor (CAR) T cells (F-CAR-T), that can afford treatment combinations to close these critical gaps and lack of knowledge for translation of the CAR-T cell therapy. Regional delivery of chimeric antigen receptor (CAR) T cells in glioblastoma represents a rational therapeutic approach as an alternative to intravenous administration to avoid the blood-brain barrier impediment. Here we developed a fibrin gel that accommodates CAR-T cell loading and promotes their gradual release. We used several bioanalytical tools such as atomic force microscopy, cryogenic scanning electron microscopy, and confocal microscopy to evaluate the porous network capability to accommodate the T cells and the interaction results. We performed immunological and functional assays were used to assess the T cells released from the gel, nutrient exchange, and phenotypical characterization. Using a model of sub-total glioblastoma resection, we demonstrate that the fibrin gel delivery of CAR-T cells within the surgical cavity enables superior antitumor activity compared to CAR-T cells directly inoculated into the tumor resection cavity.

Gene silencing of LAT1 and ASCT2 Transporters via Short Interfering Nucleic Acid Therapies upon Human Colon Cancer HCT-116 Cell Xenografts

C. Carneiro[1], P. J. Kennedy[2], S. Bessa[1], **P. Soares-da-Silva**[3,1]; [1]Phyzat Biopharmaceuticals, Porto, Portugal, [2]Phyzat Biopharmaeuticals, Porto, Portugal, [3]MedInUP – Center for Drug Discovery and Innovative Medicines, University of Porto, Porto, Portugal

Overexpression of LAT1 (SLC7A5) and ASCT2 (SLC1A5) transporter supports the continuous growth and proliferation of cancer cells and has been suggested to be a marker of colorectal adenocarcinoma prognosis (Pharmacol Ther. 230:107964,2021; Anticancer Res 22:2555-2557,2002; Mol Imaging Biol 19:421-428,2017). We aimed to characterize novel short interfering nucleic acid therapies (siNAT) targeting LAT1 and ASCT2 mRNAs in HCT-116 human colon cancer cells and evaluate its *in vitro* and *in vivo* effect. HCT-116 cells were transfected with 0.1-25 nM of double-stranded Nucleic Acid (dsNA) complexed with a commercial liposomal transfection agent. LAT1 and ASCT2 gene and protein expression were analysed by RT-qPCR and western blot, respectively. LAT1 and ASCT2 transporter activity was quantified by [^{14}C]-L-leucine and [^{14}C]-L-alanine uptake. The effect of LAT1 and ASCT2 downregulation on cell growth and viability was determined using crystal violet assay. Immune deficient female BALB/c nude mice (CAnN.Cg-Foxn1nu/Crl) were used for subcutaneous implantation of HCT-116 cells (1x10^{6}) previously treated with the transfection agent alone or complexed with anti-LAT1 or anti-ASCT2 dsNAs for evaluation of tumour growth. Animal experimental procedures followed the EU Directive 2010/EU/63 and the DGAV (project No. 34-2021). The anti-LAT1 and anti-ASCT2 dsNAs significantly decreased LAT1 and ASCT2 mRNA expression (IC_{50}=1.4 nM and 1.8 nM, respectively) causing 80%-70% knockdown of protein transporter expression and leading to > 50% reduction in substrate uptake. Treatment of HCT-116 cells with an anti-LAT1 and ASCT2 dsNAs significantly reduced cell proliferation (1-25nM), leading to 70 % arrestment in cell proliferation. Treatment of HCT-116 cells with an anti-LAT1 dsNA significantly reduced cell proliferation (>50%), and the combination of dsNA with 5-FU (5 µM) or Oxa (2 µM) had a synergistic effect on proliferation. Tumours derived from cells transfected with anti-LAT1 or anti-ASCT2 dsNAs grew 3X slower than tumours derived from cells treated with empty transfection agent. Altogether these results further support the potential or LAT1 and ASCT2 for antineoplastic treatment and exploit siNAT as tool to target LAT1 and ASCT2 in colon cancer.
Part of this work was developed within the SIRNAC project (33399), co-financed by NORTE2020, PT2020 and the European Union.

Cancer Therapy- Targeting Kinases 1

Albendazole exerts antiproliferative effects on Hs578 triple-negative breast cancer cells by inhibiting mTOR and akt signaling pathways

R. Koon, **K. Suh**; High Point University, High Point, NC.

Albendazole is an antihelminthic drug used for the treatment of a variety of parasitic worm infestations by targeting microtubules which play an important role in cell division. However, albendazole has been shown to exhibit anti-cancer properties recently. The mammalian target of rapamycin (mTOR) kinase is an important component of PTEN/PI3K/Akt signaling pathway. The mTOR signaling pathway promotes tumor progression and regulates autophagy and apoptotic cell death. Therefore, studies suggest that targeting mTOR signaling pathway could be an effective strategy for the treatment of cancer. In the present study, we investigated the growth inhibitory effect of albendazole and its associated mechanism in Hs578T triple-negative breast cancer cells. When Hs578T cells were treated with albendazole, viability was inhibited, and apoptotic cell death was induced in a dose- and time-dependent manner. Apoptosis was verified by detecting the cleavage of poly(ADP-ribose) polymerase, staining fragmented nuclei using Hoechst dye, and measuring the activity of executioner caspases. Furthermore, we observed increased expression of pro-apoptotic protein Bak which is known to be involved in pore formation on

mitochondrial outer membrane. On the other hand, the level of anti-apoptotic protein Bcl-XL was downregulated upon treatment of Hs578T cells with the drug. In cells treated with albendazole, the activity of mTOR was significantly inhibited which was measured by western blotting, immunocytochemistry, and enzyme-linked immunosorbent assays. The expression of mTOR signaling complex constituents such as Raptor and Rictor was also downregulated. This resulted in the inactivation of mTOR target proteins such as ribosomal protein S6. Finally, we performed RNA sequencing analyses to identify novel targets of albendazole. Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment analyses revealed multiple genes that are differentially expressed including the genes that are associated with DNA replication, cell cycle, and VEGF signaling pathways. Taken together, these results indicate that albendazole could be a potent inhibitor of mTOR signaling pathway in triple-negative breast cancer cells and suggest its potential use as chemotherapeutic agent against breast cancer.

Assistant Professor

J. Hong; Department of Physiology, Daegu Catholic University School of Medicine, Daegu, KOREA, REPUBLIC OF.

Lysosome is the major machinery of RTK proteolysis. Some of endocytosed RTKs return to the cell membrane after the specific ligand stimulation and signal transduction by recycling endosomes. The other endocytosed RTKs are being digested via lysosomal proteolysis after signaling processes. The ratio of recycling and lysosomal proteolysis depends on the specific receptor. Among RTKs, EGFR is majorly being degraded in lysosomes after the ligand stimulation rather than undergoing to the recycling process. However, this proteolysis is downregulated in hypoxic condition such as the central core of solid tumors. The downregulation of EGFR degradation is because of the suppressed lysosomal activity in hypoxic conditions by the suppress of the nuclear translocation of TFEB.Here we demonstrate that, in cultured mammalian cells and mouse models, the enhancement of lysosomal activity leads to the degradation of EGFR in colon cancer cells. We overexpressed V-ATPase components in DLD-1 cells that increased the proteolysis of EGFR in lysosomes. The cells were also xeno-transplanted to immune-suppressed nude mice to induce tumors. When the lysosomal activity was enhanced in DLD-1 colon cancer cells, the growth was significantly decreased. Furthermore, when the mice were treated with a tyrosine kinase inhibitor, Osimertinib, the decrease of tumor growth was much more decreased. From this study, we suggest lysosomal activation can be another therapeutic approach for EGFR-mediated cancers including colon cancers. Furthermore, this can be a new combination therapy together with the previous antibody therapies and TKI therapies.

Anti-HER2 Therapies Regulate MAF1 Expression in Breast Cancer

G. Olshefsky[1], **L. Schramm**[2]; [1]Garden City High School, Garden City, NY, [2]St. John's University, Queens, NY.

In 2022, the United States anticipates 287,850 new invasive breast cancer diagnoses. TFIIIB amplification and overexpression frequently occur in breast cancer. MAF1 negatively regulates TFIIIB. In HER2-positive breast cancer patients, compared to controls, MAF1 mRNA expression decreases. There is a significant increase in the methylation of the MAF1 promoter ($p = 2.25 \times 10^{-5}$) in HER2-positive breast cancer.

Decreased MAF1 protein expression occurs in HER2-positive breast cancer (p = 4.66 x 10^{-5}). Treatment of HER2-positive breast cancer cell lines with the anti-HER2 agent lapatinib increased MAF1 mRNA expression in BT474 (q = 0.02) and SKBR3 (q = 0.08) cells. BT-474 cells treated with Herceptin (trastuzumab) also increased MAF1 mRNA expression (FDR = 2.60 x 10^{-6}). Next, we examined MAF1 expression in response to anti-HER2 therapy (trastuzumab) in HER2-positive breast cancer patients (n = 564) using relapse-free survival status at five years (n = 1,329) as the clinical output to perform a receiver operating characteristic (ROC) analysis. Increased MAF1 mRNA expression occurs in HER2 - positive breast cancer patients treated with trastuzumab (p = 2.7 x 10^{-6}, AUC = 0.874). These data suggest MAF1 may be a predictive biomarker for anti-HER2 therapy in HER2-positive breast cancer.

B265/P1947

Concomitant inhibition of KRAS and EGFR by miR-1 and miR-155 in colon cancers

J. Kim[1], M. Hwang[1], Y. Kwon[2], W. Kim[2]; [1]Department of Pharmacology, Department of Biomedicine & Health Sciences, The Catholic University of Korea, Seoul, KOREA, REPUBLIC OF, [2]Natural Product Research Center, KIST Gangneung Institute of Natural Products, Gangneung, KOREA, REPUBLIC OF.

Colorectal cancer (CRC) is one of the most common fatal cancers worldwide. EGFR is overexpressed in CRC and has been reported to promote colon cancer growth. Colon cancer can respond to the EGFR-targeting drugs such as cetuximab. However, no effective therapeutic strategy has been developed in targeting KRAS with mutation. Here, we found novel miRNAs, which simultaneously target EGFR and KRAS in colon cancer. Target Scan Database screened 54 miRNAs for targeting EGFR and KRAS simultaneously. Of these candidates, miR-1 and 155 were validated by Western blot. Luciferase assay revealed that these two miRNAs are directly binding to the 3'-UTRs of EGFR and KRAS. Furthermore, cell proliferation assay proved that miR-1 and 155 inhibit the cell proliferation and growth. These findings demonstrate that miR-1 and miR-155 mediate down regulation of EGFR and KRAS, suggesting that targeting EGFR and KRAS with miR-1 and 155 might be useful therapeutic strategies against colon cancer growth.

Sphingosine Kinase 1 Promotes Lung Cancer Cell Growth

A. B. Nguyen[1], V. Balaji Ragunathrao[2], D. Mehta[2]; [1]Department of Biology, Villanova University, Villanova, PA, [2]Department of Pharmacology and The Center for Lung and Vascular Biology, The University of Illinois College of Medicine, Chicago, IL.

Sphingosine kinase 1 (SPHK1) is a cytosolic enzyme that generates the bioactive lipid, sphingosine-1-phosphate (S1P), from sphingosine. S1P drives the growth, vascularization, and invasiveness of tumors. SPHK1 has been shown to be highly mutated and overexpressed in many types of cancer, such as ovary, skin, breast, or lung cancer. Here we assessed the role of SPHK1 in regulating the proliferation of lung cancer using the Lewis lung carcinoma (LLC) cell line. Differences in the expression levels and localization of SPHK1 were examined in LLC cells after culturing for 24, 48, 72, 96, and 120 hours. We found that SPHK1 mRNA and protein expression increased in LLC, reaching a maximum at 96 hours. Interestingly, while SPHK1 is often characterized in the cytosol, confocal imaging showed nuclear translocation of SPHK1 at 72 hours in a subpopulation of cells, which was sustained till 120 hours. To address the causal role of SPHK1 in regulating LLC proliferation, we targeted SPHK1 using CRISPR, small interfering RNA (siRNA), and a specific small molecular inhibitor of SPHK1, PF-543. Inhibition of SPHK1 reduced LLC

viability after all treatments. CRISPR-Cas9 was more effective than siRNA as it had higher cytotoxicity of over 80%. PF-543 was tested at different concentrations, showing a gradual increase in cytotoxicity as its concentration increased from 1 nM to 100 nM and an IC_{50} of 4.9 nM. In conclusion, our study shows that SPHK1 induces the proliferation of lung cancer cells and therefore SPHK1 is a promising target to inhibit lung cancer growth.

Examining the role of EGFR family signaling in promoting prostate cancer proliferation in an androgen receptor-low environment

S. Wilkinson[1], A. Ku[1], I. King[1], A. Baj[1], D. Low[1], H. Ye[2], F. Karzai[1], S. A. Harmon[1], N. T. Terrigino[1], J. R. Bright[1], S. Y. Trostel[1], R. T. Lis[1], B. Turkbey[1], W. L. Dahut[1], A. G. Sowalsky[1]; [1]National Cancer Institute, Bethesda, MD, [2]UCLA, Los Angeles, CA.

Prostate cancer (PC) remains the second-leading cause of death among men in the United States. In patients presenting with locally-advanced disease, neoadjuvant androgen deprivation therapy may represent the last chance for a cure, as treatment-resistant micrometastic spread will ultimately drive relapse, and progress to lethal PC. To determine novel mechanisms of treatment resistance, we tested the hypothesis that mechanisms of treatment resistance are present at baseline, which would predict poor therapeutic response. Utilizing tumors from 39 patients with locally-advanced PC and RNAseq to measure differentially expressed genes as a function of posttreatment residual tumor volume, we identified pathway alterations, including EGFR family members, at baseline that promote a poor therapeutic outcome. We found that patient tumors with low androgen receptor (AR) activity at baseline exhibited a poor treatment response, potentially due to increased dependency on alternate pathways. Interestingly, these tumors also consistently exhibited a significant increase in the expression of EGFR family signaling (EGFR, HER2, and HER3) at baseline, which was positively correlated with the volume of posttreatment tumors. To determine a mechanistic role for EGFR in disease progression, PC cell lines were treated with a panel of EGFR family and androgen receptor (AR) inhibitors. Protein and RNA expression, cell viability, migration, and invasion were measured to identify the impact of dual inhibition. We found afatinib (EGFRi), lapatinib (HER2i) and neratinib (EGFR/HER2i) showed the greatest anti-tumor efficacy *in vitro*, as treatment with these agents rapidly and dynamically increased AR expression and activity. We observed synergistic effects on cell viability, proliferation, invasion, and migration by treating PC cell lines with combination therapy of anti-androgen therapy and these inhibitors. Consequently, we found that simultaneously disrupting AR activity and HER2-mediated bypass of AR blockade re-sensitized resistant PC cells to androgen deprivation therapy. These data highlight the role of EGFR and HER2 signaling in bypassing androgen inhibition to promote AR-independent PI3K-mediated proliferation pathways. As these effects were observed in a treatment-naive patient population, they represent an early divergent path in tumorigenesis, where prostate tumors initially develop to have intrinsically lower AR activity, which would contribute to treatment resistance and metastatic spread. Current work is focused on validating these findings using genetic abrogation of EGFR and HER2 in additional clinical samples, organoids, and patient-derived xenograft models.

Investigating cellular senescence as a novel treatment for glioblastoma

R. Hines[1,2], K. Morris[2], P. Vaughan[2], T. Hinchcliffe[3], P. Traktman[4,5,6,7], K. Vaughan[2,8]; [1]Graduate Division, Indiana University School of Medicine, Indianapolis, IN, [2]Biological Sciences, University of Notre Dame, Notre Dame, IN, [3]Hormel Institute, University of Minnesota, Austin, MN, [4]Biochemistry & Molecular Biology, Medical University of South Carolina, Charleston, SC, [5]Microbiology and Immunology, Medical University of South Carolina, Charleston, SC, [6]Hollings Cancer Center, Medical University of South Carolina, Charleston, SC, [7]Microbiology and Molecular Genetics, Medical College of Wisconsin, Milwaukee, WI, [8]Harper Cancer Research Institute, University of Notre Dame, Notre Dame, IN.

The reformation of the nuclear envelope at the end of mitosis is a highly regulated process. We identified a novel pathway involved in nuclear envelope reformation that, when disrupted, induces defects in nuclear lamina assembly. These defects mimic Hutchinson Gilford Progeria Syndrome (HGPS) with blebbed nuclei and uneven accumulation of Lamin A around the nuclear perimeter. As seen in HGPS, nuclear blebbing can lead to cellular senescence through the cGAS-cGAMP-STING pathway. In order to form an intact nucleus, phosphorylation of both Lamin A and Barrier - to - Autointegration (BAF) are required for their interaction at the nuclear envelope. The protein vaccinia-related kinase 1 (VRK1) has previously been shown to phosphorylate BAF. Inhibition of VRK1 through either genetic approaches or drugs in a glioblastoma (GBM) cell line resulted in blebbed and highly micronucleated nuclei. Our results indicate that targeting the reformation of the nuclear envelope could be used as a novel treatment pathway for GBM by avoiding targeting the cell cycle. Inducing nuclear blebbing and, therefore, cellular senescence would help circumvent the problems GBM treatments typically have in highly mutated GBM tumors.

B269/P1951

Loss of PRR14L Sensitizes Cells to Aneuploidy Induction

A. Liu[1], A. Narkar[1], T. Bertomeu[2], J. Zhu[3], M. Tyers[2], R. Li[1]; [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]Universite de Montreal, Montreal, QC, Canada, [3]National University of Singapore, Singapore, Singapore

One cellular state often observed in cancer is aneuploidy, which describes cells with unbalanced chromosome content. Aneuploidy is associated with a number of negative outcomes in cancer, such as drug resistance and metastasis, thus making it an attractive therapeutic target. Utilizing the MPS1 kinase inhibitor NMS-P715 to induce aneuploidy, we carried out a pooled CRISPR/Cas9 screen to identify target genes that reduce aneuploid cell fitness when lost, and identified the gene PRR14L as a potential novel target. PRR14L is a gene with currently unknown function that has previously been linked to mitosis via both midbody localization and a connection to PP2A. We subsequently generated monoclonal knock-outs of PRR14L and validated that loss of PRR14L sensitizes cells to aneuploidy. Live-cell imaging experiments have revealed that loss of PRR14L increases the frequency of mitotic slippage and consequent tetraploid daughter cells in response to MPS1 inhibitors. Current efforts to further characterize the function of PRR14L have revealed a potential link to Aurora Kinase B, and the results will be discussed.

Cancer Therapy- Drug resistance

B270/P1952

Venetoclax resensitizes cells lacking APC expression to paclitaxel treatment

J. Prosperi; IUSM-South Bend/Notre Dame, South Bend, IN

Patients with triple negative breast cancer (TNBC) are treated with traditional chemotherapy, such as paclitaxel (PTX). Despite the efficacy of taxanes, many tumors will recur due to drug resistance. Therefore, the need to understand the mechanism behind drug resistance is critical to improve patient outcome and survival. Our lab was the first to show that loss of the *Adenomatous Polyposis Coli (APC)* tumor suppressor caused resistance to PTX in the MDA-MB-157 human TNBC cell line. In the absence of APC, apoptosis induction was decreased, as measured through cleaved caspase 3 and annexin/PI staining. To understand the molecular mechanisms behind APC-mediated PTX response, we analyzed the BCL-2 family of proteins and found a robust increase of the pro-survival family member, Bcl-2. The BH3 mimetic, ABT-199 (Venetoclax), which specifically targets Bcl-2, has been used as a single or combination therapy in multiple hematologic malignancies. In addition, ABT-199 has shown promise in multiple subtypes of breast cancer. Therefore, we used ABT-199 in combination with PTX to address the hypothesis that APC-induced Bcl-2 increase is responsible for PTX resistance. Combination treatment in three CRISPR-mediated APC knockout TNBC cell lines (MDA-MB-157, MDA-MB-231, and SUM159) caused changes in cell proliferation and apoptosis. Combined, these data suggest restored sensitivity to PTX using ABT-199. Our studies are the first to show that Bcl-2 inhibition can restore PTX-sensitivity in APC mutant breast cancer cells. These studies are critical to advance better treatment regimens in patients with TNBC.

B271/P1953

Investigating the Efficacy of DPI-503 Against Drug-Resistant mtBRAF-Driven Metastatic Melanoma

S. Kumar, R. K. Mehta, M. Tan, V. Krishnamoorthy, M. Nyati; Department of Radiation Oncology, University of Michigan, Ann Arbor, MI.

Malignant melanoma remains one of the fastest-growing cancers worldwide. About 99,780 new melanomas will be diagnosed in the US in 2022. While primary cutaneous melanoma can be excised via surgery, metastatic melanoma requires advanced therapies to be managed. Approximately 50 percent of metastatic melanoma patients have a mutation in the BRAF gene. The mutation of BRAF causes its persistent activation, leading to subsequent activation of downstream signaling and cancer cell phenotypes. While BRAF antagonizing therapies such as vemurafenib exist, patients acquire resistance to vemurafenib and other therapeutics via various pathways such as mutational mechanisms. Thus, a new therapeutic is required to treat drug-resistant mutant-BRAF driven metastatic melanoma. We hypothesize novel, non-PROTAC, orally bioavailable small molecule DPI-503 causes tumor cytotoxicity via EGFR ablation leading to fewer xCT and SGLT1 nutrient transporters. Consequently, the sudden decrease in essential nutrients along with increased reactive oxidative species and mitochondrial oxygen consumption rate caused by DPI-503 may cause overwhelming tumor cell cytotoxicity faster than the cell is able to adapt. The aim of this study was to investigate the mechanism by which DPI-503-induced loss of EGFR and associated nutrient transporters affect cellular metabolism and cause cytotoxicity. The aim of this study was investigated using in vitro models including several isogenic paired melanoma cell lines that showed resistance to vemurafenib (A375/A375-MEK1, M14/MDA-MB435). Cell culture

and IC50 calculations contributed greatly to preliminary in-vito results.
Preliminary results show DPI-503 having a lower IC50 in A375-MEK than vemurafenib, suggesting that DPI-503 is a more potent inhibitor of BRAF even in metastatic melanoma cell lines. Further research including tumor growth studies and PDX models will be needed to evaluate the efficacy and safety of DPI-503 in-vito.

B272/P1954

Targeting the nuclear envelope as a potent strategy to kill chemoresistant cancer

J. Chen[1], M. Wang[1], R. Huang[1], J. Chen[2,3], B. Vanslembrouck[2,3], M. LeGros[2,3], C. Larabell[2,3], T. Wang[4,5,6], I. Shih[4,5,6], Y. Chen[1,7,8]; [1]Department of Mechanical Engineering, Johns Hopkins University, Baltimore, MD, [2]Molecular Biophysics and Integrated Bioimaging, Lawrence Berkeley National Laboratory, Berkeley, CA, [3]Department of Anatomy, University of California San Francisco, San Francisco, CA, [4]Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins Medical Institutions, Baltimore, MD, [5]Department of Pathology, Johns Hopkins Medical Institutions, Baltimore, MD, [6]Department of Gynecology and Obstetrics, Johns Hopkins Medical Institutions, Baltimore, MD, [7]The Institute for NanoBioTechnology, Johns Hopkins University, Baltimore, MD, [8]Center for Cell Dynamics, Johns Hopkins University, Baltimore, MD.

Reduced expression of lamin A/C is a feature of metastatic cancer since elevated lamin A/C levels stiffen the nucleus and impede cell migration through confinements. We explored the possibility of exploiting the fact that reduced lamin A/C in metastatic cancer makes the nucleus more susceptible to mechanical damage. We investigate whether paclitaxel (PTX), a commonly used chemotherapeutic drug for many cancer types known to induce nucleus deformity, can further stress the nucleus. We observed PTX alone failed to effectively kill metastatic ovarian cancer despite inducing multi-lobular nuclei. We next examined the co-treatment of PTX and fostamatinib, a recently approved adjuvant by FDA. Co-treatment of PTX and fostamatinib at low dosage caused significant cell death (60%), while when either drug was used alone, negligible cell death was observed. Immunostaining of lamin A/C in fostamatinib-treated cells showed little change compared to control. Examination of nuclei in co-treated cells by soft X-ray tomography revealed that the multiple nuclear lobules are connected, with surface area enlarged by 82%, diluting the nuclear lamina. We also observed that 52% of PTX/fostamatinib co-treated cells have locally depleted lamin A/C, which leads to nuclear DNA leakage into cytoplasm and cell death, likely caused by the synergistic damaging effect of both drugs. Interestingly, we found this drug combination is also effective in treating carcinoma-associated fibroblasts. In summary, we demonstrated co-treatment of PTX induced multilobular nuclei with diluted nuclear lamina, prone to rupture and subsequent cell death. Our result suggests compromising the nuclear envelope integrity with two orthogonal mechanisms, lamin A/C reduction and mechanical stress by deformation, can effectively eliminate cancer cells.

B273/P1955

ZNF217 and NRG1/ErbB3 Signaling Promote Endocrine Therapy Resistance via the Ligand-Independent Activation of ER Alpha

P. Tennakoon[1], Z. Song[1], J. Wu[1], K. Carthy[1], M. Miramontes[1], R. Goyal[2], C. Suarez[1], J. Li[1], L. E. Littlepage[1]; [1]Chemistry & Biochemistry, University of Notre Dame, Notre Dame, IN, [2]Biochemistry, University of Texas, Austin, TX.

Around 70% of breast cancer tumors are estrogen receptor positive (ER+), while ~33% of these tumors eventually relapse as recurrent metastatic tumors resistant to endocrine therapies (tamoxifen, fulvestrant). We identified the oncogene and transcription factor ZNF217 (human)/Zfp217 (mouse) as an ER modulating protein that drives tamoxifen and fulvestrant resistance. To study the role of Zfp217 in tamoxifen response *in vivo*, we treated mice with PyMT ± Zfp217 tumors with tamoxifen. Vector-expressing control tumors significantly responded to tamoxifen, while tumors overexpressing Zfp217 did not. Treatment with fulvestrant gave similar results.The objective of this study was to identify the molecular mechanism of how ZNF217 causes endocrine therapy resistance. Ligand independent activation of ER by growth factor signaling pathways is a main mechanism of endocrine therapy resistance. Significantly, ZNF217 directly activates the ErbB3/AKT signaling pathway. We investigated transcriptomic and genomic changes driven by ZNF217 & ErbB3 signaling activated by neuregulin (NRG1) and how they drive tamoxifen resistance. We identified a novel prognostic ZNF217- and NRG1 (ligand of ErbB3)-dependent gene expression signature by RNA-Seq and non-canonical ER binding sites in the genome by ChIP-Seq in MCF7 cells. We also discovered ER- and NRG1-dependent ZNF217 binding sites in the MCF7 cells using CUT&RUN sequencing. These transcriptomic and genomic changes correlated with lower survival in ER+ breast cancer patients receiving tamoxifen and identified key pathways altered in a ZNF217-dependent manner after NRG1 induction. After ChIP-Seq and CUT&RUN data integration, we identified both PCK1 and PHGDH as novel inducers of tamoxifen resistance that rewire cellular metabolism. In MCF7 cells, both genes induced endocrine therapy resistance, while their deficiency made cells more susceptible to endocrine therapy. Significantly, overexpression of Pck1 in murine mammary tumors accelerated tumor burden and endocrine therapy resistance, while Pck1 knockdown made tumors susceptible to endocrine therapy. In summary, NRG1 induces a differential ZNF217-dependent gene expression signature and non-canonical ER genomic binding in ER+ breast cancer cells. Significantly, two targets, PCK1 and PHGDH, promote endocrine therapy resistance in vivo and are themselves potential therapeutic targets.

B274/P1956

Barcode-sequencing screen for modulators of anticancer ruthenium complex sensitivity in*S.cerevisiae*.

A. Chinn, P. Hanson; Furman Univserity, Greenville, SC

Phenotypes uncovered via pharmacogenomic analyses provide a viable tool for understanding the effects of diverse drugs on cellular pathways. Furthermore, these unbiased genome-wide assays can identify genes with unanticipated and/or previously unknown roles in cellular drug responses. In this study, we analyzed pools of barcoded budding yeast (*S.cerevisiae*) deletion strains to identify genes that alter sensitivity to the anticancer ruthenium complex trans-[tetrachlorobis(1H-indazole)ruthenate(III)] (KP1019). Early experimental assays featured model populations of two strains with differing KP1019 sensitivity. In these trials, we found that the commonly used approach of treating yeast immediately after thawing produced inconsistent directional selection compared to growing yeast for five

generations prior to treatment. An analysis of a full pool of barcoded yeast deletion strains was conducted using next generation sequencing, detecting 3290 unique upstream barcodes representing 63.5% of nonessential deletion strains. While no significant pathway enrichments were found, some deletion strains were far more or far less abundant in KP1019 treatment groups compared to the controls, indicating potential roles in drug sensitivity and resistance respectively. The strain lacking the evolutionarily conserved DNA repair gene *UNGI* experienced the greatest decrease (more than 22-fold) in the presence of drug. This finding is in line with previous research showing increased KP1019 potency in other DNA repair loss-of-function yeast mutants. Additionally, yeast lacking the translation regulator (*STM1*) increased in abundance nearly 10-fold in KP1019 test groups, with the most enriched mutant (*YMR254C* at a just over 10-fold increase) lacking a gene of currently unknown function. In the context of previous studies linking KP1019 treatment to increased ribosomal protein abundance in yeast, our findings provide further evidence for the putative role of ribosomes in the cellular response to the drug. While these results offer support for current models of KP1019 action and validate the screen design, future studies may uncover novel genes and pathways that modulate KP1019 bioactivity. Improved understanding of the genetic factors that alter the efficacy of KP1019 may create opportunities for genetically tailored medicines and combination therapies in the future.

Extracellular Matrix in Pancreatic and Gastric Cancer

B275/P1957

Metaplasia- and cancer-associated fibroblasts promote dysplastic progression of human stomach metaplastic cells

E. W. Contreras-Panta[1], S. Lee[2], D. Gibbs[3], Y. Won[2], J. Min[2], C. Zhang[2], S. Hong[2], J. Roland[2], L. Ferri[4], V. Sangwan[4], J. Ragoussis[4], S. Camilleri-Broët[4], J. Caruso[5], M. Strasser[3], P. Gascard[5], T. Tlsty[5], S. Huang[3], E. Choi[2], J. R. Goldenring[2]; [1]Cell and Developmental Biology, Vanderbilt University, Nashville, TN, [2]Vanderbilt University Medical Center, Nashville, TN, [3]Institute for Systems Biology, Seattle, WA, [4]McGill University, Montreal, QC, CANADA, [5]University of California, San Francisco, San Francisco, CA.

Gastric cancer remains one of the leading causes of cancer-related death in the world. Intestinal type gastric cancer in the human stomach evolves in the setting of well-defined metaplasia intermediates. Spasmolytic Polypeptide-Expressing Metaplasia (SPEM) is considered the first type of metaplasia in the stomach. Importantly, increasing evidence has shown that SPEM can progress into Intestinal Metaplasia, Dysplasia or even cancer. However, the factors promoting this progression remain unknown. Recently, fibroblasts were reported to influence carcinogenesis in different organs. However, the roles of Metaplasia-Associated Fibroblasts (MAFs) and Cancer-Associated Fibroblasts (CAFs) in stomach metaplasia progression towards advanced neoplastic stages have not been well studied. In that regard, our lab has made efforts to establish different fibroblast and gastroid lines from human stomach resections with the objective to determine the effects of MAFs and CAFs in SPEM cells from human stomach gastroids. Using Air Liquid Interface (ALI) technique, we co-cultured metaplastic gastroid cells with either MAFs or CAFs on transwell filters. Culture of gastroid cells only and co-cultured with Normal tissue Associated Fibroblasts (NAFs) were used as control. After 14 days of ALI, we observed that gastroid cells co-cultured with MAFs and CAFs showed an aggressive growth pattern by forming polyp-like structures that protruded up from the transwell filter. In contrast, gastroid cells only or co-cultured with NAFs did not cause an aggressive growth pattern. Through immunostaining, we observed the increased expression of dysplastic markers, including TROP2 and CEACAM5, and decreased expression of

metaplastic markers, including CD44v9 and AQP5, in the gastroid cells co-cultured with MAFs and CAFs. Of special interest, dysplastic markers were prominently expressed in the polyp-like structures. Moreover, after height measurements in cross-sections, we observed significantly higher heights in the MAFs and CAFs co-culture conditions. Finally, Transmission Electron Microscopy confirmed the aggressive growth pattern of epithelial cells co-cultured with MAFs, and especially with CAFs, often showing multiple lumen structures. These findings suggest that MAFs and CAFs could promote metaplasia progression into dysplasia. Further studies will determine whether a subpopulation of MAFs and CAFs are responsible for these changes.

B276/P1958

Fibrosis to Fitness: Examining the Role of Tumor Stiffness in Pancreatic Ductal Adenocarcinoma

J. M. Rosas[1], J. Campanale[2], J. L. Harwood[2], A. A. Pitenis[3], D. J. Montell[1]; [1]Biomolecular Science and Engineering, University of California, Santa Barbara, Santa Barbara, CA, [2]Molecular, Cellular, and Developmental Biology, University of California, Santa Barbara, Santa Barbara, CA, [3]Materials Engineering, University of California, Santa Barbara, Santa Barbara, CA.

Pancreatic ductal adenocarcinoma (PDAC) remains one of the most lethal forms of cancer, with a mortality rate of ~90%. A hallmark of PDAC disease progression is an oncogenic mutation in a member of the rat sarcoma virus family, K*RAS* (*KRASG12D*), arising in the epithelia of pancreatic ducts. This mutation correlates with increased fibrosis, characterized by deposition, alignment, and maturation of extracellular matrix (ECM) proteins including collagen. ECM remodeling gives rise to stiffened pancreas tissue and compromised duct structure. Prior atomic force microscopy measurements of pancreas explants report average elastic modulus values from E=1kPa (normal) to 4kPa (PDAC). However, the relationship between tissue stiffness and duct structure during disease progression remains unclear. This work employs a hydrogel platform to study lumen formation of tissue-derived pancreas organoids in 3D. This *in vitro* platform is composed of polyacrylamide hydrogels with tunable bulk mechanical properties (elastic modulus, 500 Pa<E<100kPa). Hydrogels are processed into small particles to create microgels (100±10µm diameter) with tunable rheological properties (storage modulus, 5Pa<G'<100kPa) that control the viscoelastic behavior of the microenvironment. Microgel-based environments incorporating Matrigel™ (25, 50, and 100 vol.%) enable investigation of pancreas organoid lumen formation. After 48h in 100 vol.% Matrigel™ (G'=90±5Pa), organoids derived from healthy (Normal) and KRASG12D (Tumor) genotyped mice formed lumens with similar diameters: 130±60µm and 140±90µm, respectively. In contrast, Normal organoids form lumen with decreasing diameters in microenvironments with increasing storage modulus: soft (50 vol.% Matrigel™, G'=40±10kPa, diam.: 110±50µm); stiff (25 vol.% Matrigel™, G'=65±3 kPa, diam.: 90±40µm), suggesting lumen formation is sensitive to environmental stiffness. Tumor-derived organoids do not show similar dependence on microenvironmental stiffness and form lumens with comparable diameters across 100 vol.% Matrigel™ (150±90 µm), soft (140±80µm), and stiff (150±80µm) hydrogel environments. This work demonstrates stiffness-dependence in pancreatic ductal lumen formation specific to organoids derived from healthy tissues and an insensitivity of tumor organoids to similar mechanical stresses. These results may assist in the fundamental understanding of tumor cell fitness in stiffening microenvironments.

B277/P1959

Pathophysiological Role of Golgi Apparatus in the gastric Cancer

J. Kim[1], C. Shrestha[1], S. Cho[2], M. Hwang[1], S. Kang[1], W. Kim[2]; [1]Department of Pharmacology, Department of Biomedicine & Health Sciences, The Catholic University of Korea, Seoul, KOREA, REPUBLIC OF, [2]Natural Product Research Center, KIST Gangneung Institute of Natural Products, Gangneung, KOREA, REPUBLIC OF.

Gastric cancer (GC) has a high incidence and mortality rate with a dismal 5-year survival rate due to poor prognosis in early stages. As reported, epithelial-mesenchymal transition (EMT) activation leads epithelial cells to lose its intercellular adhesions and develops migratory fibroblastic properties and promotes cell invasion, metastasis and chemo-resistance properties; however the molecular mechanisms are still unknown. Here, we show the structural and functional differences of Golgi Apparatus (the GA) between diffuse and intestinal type GC cell lines. Diffuse GC cell lines associated with EMT-subtype. Of interest, the diffuse type GC cell lines had a more compacted the GA, while the intestinal type GC cell lines had dispersed the GA. In addition, cell invasion, migration assays showed that diffuse type GC had higher migration and invasion. These results demonstrated that compactness of Golgi structure associates with metastasis, invasion and cell growth in GC.

B278/P1960

A novel role for the GEF DOCK8 as a key regulator of lysosome-mediated pancreatic cancer invasion

O. L. Gutierrez Ruiz[1], K. M. Johnson[2], E. Krueger[2], R. E. Nooren[1], N. Cruz-Reyes[1], C. J. Holtz Heppelman[3], M. Fernandez-Zapico[4], M. McNiven[2], G. Razidlo[2]; [1]Biochemistry and Molecular Biology, Mayo Clinic Graduate School of Biomedical Sciences, Rochester, MN, [2]Division of Gastroenterology & Hepatology, Mayo Clinic, Rochester, MN, [3]Mayo Clinic, Rochester, MN, [4]Division of Oncology Research, Mayo Clinic, Rochester, MN.

Metabolic reprograming and increased lysosome activity are features of pancreatic ductal adenocarcinoma (PDAC) orchestrated by the oncogene KRAS. Lysosomes serve as a signaling platform for nutrient homeostasis and confer pro-invasive abilities during metastasis. Yet, how oncogenic KRAS regulates lysosome function to potentiate tumor cell invasion remains unclear. Using comparative proteomic analysis of isolated lysosomes, we identified that oncogenic KRAS enhances the aberrant expression of DOCK8 and induces its novel recruitment to lysosomes in a subset of PDAC cells, as confirmed by fluorescence microscopy and immunoblotting. DOCK8 is a guanine nucleotide exchange factor (GEF) primarily expressed in immune cells where it mediates cell migration by activating the Rho GTPases Rac1 and Cdc42. Upon its ectopic expression in pancreatic cancer cells, we identified DOCK8 as a novel pro-invasive factor as depletion of this GEF by siRNA or knockout significantly decreases tumor cell invasion, and conversely, overexpression of DOCK8 increases invasion in a GEF dependent manner. We sought to determine how this lysosome-associated GEF contributes to invasive migration. While DOCK8 does not regulate global lysosome function, it does selectively impact lysosome size, motility, and specific proteolytic capacity. Interestingly, we observed that DOCK8 is required to stimulate the actin nucleation machinery at the lysosome surface where it drives actin-mediated lysosomal propulsion, thereby regulating lysosomal trafficking velocity. Furthermore, we found that depletion of DOCK8 markedly reduces lysosome-dependent degradation of the extracellular matrix due to significantly reduced levels and activity of the lysosome-associated protease Cathepsin B, which has been described to support tumor cell invasion. Importantly, this degradation defect can be restored by

re-expression of Cathepsin B. In summary, we have identified the GEF DOCK8 as a key pro-invasive factor that is aberrantly expressed in a subset of pancreatic cancers and describe a novel mechanism by which DOCK8 regulates actin polymerization at lysosome membranes to promote their motility and proteolytic capacity to mediate KRAS-driven pancreatic cancer invasion.

B279/P1961

Bioinformatic analyses reveal a novel role for Ang-Tie2 signaling in pancreatic cancer-associated fibroblasts

J. C. Gardiner, E. Cukierman; Fox Chase Cancer Center, Philadelphia, PA

Pancreatic cancer (PC) is a devastating disease with a five-year survival rate of ~11%. Its aggressiveness is largely mediated by the expansive tumor microenvironment that includes cancer-associated fibroblasts (CAFs) and the dense extracellular matrix (ECM) they produce. Recent work from our lab indicated that the synaptic neuronal protein, Netrin G1 (NetG1), is pathologically upregulated in pancreatic CAFs and its loss alters the fibroblasts' ability to perform tumor supportive functions (*e.g.* inflammatory cytokine secretion). Additionally, tissue microarray analysis showed that PC patients expressing higher levels of NetG1 in fibroblasts had poorer overall survival than patients with lower NetG1 expression, suggesting that NetG1 may demarcate tumor-supporting CAFs. Thus, the goal of this project is to determine whether comparisons of NetG1 high and low expressing CAFs could elucidate other novel regulators of CAF pro-tumor function. Using publicly available transcriptomics data of PC patient-matched normal fibroblasts and CAFs, CAFs were first stratified into NetG1^{low} or NetG1^{high} expressing cohorts to identify differentially expressed genes (DEG). Network and computational analysis revealed a core signature comprising 67 genes represented in 16 clusters from the initial 530 DEG input list. Interestingly, the largest cluster was enriched for "Tie2 Signaling", which is typically associated with angiogenesis and endothelial cell function but not with PC due to the blood vessel collapse that arises from the dense ECM. Western blot analysis demonstrated that our patient-derived pancreatic CAFs amply express Tie2 whose activity (denoted by phosphorylation) increases upon stimulation with the angiopoietin (Ang) ligands. Moreover, Ang stimulation of Tie2 decreased CAF interleukin-6 and interleukin-8 secretion while small molecule inhibition increased cytokine secretion. Collectively, these data suggest that Ang/Tie2-mediated signaling can influence CAF pro-tumorigenic functions and may provide a novel target to normalize the tumor-enabling microenvironment in patients.

B280/P1962

The effect of Hippo pathway dysregulation on *Helicobacter pylori*-mediated gastric cancer

B. Yu[1], S. Lee[1], B. Hwang[1], H. Jeong[2], K. Nam[2], Y. Lee[1]; [1]Department of Internal Medicine, Yonsei University College of Medicine, seoul, KOREA, REPUBLIC OF, [2]Severance Biomedical Science Institute and Brain Korea 21 PLUS Project for Medical Science, Yonsei University College of Medicine, seoul, KOREA, REPUBLIC OF.

BACKGROUND: *Helicobacter pylori* is known to activate chronic pre-inflammatory signal pathways in gastric epithelial cells, may participate in gastric carcinogenesis. Hippo pathway dysregulation is known to play an important role in the prognosis of cancer progression and metastasis. However, the role of YAP/TAZ, a major gene in the Hippo pathway in *H. pylori*-mediated gastric cancer is not well understood. The purpose of this study was to investigate the role of Hippo pathway in the gastric carcinogenesis following chronic infection with *H.pylori* based on clinical/molecular/histological observations. **Materials**

and Methods: Clinically derived gastric organoids, human gastric epithelial cell lines (AGS, MKN74, GES-1), *H. pylori* strains Hp 60190 (CagA (+) and CagA (-)) were used. We evaluated the effects of YAP/TAZ on inflammatory response, EMT, invasion and gastric cancer-associated tumorigenic properties using not only *H. pylori*-infected gastric epithelial cell lines, but also human gastric organoids with excellent physiological similarity. Organoids were cultured long-term in media containing various growth factors. Gastric cancer mice were established, and EMT gene analysis was performed using WB, PCR and IHC. Electron microscopy images and TEER were measured in infected 2D organoids. **RESULTS:** Gastric organoids contained various types of normal gastrointestinal cells and showed major characteristics of gastric mucosa such as MUC5AC, MUC6, and LGR5. Mucosal surfaces secreted mucus that could overcome a few bacteria. *H. pylori* infection caused inflammation lasting more than 72 hours, and IL-8 , an inflammatory mediator, was overexpressed in CagA positive strains. It was confirmed that *H. pylori* infection induces overexpression and nucleus translocation of YAP/TAZ, which converts gastric epithelial cells into mesenchymal cells. YAP/TAZ overexpression was significantly correlated with the junction protein ZO-1, suggesting an important role in gastric cancer progression. *H. pylori* attachment reduced expression of the junctional proteins (E-cadherin, Zo-1). We confirmed that *H. pylori* preferentially attaches to the gap between cells in order to reach the parietal cell located at the base of the upper gland via EM image. **CONCLUSION:** *H. pylori* infection accelerates gastric carcinogenesis by inducing persistent inflammation, loss of junction protein, through Hippo pathway dysregulation. This disrupts the normal morphology of cells and induces migration, invasion and EMT processes. Our findings help to understand the regulatory circuits of inflammation, defense, and gastric carcinogenesis in the interactions between *H. pylori* and the epithelial surface.

B281/P1963

Hyaluronic acid and glycosylation regulate pancreatic cancer cells glycocalyx/actin cortex architectures and mechanical properties

A. Massey; National Institutes of Health, Bethesda, MD

Pancreatic cancer is currently one of the most lethal malignancies worldwide; this is principally due to difficulty with early detection and poor response rates to conventional chemotherapeutics. One of the reasons behind this is the glycocalyx - a dense, brush-like layer covering cells. Normally, this structure normally acts as a protective barrier. In cancer however, various components of the glycocalyx are either upregulated or aberrantly glycosylated which can enhance tumor progression through factors such as immune evasion, metastasis, and drug resistance. Although these effects are understood biochemically, less is known about how the glycocalyx affects cancer cells at a biophysical level. In this study, we investigated the biophysical effects of glycocalyx architectural modulation in pancreatic cancer cells via atomic force microscopy and confocal imaging. Our preliminary results show a distinct architectural change in the glycocalyx with hyaluronic acid perturbations via hyaluronidase and aggrecan treatments, as well as with a perturbation of the glycosylation status with PNGase- and neuraminidase-induced enzymatic degradation. Both types of perturbations led to significant changes in the stiffness of normal and cancerous cells, with a differential trend noted between normal and cancerous cells. Changes to both the glycocalyx and actin cytoskeleton structure were observed with these treatments, suggesting that modulations to the glycocalyx directly impact the underlying actin cortex. Future studies will examine how the modulation of different transmembrane proteins affect cellular mechanics and the overall structure of the glycocalyx.

Limitless replicative potential is a defining capability of cancer. Telomere maintenance in cancer cells typically depends on reactivation of telomerase expression to allow somatic cells to bypass replicative senescence. *TERT,* the reverse transcriptase component of telomerase, promoter mutations have been found ~75% of melanoma and create *de novo* E-twenty six (ETS) transcription factor binding motifs which function to increase *TERT* expression. *TERT* promoter mutation acquisition alone extends the proliferative capacity of cells but cannot prevent bulk telomere shortening and additional somatic changes are therefore required for full immortalization. Here, we identified a cluster of variants in 5' region of *ACD* gene encoding TPP1. TPP1 is a component of the shelterin complex and functions in both telomerase recruitment and repeat addition processivity. The two most common re-occurring variants in *TPP1* promoter create or modify ETS binding sites and increase *TPP1* expression similar to *TERT* promoter mutations. TPP1 over-expression has a synergistic effect with increased TERT expression on telomere lengthening in primary BJ fibroblasts. We engineered the two most frequent *TPP1* promoter variants into human melanoma cell lines using CRISPR/Cas9-mediated genome editing. Introduction of the *TPP1* promoter variants at the endogenous locus led to increased *TPP1* gene expression compared to the parental cell lines. Analysis of whole genome sequencing of melanoma suggests that ~5% of cutaneous melanoma have both *TERT* promoter mutations and *TPP1* promoter variants. Our findings suggest that *TPP1* promoter variants cooperate with *TERT* promoter mutations to enhance telomere maintenance and immortalization in melanoma.

ARID1A loss leads to enhancement of genomic instability by epigenetic dysregulation in aggressive Osteosarcoma

K. Fatema[1], Y. Wang[2], S. Plyler[1], A. Pavek[1], K. Jones[3], J. Barrott[1]; [1]Department of Biomedical and Pharmaceutical Sciences, Idaho State University, Pocatello, ID, [2]Huntsman Cancer Institute, University of Utah, SLC, UT, [3]Huntsman Cancer institute, University of Utah, SLC, UT.

Osteosarcoma is the most common pediatric malignant bone tumor in the USA. Genetically it is the most complex cancer and is associated with quick progression towards metastasis, for which there are limited targeted therapies. Genetic mutations to use as biomarkers are muddied by the complex genomic instability existing at baseline in most osteosarcomas. Moreover, a significant drop in survival occurs because of our lack of differentiating between responders and non-responders to conventional chemotherapies early in the treatment regimen.With the purpose of understanding the molecular mechanisms associated with chemoresistance and metastasis, we identified an epigenetic modifier, ARID1A, to be responsible for a more aggressive osteosarcomagenesis in a forward genetic screen. Arid1a is a member of an epigenetic chromatin remodeling complex, SWI/SNF, and has been implicated in the progression and worse prognosis of other cancers. We studied Arid1a deletion in genetically engineered mouse models as well as human osteosarcoma cell lines to evaluate its impact. Furthermore, upon loss of Arid1a, genomic instability was enhanced, which we predict can serve as a biomarker for chemosensitivity. Gene expression analysis and ATAC-seq data further implicate disruption of DNA repair pathways upon deletion of Arid1a. Arid1a resulted in a general trend of chromatin compaction, which we posit results in the negative regulation of important tumor suppressor genes. Using ClaraT bioinformatics tools to highlight the involvement of specific hallmarks of cancer, it was determined that genomic instability and EMT-related pathways were enhanced in the Arid1a knockout models. This is consistent with our gross phenotypic analysis of our mice that exhibited more tumors per mouse and more metastatic tumors in the Arid1a knockout mice. Not only that, but the most recent implementation of Nanopore sequencing also provided convincing evidence toward genomic instability to be a precursor to aggressiveness in osteosarcoma.In conclusion, the loss of Arid1a in osteosarcoma enhances the aggressive and metastatic phenotype, correlating to decreased chemosensitivity. Efforts to better understand the intersection between genomic instability and epigenetic dysregulation can lead to earlier decision-making to pursue alternative and sometimes experimental therapies.

Non-secretory alpha1-antitrypsin isoform produced from _SERPINA1_ long transcripts

A. A. Maslakova[1], S. A. Golyshev[2], D. M. Potashnikova[1], A. M. Moisenovich[1], I. V. Orlovsky[3], M. A. Rubtsov[1], O. V. Smirnova[1]; [1]Faculty of Biology, M.V. Lomonosov Moscow State University, Moscow, RUSSIAN FEDERATION, [2]A.N. Belozersky Institute of Physical and Chemical biology, M.V. Lomonosov Moscow State University, Moscow, RUSSIAN FEDERATION, [3]Unaffiliated, Moscow, RUSSIAN FEDERATION.

SERPINA1 gene encodes an archetypical serpin (serine protease inhibitor) - alpha1-antitrypsin (AAT). There are a number of *SERPINA1* long transcripts containing *SERPINA1* main ORF, which are believed to give rise to the same protein of 418 a.a.r. After processing by a secretory machinery, glycosylated mature 394 a.a.r. AAT exits the cell to protect the body from excessive proteolysis. Besides its

extracellular activity, it is now established that AAT may act inside the cells, either exogenously added or endogenously produced. In the first case, it inhibits non-target proteases such as caspases protecting lung endothelial cells from apoptosis [Petrache I. et al., 2006]. In the latter case, an intracellular AAT protects cancer cells from autophagic cell death [Shapira M.G. et al., 2014]. Here we hypothesized that intracellular AAT can be produced by alternative translation from long *SERPINA1* transcripts. We defined DU145 (prostate)- and HepG2 (liver)-specific *SERPINA1* long transcripts by 5'-RACE and individually probed their translation in living cells by fusing with eGFP. Western blot analysis of cell lysates and secretomes showed that a non-secretory isoform is translated from individual long transcript alongside with the secretory antitrypsin. The rate of the main ORF translation (a secretory AAT production) inversely depends on the length of the transcript's 5'-UTR, which confirms the earlier data on the predicted negative regulation of translation by uORFs [Corley M., 2017]. Unlike the "main" protein product, non-secretory isoform is produced at the nearly same rate from all long transcripts. Although intracellular AAT would be advantageous for tumor cells, it is unclear whether alternative *SERPINA1* translation is a phenomenon of cellular transformation or a normal cellular process. We believe that alternative splicing of *SERPINA1* pre-mRNA is the cellular mechanism to regulate the balance between secretory and intracellular antitrypsin. This work was supported by RFBR project (№16-34-01095 mol_a), Scientific Project of the State Order of the Government of Russian Federation to Lomonosov Moscow State University (№121032300075-6) and the Interdisciplinary Scientific and Educational School of Moscow University «Molecular Technologies of the Living Systems and Synthetic Biology». Part of this study was performed using equipment obtained under MSU Program of Development (BD FACSAria SORP cell sorter).

The RNA binding domains 3 and 4 of Nucleolin are predicted to be drivers of nucleolin -miRNA interactions

A. San[1,2], D. Palmieri[3], A. Saxena[1,2,4], **S. Singh**[1,2,4]; [1]Biology, Brooklyn College, CUNY, Brooklyn, NY, [2]The Biochemistry PhD Program, The Graduate Center of the City University of New York, New York, NY, [3]Department of Cancer Biology and Genetics, The Ohio State University Wexner Medical Center, Columbus, OH, [4]The Biology PhD program, The Graduate Center of the City University of New York, New York, NY.

RNA binding proteins (RBPs) regulate many important cellular processes through their interactions with RNA molecules. RBPs are critical for posttranscriptional mechanisms keeping gene regulation in a fine equilibrium, the dysregulation of which is an established hallmark of tumorigenesis. Human nucleolin (NCL) is a multifunctional RBP that interacts with different types of RNA molecules, in part through its four RNA binding domains (RBDs). Particularly, NCL interacts directly with microRNAs (miRNAs) and is involved in their aberrant processing linked with many cancers, including breast cancer. However, the molecular details of the NCL-miRNA interaction remain obscure. In this study, we used an *in silico* approach to characterize the molecular details as to how NCL targets miRNAs. Here, we present structural models of NCL-RBDs and miRNAs, as well as predict scenarios of NCL-miRNA interactions generated using docking algorithms. Our study suggests a predominant role of NCL RBDs 3 and 4 (RBD3-4) in miRNA binding. We provide detailed analyses of specific motifs/residues at the NCL-substrate interface in both these RBDs and miRNAs. Finally, we propose that the evolutionary emergence of more than two RBDs in NCL in higher organisms coincides with its additional role/s in miRNA processing. Our study shows that RBD3-4 display sequence/structural determinants to specifically recognize miRNA

precursor molecules. The insights from this study can ultimately support the design of novel antineoplastic drugs aimed at regulating NCL-dependent biological pathways with a causal role in tumorigenesis.

A genome-wide screen for USP28-dependent control of cell proliferation reveals genes important for mitotic progression and p53 regulation

B. E. Mierzwa[1,2], F. Meitinger[1,2,3], A. Desai[1,2], K. Oegema[1,2]; [1]Ludwig Institute for Cancer Research, La Jolla, CA, [2]University of California San Diego, La Jolla, CA, [3]Okinawa Institute of Science and Technology, Onna, JAPAN.

The deubiquitinase USP28 is a tumor suppressor and an essential component of a recently identified pathway called the mitotic stopwatch that monitors mitotic duration to suppress the proliferation of cells produced after prolonged mitosis. When mitotic duration surpasses ~3X its normal length, the stopwatch stabilizes p53 in the resulting daughter cells, leading to cell cycle arrest or death. To better understand the pathways that control mitotic duration, how USP28 controls daughter cell progression through G1, and whether USP28 interfaces with other cellular pathways, we performed a genome-wide CRISPR/Cas9 screen in the p53-positive cell line RPE1 to identify genes whose knockout leads to an acute differential effect on proliferation in the presence or absence of USP28. In this screen, USP28 WT and USP28(-/-) RPE1 cells were transduced with a pooled lentiviral CRISPR sgRNA library, Cas9 expression was induced, and samples were taken at timepoints between 0 and 14 days after induction to monitor the dropout kinetics of gRNAs corresponding to each gene. Genes whose gRNAs dropped out with different kinetics in USP28(-/-) and USP28 WT were identified. Genes required for mitotic progression were expected to drop out more slowly in USP28(-/-) cells, which lack a functional mitotic stopwatch. Indeed, in a ranked list of essential genes whose knockouts dropped out with slower kinetics in USP28(-/-) compared to USP28 WT, 55 of the top 130 genes had been previously implicated in mitotic pathways, such as spindle assembly, kinetochore and centrosome function, and promotion of mitotic exit. In a live imaging-based secondary screen, we have so far directly monitored mitotic timing for 72 of the top 100 genes, of which 46 exhibited mitotic delays. Notably, a number of the high-confidence essential genes that dropped out more slowly in USP28(-/-) did not regulate mitotic progression. Among these is a group of about 10 genes that appear to be negative regulators of the p53 pathway. We are currently investigating how modest p53 elevation could differentially suppress the growth of USP28 WT cells. Motivated by the frequent loss of USP28 in cancer, we are also characterizing genes whose gRNAs drop out more rapidly in USP28(-/-) compared to USP28 WT cells, which is leading us to identify pathways whose inhibition is synthetically lethal with loss of USP28.

B287/P1969

Uncovering Dynamics of p53 Using Cryo-EM Models

M. J. Solares[1], G. Jonaid[1], D. F. Kelly[2]; [1]Huck Institutes of Life Sciences, Penn State University, University Park, PA, [2]Biomedical Engineering, Penn State University, University Park, PA.

In the war against cancer, we have discovered the most deregulated protein in all cancer: tumor suppressor TP53 (p53). Found implicated in half of all cancer cases, plays a pivotal role in cell pathways ranging from DNA repair, cell cycle arrest, and apoptosis. Unfortunately, little structural information is available. The N-terminal domain (NTD) and C-terminal domain (CTD) are unable to be resolved due to

their flexible and disordered nature. These regions hold key regulatory roles and the source of many conflicting theories behind the mechanisms of action. There is an immense need for full, length p53 structures from cancer cells. We have overcome limitations to traditional cryo-electron microscopy (EM) techniques by adapting material science and biochemical knowledge to resolve the first full-length p53 monomer and dimer. First, we extracted and enriched p53 oligomers from a glioblastoma cells (U87MG) to preserve disease-related modifications. Second, we have replaced conventional copper grids with silicon nitride-based microprocessor chips (microchips) which are known for their pristine flat surfaces and reliable ability to perform well under extreme conditions. Microchips were functionalized with an added layer of nickel-NTA to increase capture of p53 in appropriate ice thickness. Finally, we have adapted new flexible model fitting techniques with ISOLDE and PHENIX software packages to create biologically *and* energetically relevant ribbon structures to verify our reconstructions. Our full length model of p53 monomers helped inform the dimer reconstruction (~4.2 Å). Interestingly, there was no density available that would correspond to DNA leading us to believe that we had resolved an "inactive state" dimer. By observing the interface of inactive p53 dimer and comparing it to an active or DNA-bound dimer, we were able to identify the residues that could mediate the protein-protein interaction. There are potential residues that may be ubiquitinated to block MDM2 binding, a well-known regulatory partner, to sequester p53 in the cell or acetylated to initiate apoptotic pathways. Further, several "hot spot" mutations fall within or are adjacent to this interface region, which may be a key therapeutic target in the future. With these insights, we were able to reconstruct a possible model to explain the conformational changes p53 dimers follow as they transition from an inactive to an active DNA-binding state. This wealth of information can help aid in deciphering several mysteries behind p53. We have allowed previously incomplete models to guide diagnosis and treatments, which has allowed the emergence of competing theories behind a mechanism of action. By starting to pinpoint real mechanisms of action of p53, we can help shape the future of oncological research.

Identifying Golgi glycosyltransferase *B4GALT1* as a p53-responsive gene in lung cancer

S. Bui, D. Stark, A. Houmani, Y. Wang; Molecular Cell and Developmental Biology, University of Michigan, Ann Arbor, MI.

Aberrant glycosylation, a well-recognized cancer hallmark, plays an essential role in tumor initiation and progression via cell adhesion, cell-cell recognition, intracellular signaling, and ECM interactions. Although cancer-associated glycan antigens have been identified across cancer glycomes, a group of antigens was recently reported as a result of incomplete galactose-capping on GlcNAc residues. Galactosylation is performed by a set of β-1,4-galactosyltransferases (B4GALTs), with B4GALT1 as the major isoenzyme for this reaction. However, the potential regulation network of the B4GALT1 and its significance in cancer remains to be determined. Expression of B4GALT1 in lung cancer was identified in Human Protein Atlas and Oncomine. Survival analyses were performed with Kaplan-Meier plotter. Human lung cancer cell lines of varying tumor protein p53 (p53) statuses were treated with cisplatin and cycloheximide then characterized through qPCR and Western blot. Lectin-binding was used to detect cell surface galactosylation using high resolution microscopy. Functional assays to assess migration and cell adhesion/spreading were conducted in WT & p53 knock-out A549. After bioinformatic analysis of putative p53-binding domains in the B4GALT1 promoter, these regions were cloned into a Luciferase reporter and tested. Bioinformatic analysis identified a significant correlation with reduced expression of B4GALT1 and p53; interestingly, this was associated with poor prognosis in lung cancer patients.

Depleting p53 markedly reduced B4GALT1 at both the mRNA and protein levels. Meanwhile, pharmacological induction of p53 stimulates expression of the Golgi enzyme, and augments the level of β1,4-galactosylation. Systematic screening of 13 alternative promoters in the BGALT1 locus and the canonical promoter upstream of the transcription start site, revealed four possible p53-consensus binding sites. Furthermore, p53-mediated down-regulation of B4GALT1 reduced galactosylation levels of intracellular and cell surface proteins, and consequently decreased cell adhesion/spreading and enhanced cell migration. Restoring B4GALT1 in p53-deficient cells phenocopied p53 wildtype cells in functional assays. The positive correlation between p53 and B4GALT1 was confirmed in 10 different cancer cell lines, suggesting a clinically relevant role for this protein in tumorigenesis. Thus, our study reveals B4GALT1 is a target of p53 and provides a genetic and biochemical mechanism leading to glycosylation aberrations potentially related to carcinogenesis. Together these data suggests an exciting avenue for developing new therapeutic strategies in cancers with p53-deficiency which may leverage cell surface glycosylation and specifically use B4GALT1 as a biomarker.

Cell cycle arrest mediated by endoplasmic reticulum-resident transcription factor OASIS suppresses glioblastoma development.

A. Saito, Y. Kamikawa, T. Ito, K. Imaizumi; Institute of Biomedical & Health Sciences, Hiroshima University, Hiroshima City, Japan

Cells survey the internal and external conditions to determine to progress or stop cell cycle for the maintenance of the DNA accuracy. DNA damages caused by the various insults such as double strand break and incomplete replication induce cell cycle arrest and its repair. Old Astrocyte Specifically Induced Substance (OASIS) is an endoplasmic reticulum (ER)-resident transmembrane transcription factor. OASIS is cleaved in response to ER stress by regulated intramembrane proteolysis (RIP), subsequently generating the N-terminal fragments containing a basic leucine zipper (bZIP)-type DNA binding domain, which act as a transcription factor. Our previous studies have demonstrated that OASIS is preferentially expressed in specific cells including astrocytes and osteoblasts to regulate their differentiations. Additionally, OASIS is upregulated in long-term-cultured astrocytes undergoing cell cycle arrest due to loss of DNA integrity by repeated replication. However, the roles of OASIS in cell cycle have not been explored. We found that OASIS arrests cell cycle of astrocytes at G2/M phase after DNA damage via direct induction of p21. Although p21 is known as a direct target of p53, the cell cycle arrest by OASIS-21 axis does not have any crosstalk with p53-p21 signaling pathway. In a brain injury model, *Oasis*-/- reactive astrocytes surrounding the lesion core showed the sustained growth and the inhibited cell cycle arrest, resulting in prolonged gliosis. Intriguingly, a definite number of glioma and glioblastoma patients was included in the category featuring quite low expression level of OASIS due to DNA methylation in its promoter. The several number of glioblastoma cell lines also showed the low expression level of OASIS accompanied by hypermethylation of its promoter. Specific removal of this hypermethylation in glioblastoma transplanted to nude mice by epigenomic engineering suppressed its tumorigenesis. Taken together, OASIS is novel cell cycle inhibitor of astrocytes, and has potential to act as tumor suppressor for glioblastoma. The discovery of key molecule linking with the glioblastoma suppression contributes to elucidate the precise mechanisms for the glioblastoma development, that may lead to the novel therapeutic approaches targeting OASIS.

Penta-O-galloyl-β-D-glucose (PGG) targets aggressive androgen independent prostate cancer by ROR1 inhibition

V. Sivaganesh, A. Iskander, T. Ta, B. Peethambaran; Saint Joseph's University, Philadelphia, PA

Late stage prostate cancer is a debilitating form of cancer due to its ability to progress aggressively despite androgen deprivation therapy (ADT). Though prostate cancer initially responds to ADT, late stage prostate cancer can survive by activating a myriad of oncogenic signaling cascades that are independent of the androgen signaling axis. Therefore, we must continue to explore prostate cancer associated markers that have potential for targeted therapy, such as the Receptor Tyrosine Kinase Like Orphan Receptor 1 (ROR1). Furthermore, plant-derived compounds may serve as an abundant resource for targeted therapeutics. In this study, we explore the mechanism of ROR1 inhibition by a plant-derived gallotannin Penta-O-galloyl-β-D-glucose (PGG), which mitigates oncogenic signaling cascades and suppresses aggressive prostate cancer phenotypes. Results suggest that ROR1 was highly expressed in the androgen receptor negative, androgen-independent (ARneg-AI) PC3 cell line. Hence, PGG exhibited greater cytotoxic and apoptotic activity in PC3 (IC50 of 31.64 μM) in comparison to normal prostate epithelium RWPE-1 (IC50 of 74.55 μM). PGG inhibited ROR1 and downstream oncogenic signaling, which was corroborated by diminished migration and invasion of PC3 cells upon PGG treatment. PGG was also able to suppress migration and invasion of ARneg-AI DU145, which exhibited moderate levels of ROR1 in comparison to PC3. Throughout the study, PGG minimally affected RWPE-1. These results suggest that PGG, via the inhibition of ROR1, enables the selective targeting of aggressive ROR1-expressing prostate cancers. Furthermore, this study provides insight into how ROR1 drives oncogenesis in ARneg-AI prostate cancer.

B291/P1973

Reassessing cobalamin requirements for cell culture

D. J. Elzi, R. Jacob, V. I. Rebel; bioAffinity Technologies, San Antonio, TX

Cobalamin (Vitamin B12) is an essential co-factor for the synthesis of components required for cell growth and maintenance. Cobalamin is important for one-carbon metabolism which is involved with genome methylation and nucleotide synthesis. Cancer cells have increased metabolism, and we hypothesized that their proliferation would be negatively affected if grown in cobalamin-deficient medium. To test this, we grew cells in defined serum-free medium (SFM) with or without cobalamin. The cobalamin concentration used in these cultures was 1.65×10^{-11} M, similar to that contained in a 10% FBS solution. The serum-free media was based on either DMEM (DMEM-SFM) or MEM (MEM-SFM), to which defined growth factors, amino acids, and lipids were added. Neither DMEM-SFM or MEM-SFM had detectable cobalamin as measured by ELISA, which had a detection limit of 5.38×10^{-11} M cobalamin. Reagents required to propagate cells other than the SFM all tested negative for cobalamin by the same ELSA. We adapted cancer cell lines from lung (H460), breast (MDA-MB-231), prostate (PC3, DU145), and brain (U251) tumors to DMEM-SFM, and two Burkitt lymphoma cell lines (NAMALWA and RAJI) to MEM-SFM. We found that except for PC3 and the Burkitt lymphoma cell lines, all other cell lines required an extracellular matrix when cultured under serum-free conditions. We were unable to identify a cobalamin-free source of extracellular matrix (they contained at least 7.37×10^{-11} M cobalamin) and focused therefore on those cells which did not require it. PC3 cells grew similarly in DMEM-SFM with or without cobalamin, as measured by cell confluency. Nine-week growth curves of NAMALWA cells, as

calculated by population doubling, were also similar in both media, while RAJI cells formed tight clusters in both media which we were unfortunately unable to reliably quantify. These findings suggest that cancer cells may require far less cobalamin (10^{-11} M or less) for cell growth than currently recommended (10^{-9} M or higher). Studies aimed at understanding the physiological role of cobalamin in cellular functions should therefore reconsider the routine usage of cobalamin supplementation if cell cultures are used.

B292/P1974

Mad1 upregulation in breast cancer: causes and consequences

S. E. Copeland, J. Wan, A. Roopra, B. A. Weaver; UW-Madison, Madison, WI

Mitotic arrest deficient-1 (Mad1), an essential component of the mitotic checkpoint, is upregulated in 20% of breast cancer patients. Upregulation of Mad1 causes destabilization of the p53 tumor suppressor as well as chromosome missegregation during mitosis. Patients with high levels of Mad1 mRNA expression have a poorer prognosis than patients with intermediate or low levels of Mad1, and Mad1 upregulation is sufficient for transformation and promotion of orthotopic tumor growth in immunocompromised animals. Unlike many kinetochore proteins, Mad1 is not transcriptionally regulated by the transcription factor FoxM1. Thus, the mechanism for upregulating Mad1 in cancer, as well as the functional consequences in the context of an intact immune system, remain unknown. Bioinformatics analysis identified Histone Deacetylase 1 (HDAC1) as a likely cofactor involved in Mad1 transcriptional regulation. Consistent with this, HDAC inhibition with Trichostatin A (TSA) or Valproic Acid (VPA) increases Mad1 mRNA and protein levels 5- to 10-fold in multiple breast cancer cell lines. HDAC inhibition also induces Mad1 nuclear puncta, a localization pattern seen in primary breast cancer and breast cancer cell lines following Mad1 upregulation. To identify which transcription factor targets HDAC1 to the Mad1 promoter, we developed a Mad1 promoter reporter assay, which has identified a repressive region of the Mad1 promoter. Ongoing work will identify the transcription factor(s) responsible for negative regulation of Mad1. To determine the consequences of Mad1 upregulation, we have generated a tetracycline (tet)-inducible Mad1 mouse model by inserting a tet responsive promoter and HA tag before the first coding exon of the Mad1 gene. Mice containing one allele of tet-inducible Mad1 and two alleles of a ubiquitously expressed reverse tet-transactivator (rtTA-M2) show inducible expression of HA-Mad1 following one week or one month of exposure to the tet analog doxycycline. HA-Mad1 expression results in decreased p53 levels and increased mitotic defects in colon. We are currently testing whether Mad1 upregulation promotes colon tumor initiation or progression in the context of inflammation. To determine whether Mad1 upregulation plays a causal role in breast cancer, we are generating HA-Mad1 mice that express the tet-transactivator under control of a mammary-specific promoter (MMTV-tTA). Ongoing experiments will determine whether upregulation of Mad1 is sufficient to induce tumorigenesis in the presence of an intact immune system.

B293/P1975

Investigating the chromatin architecture of telomeres in high-risk neuroblastoma

C. Gilmore; St. Jude Children's Research Hospital, Memphis, TN

Neuroblastoma is a devastating pediatric solid tumor affecting about 800 children in the US each year. It has been established that risk-stratification of neuroblastoma can be distinguished based on telomere maintenance mechanisms. Typically, telomeres shorten with every cell division until they reach a

threshold length that causes a cell to undergo p53-mediated senescence. Cancer cells, including those in high-risk neuroblastoma, bypass senescence by lengthening their telomeres to enable replicative immortality. There are two known ways in which cancer cells can lengthen their telomeres: reactivation of telomerase, which is transcriptionally silenced in somatic cells, or through a homologous recombination-based method, alternative lengthening of telomeres (ALT). Genetic aberrations in two genes associated with telomere maintenance mechanisms are indicators of high-risk disease in neuroblastoma patients, and interestingly these two mutations are never seen in the same tumor. Mutations in the chromatin remodeling protein ATRX are associated with ALT while *MYCN* amplification, the number one indicator of high-risk disease, is associated with the upregulation of telomerase. However, the role of *ATRX* mutations in ALT remains poorly understood. We hypothesize that ALT+ tumors have an altered chromatin architecture at telomeres that allow for a cell to be permissive to homologous recombination at telomeres. To investigate the chromatin architecture at individual telomeres, we have used lattice lightsheet microscopy to determine the association of individual telomeres with chromatin marks HP1 and H3.3. Further, we have used correlative light electron microscopy to determine the compaction of chromatin at telomeres in the high resolution to determine if telomeres in ALT+ versus telomerase+ cells localize differently to euchromatin or heterochromatin. These methods will provide individual telomere resolution of chromatin architecture, which has been highly debated in normal cells and cells using telomerase or ALT. ALT is extremely heterogenous, varying drastically from cell-to-cell and telomere-to-telomere and thus the ability to interrogate the nuclear organization of telomeres at the single telomere level will provide insight not achievable with most standard methods. Telomere maintenance is an important yet not fully understood aspect of tumor biology and clearly plays a role in high-risk neuroblastomas. These mechanisms could be a target for therapeutics because of their unique and essential role in cancer cells. These studies will ultimately help address why certain cells undergo one telomere maintenance mechanism over the other and help elucidate the role of mutations in chromatin remodeling protein ATRX in high-risk ALT+ tumors.

Epigenetics and Chromatin Remodeling

B295/P1976

Examining roles for the Mi-2 chromatin re-modeler in cell cycle exit

E. Buchert, Y. Ma, L. Buttitta; University of Michigan, Ann Arbor, MI.

Precise coordination of the cell cycle and differentiation is crucial to proper organ development. Upon terminal differentiation, many cells will exit from the cell cycle altogether and transition to a postmitotic state. We have investigated how cell cycle genes are robustly silenced at cell cycle exit using *Drosophila melanogaster* and have uncovered changes in chromatin accessibility at enhancers of specific cell cycle genes that are rate-limiting for cell cycle progression. Importantly, we find that the closing of these enhancers is developmentally controlled and not influenced directly by the cell cycle, suggesting the differentiation process acts in part through chromatin remodeling to coordinate cell cycle exit with terminal differentiation. We hypothesize that closing of chromatin at rate-limiting cell cycle genes contributes to the robustness of cell cycle exit in terminally differentiated cells. To identify the remodelers involved, we performed a genetic screen and identified Mi-2, a member of the NuRD complex, as a candidate involved in chromatin closing at cell cycle exit. To investigate the localization of Mi-2, we developed a modified CUT&RUN protocol, that works on terminally differentiated *Drosophila* tissues, which are often encased in cuticle. We have confirmed that this protocol can also be used with

ATAC-seq, to examine chromatin accessibility changes in cuticle-bound tissues. In addition, we have validated a functional, endogenously tagged Mi-2 that we will use to study Mi-2 localization on the genome during terminal differentiation. These custom tools and protocols provide us with the opportunity to study how Mi-2 function affects chromatin accessibility during terminal differentiation and determine where Mi-2 is binding in the genome at cell cycle exit.

B296/P1977

Regulation of the chromatin landscape and gene expression through the microbiota

L. A. Gates[1], B. S. Reis[2], P. J. Lund[3], M. Leboeuf[1], M. Paul[4], T. S. Carroll[4], B. A. Garcia[3], D. Mucida[2], C. Allis[1]; [1]Laboratory of Chromatin Biology & Epigenetics, The Rockefeller University, New York, NY, [2]Laboratory of Mucosal Immunology, The Rockefeller University, New York, NY, [3]Department of Biochemistry and Molecular Biophysics, Washington University School of Medicine, St. Louis, MO, [4]Bioinformatics Resource Center, The Rockefeller University, New York, NY.

While the microbiota has key roles in physiology and human health, understanding the mechanistic basis of how the microbiota regulates cellular processes in the context of a complex tissue system remains a major challenge. The commensal microbiota in the mammalian intestine generates diverse metabolites that act on neighboring host cells and impact physiology. One such class of microbial metabolites are short chain fatty acids (SCFAs), which accumulate to high concentrations in the intestinal lumen through the fermentation of dietary fiber. SCFAs impact signaling, cellular metabolism, and the chromatin landscape. One way that SCFAs impact chromatin are through being deposited onto histones as chemical modifications, called histone acyl marks. Certain histone acyl marks have been reported to positively regulate gene expression, including the well-studied histone acetylation. However, the functional roles of other less-characterized histone acyl marks and especially their physiological roles *in vivo* are largely unknown. We hypothesized that SCFAs can be written onto chromatin as histone acyl marks in the intestine, which then function in mediating key transcriptional programs in response to environmental changes. Using the mouse intestinal tract as a model, we demonstrate that select acyl modifications on histones are dependent on the presence of microbes, which occurs in a tissue and cell-specific manner. We have furthermore characterized several specific acyl marks that were previously unstudied and found that they are associated with active gene regulatory elements in primary intestinal epithelial cells. These histone acyl marks are regulated by the presence of specific microbial metabolites, which induce the expression of select metabolic gene programs. Together, these studies demonstrate that the microbiota, microbial metabolites, and chromatin are coupled in the intestine. Our studies have thus explored the fate of SCFAs that are deposited onto chromatin and revealed roles of understudied histone modifications. In addition, these findings will help elucidate mechanistic roles of microbial metabolites and their function in gene regulation.

Cell cycle defects in zebrafish hepatocytes with epigenetic damage due to *uhrf1* loss

B. Madakashira Pranesh, K. C. Sadler; Biology, New York University Abu Dhabi, Abu Dhabi, UNITED ARAB EMIRATES.

Cancer is characterized by aberrant changes to the epigenetic landscape, with the global loss of DNA methylation as an early feature in most types of cancer. We discovered that the ubiquitin like,

containing PHD and RING Finger Domains 1 (Uhrf1), a key component of the DNA maintenance methylation machinery that promotes heterochromatin, is an oncogene when over expressed and its absence causes cell cycle arrest and cell death in zebrafish livers. Mutation of *uhrf1* or its partner, DNA methyl transferase 1 (*dnmt1*), have global DNA hypomethylation and display a similar phenotype characterized by failure of hepatic outgrowth. Surprisingly, *uhrf1* mutant livers display a unique cell cycle arrest characterized by prolonged DNA replication and hepatocyte cell death whereas hepatocytes in *dnmt1* mutants withdraw from the cell cycle. Uhrf1 directs Dnmt1 for degradation and therefore Dnmt1 is elevated in *uhrf1* mutants. *dnmt1* knockdown in *uhrf1* mutants rescued the DNA replication defect, suggesting that the *uhrf1* mutant phenotype could be partly attributed to elevated *dnmt1* levels. *uhrf1* loss in the liver also disrupts normal hepatocyte nuclear morphology and nuclear rim organization. We found that nearly all *uhrf1* deficient hepatocytes were devoid of heterochromatin marked by DAPI staining, H3K9me3 and that lamin B2 staining was either missing or in the nucleoplasm. The fact that loss of *dnmt1* phenocopies nuclear rim phenotype (loss of lamin B2) in *uhrf1* mutant points to DNA methylation directing this effect. Blocking S-phase entry with the cdk 4/6 inhibitor and chemotherapeutic, Palbociclib, rescued the liver size, cell cycle defect, cell death and also nuclear morphology significantly in *uhrf1* mutants. These studies show that DNA methylation is essential for genome organization, dictating hepatocyte nuclear shape and morphology. In contrast, *uhrf1* and *dnmt1* function uniquely during cell cycle, with *uhrf1* playing an active role in S-phase timing and cell cycle progression, along with keeping Dnmt1 levels in check. Taken together, these results indicate a novel cell cycle promoting function of *uhrf1* during liver development that could be largely independent of its role in DNA methylation.

Exploiting epigenetic sensitivities of cells lacking the retinoblastoma tumor suppressor pRB

G. Zamalloa[1], M. Pruitt[1], N. Hermance[1], H. Gali[2], R. Flynn[2], A. Manning[1]; [1]Biology and Biotechnology, Worcester Polytechnic Institute, Worcester, MA, [2]Boston University, Boston, MA.

The retinoblastoma tumor suppressor (pRB) has multifaceted roles in the regulation of gene expression, chromatin structure, and genome integrity. Prior work from our group and others have demonstrated that loss of pRB activity leaves cells sensitive to replication stress and the acquisition of replication-dependent DNA damage. To test whether these features of pRB deficient cells may represent an exploitable weakness, we performed an imaging-based screen to identify epigenetic regulators that, when inhibited, cooperate with depletion of pRB to promote DNA damage and compromise cell viability. From the 96 drugs tested, we found that inhibition of Poly ADP-Ribose Polymerase 1 (PARP1) differentially promotes DNA damage in pRB-deficient cells compared to isogeneic control cells. My data demonstrates that pRB-deficient cells treated with PARP inhibitors exhibit replication stress in the form of single-stranded DNA gaps, such that many cells fail to progress to mitosis, while those that do progress exhibit late-replicating regions that become susceptible to DNA damage upon mitotic onset. This sequence of assaults to genome integrity compromise continued cell proliferation and increased cell death. Importantly, we have recapitulated this sensitivity to PARP1 inhibition in RB1-null cancer cells, suggesting that PARP1 is a clinically relevant therapeutic target in pRB-deficient cancers.

Bisphenol A Increases BRF2 Expression in Y79 Human Retinoblastoma Cells

A. O'Connor[1], W. Johnson[1,2], L. Schramm[1,3]; [1]Department of Biological Sciences, St Johns University, Queens, NY, [2]Department of Biology, University of Virginia, Charlottesville, VA, [3]Environmental Studies Program, St Johns University, Queens, NY.

Accurate RNA polymerase III transcription requires TFIIIB. Deregulation of TFIIIB activity occurs in various human cancers, including lung, breast, liver, prostate, and blood cancers. In general, oncogenes, tumor suppressors, and MAF1 regulate TFIIIB activity. TFIIIIB activity is regulated by polyphenols, including the flavonoids epigallocatechin gallate (EGCG) and daidzein, in the context of cervical and breast cancer, respectively. This study aims to determine if the polyphenol bisphenol A (BPA), classified as a xenoestrogenic environmental pollutant, regulates TFIIIB activity in vitro. We performed differential gene expression analyses of publicly available RNA sequencing datasets. TFIIB-related factor 2 (BRF2) expression is significantly increased in Y79 retinoblastoma cells treated with 40 mM BPA for 48 hours. MAF1 expression is significantly increased in two of three differential gene expression analyses performed. However, we did not observe consistent and significant changes in the expression of the TFIIIB subunits B-related factor 1 (BRF1) or B double prime 1 (BDP1). BPA has been classified as an endocrine disruptor and demonstrated to have both agonist and antagonist effects through nuclear steroid hormone receptors. Specifically, BPA has been demonstrated to bind to the androgen receptor (AR), estrogen receptor alpha (ESR1), and beta (ESR2) receptors. To determine if BPA regulates BRF2 and MAF1 expression through androgen or estrogen receptors, we analyzed TFIIIB and MAF1 promoters to identify putative androgen and estrogen binding sites. We identified putative AR, ESR1, and ESR2 binding sites in both BRF2 and MAF1 promoters. Interestingly, the BDP1 promoter has no putative ESR2 binding sites and the BRF1 promoter binding sites but does not contain AR binding sites. Our data suggest BPA may modulate BRF2 and MAF1 expression in BPA-treated Y79 cells through a combination of nuclear hormone receptor cross-talk.

B300/P1981

The Synthetic Opioid Fentanyl Negatively Regulates RNA Polymerase III Subunits POLR3A and POLR3B Expression in Hepatocarcinoma Cells

W. Johnson[1,2], A. O'Connor[1], L. Schramm[1,3]; [1]Department of Biological Sciences, St. John's University, Queens, NY, [2]Department of Biology, University of Virginia, Charlottesville, VA, [3]Environmental Studies Program, St. John's University, Queens, NY.

The increase in consumption and pharmaceutical availability of opioids, synthetic opioids, and fentanyl derivatives, has led to an increased rate of opioid-related dependencies and deaths within the United States spurring a national opioid epidemic. From 1999-2020, over 564,000 Americans have died from opioid overdoses. The current synthetic opioid fentanyl epidemic began in 2013. Opioids induce acute toxic leukoencephalopathy (ATL) and delayed post-hypoxic leukoencephalopathy (DPHL). Specific core RNA polymerase III subunits are deregulated in leukodystrophy and leukoencephalopathy. The aim of this study is to determine if the synthetic opioid fentanyl regulates core RNA polymerase III subunit expression *in vitro*. We performed transcriptomic differential gene expression analyses of publicly available RNA sequencing datasets of HepG2 cells exposed to 100 ng/ml fentanyl or untreated. Fentanyl treatment of HepG2 cells significantly, and specifically, decreased RNA polymerase III subunit A (POLR3A) and RNA polymerase III subunit B (POLR3B) expression. We observed no change in RNA

polymerase III subunit K (POLR3K), TFIIIB, and MAF1 expression in response to fentanyl. To identify a potential mechanism for the observed fentanyl-induced decrease in POLR3A and POLR3B expression, we analyzed select core RNA pol III subunit promoters for putative transcription factor binding sites previously demonstrated to be regulated by fentanyl. Neuronal Differentiation 1 (NEUROD1), a basic-loop-helix transcription factor, known to be regulated by opioids and has been implicated in morphine tolerance was of interest in this study. Strikingly, we identified four putative NEUROD1 binding sites in the POLR3A promoter and five NEUROD1 binding sites in the POLR3B promoter. No NEUROD1 binding sites were identified in the RNA polymerase III subunit H (POLR3H) promoter and two putative NEUROD1 binding sites in the POLR3K promoter. Neither POLR3H nor POLR3K gene expression was altered in response to fentanyl. We identified no neuronal differentiation 2 (NEUROD2) or neurogenin 2 (NEUROG2) binding sites downstream of the transcription start sites in POLR3A, POLR3B, POLR3H, or POLR3K promoters. Together, these data suggest that fentanyl regulates POLR3A and POLR3B expression in HepG2 cells, and the regulation may occur through the activity of NEUROD1.

Rrp5 knockdown alleviates growth suppression in a *saccharomyces cerevisiae* ALS/FTD FUS model

S. Cobos[1,2], S. A. Bennett[1,2], E. Son[2], R. Segal[2], M. Kozlov[2], M. P. Torrente[3,2]; [1]The Graduate Center, New York, NY, [2]Brooklyn College, Brooklyn, NY, [3]The Graduate Center, New York City, NY.

Amyotrophic lateral sclerosis and frontotemporal dementia (ALS/FTD) comprise a neurodegenerative disease spectrum, affecting thousands of people around the world. Symptoms typically manifest after age 60, when breakdown of different neuronal types in distinct locations of the nervous system occurs. The exact mechanism behind ALS/FTD progression remains elusive. Mutations in the *fused in sarcoma* (*FUS*) gene lead to misfolding and aggregation of the FUS protein, a common hallmark of ALS/FTD pathology. As genetics alone fails to explain the role that FUS aggregates play in ALS/FTD pathology, we seek to explore the epigenetic channels linked to protein aggregation. A *Saccharomyces cerevisiae* FUS overexpression model revealed decreases in levels of H3K9ac, H3K14ac, and H3S10ph. Treatment with the HDAC inhibitor Trichostatin A led to improved cell viability and restoration of H3K9ac and H3K14ac levels in the same model. Here, we shed light on how the epigenetic landscape connects to FUS proteinopathy. Co-immunoprecipitation paired with tandem mass spectrometry revealed 39 putative FUS binding partners, including the RNA binding protein Rrp5. Rrp5 is a conserved rRNA biogenesis protein found in both humans and yeast that is essential for the generation of mature 18S rRNA. Here, we show that an Rrp5 knockdown strain is resistant to growth suppression elicited by FUS overexpression. These findings reveal mechanistic details tying FUS aggregation to the epigenome, expanding our knowledge of how FUS aggregates lead to toxicity in ALS/FTD.

A High-Throughput RNA Imaging CRISPR Screen Identifies the Cohesin Complex as a Regulator of Interferon Stimulated Genes

L. Ozbun[1], A. Carcamo[1], L. Rinaldi[2], G. Fettweis[2], S. Kim[2], G. Hager[2], **G. Pegoraro**[1]; [1]High-Throughput Imaging Facility, NCI/NIH, National Cancer Institute/NIH, MD, [2]Hormone Action and Oncogenesis Unit, NCI/NIH, National Cancer Institute/NIH, MD.

Automated and multiplexed visualization of RNA species *in situ* can be harnessed as a novel class of assays for chemical or functional genomics screens to discover cellular processes regulating gene

expression programs. To this end, we miniaturized Hybridization Chain Reaction amplified RNA FISH (HCR RNA FISH) in a high-throughput format. We first optimized all the HCR-RNA FISH staining, imaging, and quantification steps using automated liquid handling, high-throughput microscopy, and high-content image analysis in a 384-well format. As a proof of principle for the applicability of high-throughput HCR-RNA FISH, we then used this technique to measure changes in the *IFIT3* mRNA levels in an arrayed CRISPR-Knock Out (KO) screen of 860 human epigenetics genes to systematically identify cellular pathways involved in the transcriptional response of Interferon Stimulated Genes (ISG) to interferon-γ. The screen and additional validation experiments revealed that knock-out of several components of the Cohesin complex, or of the Cohesin loading factors NIPBL and MAU2, leads to a substantial increase in the upregulation for several different ISG induced by interferon-γ. Knock-out of several subunits of the NuA4 acetylase complex, and of the Cyclin Kinase sub-Module (CKM) of Mediator had a similar effect. These results were further confirmed in qRT-PCR experiments, which also showed that knock-out of NIPBL leads to an increase the basal level of expression of ISGs in the absence of interferons. Interestingly, in these experimental conditions the upregulation of ISG does not seem to depend on the DNA Damage Response (DDR), nor on activation of the cGAS-STING-IRF3 axis. Finally, differential RNA-seq experiments in a cell line expressing a chemically degradable version of the Cohesin subunit RAD21 showed strong upregulation of a wide range of ISG 24 hrs post RAD21 depletion. Altogether, these results show the utility of high-throughput HCR RNA FISH for CRISPR functional genomics screens, identify multiple protein complexes whose depletion results in upregulation of ISG in the presence of interferon-γ, and point to a strong, yet not fully characterized, mechanistic role for the Cohesin complex in the regulation of this transcriptional program.

Genomewide Methylation in Serum Exosomes of Pregnant Women Experiencing Preeclampsia

U. S. Shinde[1], T. Madan[2], D. Das[3], N. H. Balasinor[4]; [1]Neuroendocrinology, ICMR- National Institute for Research in Reproductive Health, Mumbai, Mumbai, INDIA, [2]Innate Immunity, ICMR- National institute for research in reproductive health, Mumbai, Mumbai, INDIA, [3]Stem Cell Biology, ICMR- National institute for research in reproductive health, Mumbai, Mumbai, INDIA, [4]Neuroendocrinology, ICMR-National institute for research in reproductive health, Mumbai, Mumbai, INDIA.

Preeclampsia (PE) is a pregnancy-related disorder, characterized by new onset hypertension with multi-system involvement occurring after the 20th week of gestation. One of the factors causing PE is defective placental development. Currently, available serum biomarkers are unable to detect PE in the early stages. Exosomes are extracellular vesicles secreted by the trophoblast during pregnancy by the 6th week of gestation. Exosomal concentrations are altered in placental disorders. Due to the inaccessibility of placental tissue, exosomal factors could act as a better predictor of PE. Several studies have reported preeclampsia-specific DNA methylation changes in the placenta. Early epigenetic changes during pregnancy can have an impact on trophoblast function, contributing to PE as evidenced by the strong association between altered gene expression and methylation in pre-term PE placentas and first trimester trophoblasts. The objective of this study was to analyze the serum exosomal DNA methylome signatures by Whole genome bisulfide sequencing (WGBS) from 3rd-trimester pregnant women experiencing early preeclampsia (EOPE) and normative pregnant women. Serum was collected from 3rd-trimester control and EOPE women. Exosomes were isolated and the characterization of exosomes was done using Transmission Electron Microscopy (TEM), Nanoparticle Tracking Analysis (NTA), and expression of exosomal protein markers like CD63, CD81, and TSG101 by western blotting. The results of

TEM and NTA showed that exosomes were in the desired size range (50-150nm). DNA was extracted from serum exosomes and pooled exosomal DNA (N=5) samples were subjected to WGBS sequencing. With the cut-off threshold set at <5% methylation difference, we obtained a total of 355 differentially methylated CpGs (DMCs), of which, the majority were of mitochondrial origin. A growing body of research has reported that oxidative stress, decreased trophoblast differentiation, and invasion, both of which have been linked to preeclampsia pathogenesis, are related to mitochondrial dysfunction. Therefore, DMCs of the mitochondrial genes like MT-TL1, MT-CO2, MT-ND2, MT-RNR2, MT-CYB, MT-TF, MT-ND6, MT-CO3, MT-ATP8, MT-NDL4, MT-ND5 were selected for validation by pyrosequencing in the study population. Overall, this study suggests that the DNA methylome of exosomes in the serum of women with preeclampsia could be further investigated for potential diagnostic biomarkers.

Integrated epigenetic and transcriptome analysis in multiple sclerosis

Q. Ma, S. J. Caillier, S. Muzic, M. R. Wilson, R. G. Henry, B. A. C. Cree, S. L. Hauser, A. Didonna, J. R. Oksenberg; UCSF, San Francisco, CA.

The most accepted model of multiple sclerosis (MS) pathogenesis involves multi-layered interactions between complex genetic and environmental influences. Genome-wide association studies have identified 233 genome-wide significant loci associated with susceptibility, collectively highlighting the importance of adaptive and innate immune responses in driving risk. Despite this progress, the current MS genetic map only partially accounts for the estimated disease heritability. Like other complex genetic traits, epigenetic effects are a reasonable explanation for the missing heritability in MS. Epigenetic modifications can regulate gene expression in a heritable fashion without altering the DNA sequence. Moreover, environmental signals may influence epigenetic modifications contributing to the phenotype, possibly linking environmental risk factors to genetic susceptibility. Bisulfite sequencing (BS-seq) remains the gold standard method to profile genome-wide DNA methylation at a single nucleotide resolution. To gain additional insights into immune cell-type specific epigenetic regulations in MS, we applied BS-seq to conduct a genome-wide analysis of DNA methylation patterns in CD4+ and CD8+ T cells, CD14+ monocytes, and CD19+ B cells isolated from 29 untreated, recently diagnosed MS patients and 24 healthy controls. We show that CD19+ B cells from new-onset untreated cases display more significant methylation changes, primarily DNA hypomethylation, compared to the other cell types. Altogether, 4,933 MS-associated differentially methylated regions were identified in B cells. This epigenetic signature underlies specific genetic programs involved in B cell differentiation and activation. Integration of the methylome with changes in gene expression and susceptibility-associated loci further confirms that hypomethylated regions are linked to the upregulation of cell activation transcriptional programs. Potential therapeutic targets, including SLAMF7, were identified. We further apply a trimodal single-cell assay, named TEA-seq that simultaneously measures gene expression, epigenetic modification, and cell surface markers on paired cerebrospinal fluid and blood mononuclear cells, with the goal of generating a multi-cellular, multi-omics atlas associated with MS. Altogether, our results pinpoint the role of aberrant DNA methylation in connecting defects in the periphery with central nervous system autoimmunity and corroborates the key role of B cells in the initial stages of MS.

B305/P1986

C9orf72 Dipeptide Repeat Proteinopathy in Yeast is Accompanied by Alterations in Histone H3 and H4 Post-Translational Modifications

C. Janani[1,2], S. N. Cobos[1,3], A. Grebe[4,5], M. P. Torrente[1,6]; [1]Department of Chemistry, Brooklyn College, Brooklyn, NY, [2]Scholars Program, Brooklyn College, Brooklyn, NY, [3]PhD. Program in Chemistry, CUNY Graduate Center, New York, NY, [4]PhD. Program in Biochemistry, CUNY Graduate Center, New York, NY, [5]Department of Biology, City College of New York, New York, NY, [6]PhD. Programs in Chemistry, Biochemistry, and Biology, CUNY Graduate Center, New York, NY.

Amyotrophic Lateral Sclerosis (ALS) is an incurable neurodegenerative disorder characterized by progressive paralysis. While most cases have no known genetic component, the most common genetic cause for the disease is an accumulation of hexanucleotide repeat expansions in the C9orf72 gene which lead to the production of dipeptide repeat proteins. Among these, a proline and arginine (PR) repeat protein leads to cytotoxicity. To better understand how these dipeptide repeat proteins interact with the epigenome, specifically histone post-translational modifications (PTMs), we characterized histone PTM levels on various lysine residues on Histone H3 and H4 in the context of a yeast PR_{50} overexpression model. We find significant increases in the levels of H3K9ac, H3K14ac and H3K27ac, as well as an increase in the levels of H4K16ac. Acetylation levels on other sites remain unaffected. In addition, we found significant increases in the levels of H3K4me1, H3K4me2, H3K36me2, H3K36me3 and H3K79me3. We hypothesize that increased activity of the histone acetyltransferase GCN5 is responsible for enhanced acetylation of H3K9ac, H3K14ac and H3K27ac. Furthermore, the increase in H3K4me1 may be impacting GCN5 acetylation site preferences. Overall, these changes show that PR_{50} proteinopathy in yeast is connected to the epigenome. A better understanding of the epigenetic mechanisms at play in ALS may illuminate potential therapeutic targets for ALS and other neurodegenerative diseases.

B306/P1987

Discovering mechanisms regulating centromeric boundary maintenance and genome stability

P. Sidhwani, A. Straight; Stanford University, Stanford, CA.

As cells divide, they must precisely distribute their chromosomes to daughter cells for development to proceed normally. This process, known as “chromosome segregation,” is facilitated by specialized regions of the chromosome: the core centromere, which serves as a point of attachment of the chromosome to the mitotic spindle, and the pericentromeres, which flank the core centromere to facilitate proper sister chromatid cohesion and alignment in metaphase. In addition to being functionally distinct, the core- and peri-centromeric regions are also structurally distinct. The core-centromere contains nucleosomes with the histone H3 variant CENP-A whereas the pericentromere is highly condensed by the constitutive heterochromatic mark H3K9me3. In fission yeast, tRNA transcription maintains the boundary between these regions, preventing heterochromatin spread into the core centromere. However, the mechanisms regulating centromeric boundaries in humans remain largely unknown. In our work, we describe a novel assay to discover regulators of centromeric boundary maintenance in humans using CRISPR screening. Our studies promise to provide new insights into the regulation of constitutive heterochromatin and boundary maintenance in humans, with broader implications in identifying genetic risk factors for diseases like cancer.

B307/P1988

TDP-43 represses cryptic exons in transcription machinery to regulate DNA demethylation at neuronal enhancers

S. Hill[1], S. Seddighi[1], Y. Qi[1], W. Wu[1], D. Ramos[1], J. Reyes[1], D. Wang[1], E. Callen[1], C. Esnault[1], R. Dale[1], S. Coon[1], S. Coon[1], M. Prudencio[2], M. Prudencio[2], L. Petrucelli[2], J. Lippincott-Schwartz[3], A. Nussenzweig[1], M. Ward[1]; [1]National Institutes of Health, Bethesda, MD, [2]Mayo Clinic, Jacksonville, FL, [3]Janelia Research Campus, Howard Hughes Medical Institute, Ashburn, VA

Epigenetic features, such as DNA methylation, are regulated to control chromatin structure and gene expression. In neurons, altered DNA methylation has been linked to age-related neurodegenerative diseases including Alzheimer's disease and related dementias (ADRD), yet the relationship between DNA methylation and neurodegeneration remains unclear. Unlike dividing cells that can passively demethylate DNA during replication, neurons use active DNA demethylation, which involves excision of methylated cytosines and DNA repair. We recently developed a new method, Synthesis-Associated Repair sequencing (SAR-seq), to capture and sequence sites of recurrent DNA synthesis or repair. Using this method, we discovered ~30,000 sites of DNA synthesis across the neuronal genome at enhancers, likely playing key roles regulating active DNA demethylation. To investigate the relationship between methylation and neurodegenerative disease-associated proteins, we used human induced pluripotent stem cell-derived neurons (i^3Neurons) and CRISPR interference (CRISPRi) to knock down TDP-43, a hallmark of ALS, FTD and AD. In TDP43-knockdown (KD) i^3Neurons, we observed substantial reduction of SAR-seq intensity. TDP-43 is an RNA-binding protein and splicing repressor that prevents intronic sequences, called cryptic exons, from being included into mature RNA transcripts. We performed RNA-seq in TDP-43 KD i^3Neurons and found 100s of destabilized transcripts with cryptic exons. We determined that two of the destabilized genes are also essential for neuron survival and belong to the TFIIH complex, which regulates transcription initiation. We found that TFIIH components localize to SAR-seq sites and TFIIH inhibition reduces SAR-seq intensity, suggesting that TFIIH acts upstream of active demethylation. Furthermore, we found that TDP-43 KD i^3Neurons display reduced transcription, and that rescue of TFIIH components in these neurons restored transcriptional activity. These data are consistent with a model where TDP-43 splices TFIIH components, which are required for transcription, which then acts upstream of active DNA demethylation, and suggest a novel mechanism through which TDP-43 may regulate transcription and DNA demethylation.

B308/P1989

Formation and unique chromatin architecture of biomolecular condensates by the YAP1-binding transcription factor TEAD1 in renal cell carcinomas

J. Demmerle, B. He, D. Cai; Johns Hopkins Bloomberg School of Public Health, Baltimore, MD

The chromatin adaptor protein YAP1 is an important regulator of transcriptional activation and chromatin architecture in response to Hippo pathway signaling. YAP1 binds TEAD-family transcription factors and forms phase-separated biomolecular condensates, specifically transcriptional hubs, in response to hyperosmolarity and other cellular and environmental cues. In Renal Cell Carcinoma (RCC), a particularly lethal form of kidney cancer with poor treatment options, YAP1 and its transcription factor partner TEAD1 are often up-regulated and indicate poor prognosis. We have found that in certain patient-derived RCC cell lines with high levels of YAP1 and TEAD1 expression, TEAD1 forms atypical large nuclear foci, distinct from normal kidney cells and other subtypes of RCC. These few large TEAD1 foci are

co-occupant with the repressive histone mark H3K9me3 and are generally located near the nuclear periphery or nucleolus. This is in contrast to TEAD1 patterns both in normal cells and within other regions of the same nuclei, where TEAD1 is distributed into many sub-resolution foci and associates with markers of active chromatin. As YAP1-TEAD complexes are important mediators of chromatin architecture and genome organization, these findings provide insight into how those mechanisms can be hijacked in cancer. We also investigate the roles of small-molecule YAP1-TEAD inhibitors as tools to manipulate chromatin landscapes. We have used a combination of high-resolution microscopy, ChIP-seq, and biochemical methods to identify the unique chromatin architecture of these cancer-associated large TEAD1 foci, and propose that they represent a novel subtype of biomolecular condensate where normally activating transcription factors are recruited into repressive heterochromatin.

B309/P1990

Comparison of the transcriptional and epigenetic landscape in CDK4/6 inhibitor and doxorubicin mediated therapy induced senescence

J. Yeung[1], J. Rendleman[1], N. Pagane[2], I. Duba[1], A. Scortea[1], L. Anderson[1], R. Hosuru[3], M. Klein[4], A. Koff[4], V. Risca[1]; [1]Rockefeller University, New York, NY, [2]Massachusetts Institute of Technology, Cambridge, MA, [3]University of Pittsburgh, Pittsburgh, PA, [4]Memorial Sloan Kettering Cancer Center, New York, NY

Liposarcomas are rare cancers that often undergo amplification of the 12q13-15 locus, which encodes for cyclin-dependent kinase CDK4; CDK4/6 inhibitors (CDK4/6i) therefore offer a promising targeted therapy for these tumors, in which therapeutic and surgical options are scarce. CDK4/6i can lead to either reversible or irreversible exit from the cell cycle (quiescence or senescence, respectively), but the underlying mechanisms are not well understood, as most types of senescence are thought to involve some DNA damage signaling as the trigger. We used ATAC-seq and RNA-seq in a liposarcoma cell line model to determine the shared and distinct transcriptional and chromatin regulatory signatures associated with cell cycle arrest and senescence caused by palbociclib, a CDK4/6i and doxorubicin, an inhibitor of topoisomerase II that induces cell death or senescence through DNA damage. ATAC-seq analysis shows dynamic patterns of accessibility as cells transition from quiescence to senescence over 28 days of CDK4/6i treatment. NF-kB motifs in promoter-proximal regions displayed increased accessibility as cells commit to the senescence state. Furthermore, we observe differences in accessibility and gene expression between CDK4/6i and doxorubicin induced senescence around chr6 q21-22 locus that contains the genes, *FRK and FYN*. These genes encode Src tyrosine kinases which negatively regulate cell proliferation and has been implicated as a tumor suppressor through upregulation of p21, an endogenous CDK4/6 inhibitor. Interestingly, FRK and FYN's expression levels are significantly higher in CDK4/6i than doxorubicin. Hierarchical clustering of RNA-seq data identify a shared cell cycle arrest signature in both types of therapies characterized by genes enriched in TNFA via NFKB signaling pathway. To further the changes in cellular inflammatory and immune responses, we compared senescence associated secretory phenotype (SASP) genes' expression between the two conditions. Highest-expressed SASP genes in doxorubicin-induced senescence take part in interleukin signaling, whereas CDK4/6i specific SASP genes are characterized by roles in extracellular matrix remodeling and regulation of insulin-like growth factor. These findings provide further evidence of shared and unique epigenetic and transcriptional changes in different types of therapy-induced senescence.

B310/P1991

Identification and characterization of conserved methylation-dependent/independent DNA regulatory elements across mammalian SLC9C1 genes

J. A. Abele, C. C. Gardner, T. Winkler, P. F. James, S. Anas, C. Reckers; Miami University, Oxford, OH.

Sodium Hydrogen Exchangers (NHEs) are an important family of proteins involved in regulating intracellular pH. In sperm, NHEs have been shown to be essential for cell motility and fertilization. The SLC9C1 gene, which encodes for the NHE10 protein and is exclusively expressed in the testis/sperm, has been shown to be critical for male fertility. SLC9C1 knockout male mice are infertile due to immotile sperm. Recently, an infertile human male with a frame-shift deletion in the SLC9C1 gene resulting in loss of exon 22 was identified. A separate study found that men with decreased sperm motility have significantly decreased levels of NHE10 protein in their sperm cells. Studies have also found that aberrant DNA methylation of promoter regions of genes involved in sperm motility are associated with low sperm motility. We decided to study if SLC9C1 gene expression is regulated by DNA methylation and if this is epigenetic mechanism is conserved across mammalian species. To do this we first performed bioinformatic analyses on mouse, rat, and human SLC9C1 and found that there is a conserved CpG Island (CpGI) just upstream of the promoter. Bisulfite sequencing analysis on DNA isolated from lung (a somatic tissue) and testis uncovered differential methylation of the CpGIs and the promoters between these tissues. In testis, SLC9C1 is hypomethylated, while in lung it is hypermethylated. The potential regulatory elements were then cloned into luciferase expression vectors and transfected into either HEK293 cells (a somatic cell line) or GC-1 SPG cells (a spermatogonial cell line) and dual luciferase assays were performed to test the DNA regulatory activity of the promoter and CpGI. Both the CpGIs and promoter regions exhibit promoter activity and these regulatory elements are methylation sensitive. In addition, the CpGI exerts regulatory effects on the native as well as exogenous promoters. Our work has shown that the SLC9C1 promoter and the conserved (with respect to relative location) CpGI upstream of the promoter perform similar regulatory functions across mammalian species and are methylation sensitive. This work lays the groundwork for future experiments to perform targeted DNA methylation or demethylation of the SLC9C1 gene to identify specific CpGs in these regions necessary for the methylation-sensitive regulatory activity.

B311/P1992

Functions of the chromatin regulator Set4 in highly regulated stress response gene expression programs

M. Negesse, Y. Jethmalani, M. Ramos, D. Park, E. Green; University of Maryland, Baltimore County, Baltimore, MD

Chromatin regulation is a dynamic process and an essential aspect of cell growth and survival. It further allows cells to adapt to changing environmental conditions, by regulating the expression of genes essential for survival during stress. One essential class of chromatin regulators are methyltransferases, a class of enzymes that methylate histones to promote differential gene expression. The yeast chromatin regulator Set4 is a member of the Set3 subfamily of SET-domain containing methyltransferases that appear to have inactive catalytic domains. In budding yeast, this family consists of Set3 and Set4, and there are orthologs in worms, flies, mice, and humans, such as MLL5 and SETD5. In addition to the conserved SET domains, the majority of these factors include PHD fingers that bind to H3K4 methylation and facilitate their recruitment to chromatin. Interestingly, the Set4 PHD finger is not known to bind

histones in standard assays and the mechanism by which it is recruited to chromatin is unknown. We have previously shown that Set4 is important for promoting cell survival in oxidative stress and recent work has indicated a role for Set4 in promoting survival and cell wall integrity during hypoxia. This appears to be largely due to the regulation of hypoxia-induced gene expression programs, including a large subset of genes encoded within subtelomeres. We have determined that Set4 plays a clear role in chromatin regulation within these regions, including regulating the association of histone deacetylases and the levels of histone acetylation. This appears to be through the regulated recruitment of Set4 to chromatin. Here, we will present our current model for understanding the regulation of stress response genes by Set4 under different conditions and possible models for how Set4 might be regulated at chromatin. Altogether, this work provides new insights into a poorly understood chromatin regulator which plays critical roles during stress responses.

Regulation of chromatin remodeling enzymes during quiescence entry and exit

C. Cucinotta; Fred Hutchinson Cancer Research Center, Seattle, WA

Most cells on earth are nondividing, yet studies of chromatin regulation have often focused on proliferating cells. We uncovered specialized functions of chromatin remodelers in the nondividing cellular state of quiescence. Quiescence is a reversible G0 essential for long-term survival, wound healing, stem cell differentiation, and immune cell activation. During quiescence entry, histones are stripped of acetylation marks, and transcription is shut down. Despite this repressive chromatin architecture, we demonstrated that Pol II reactivation occurs within minutes of exit. By mapping each chromatin remodeling enzyme in quiescent cells, we identified quiescence-specific binding profiles, suggesting specialized roles for these remodelers in quiescence. We uncovered new functions for one such chromatin remodeler in slowing quiescence escape. We previously reported that the RSC chromatin remodeler binds and poises the genome for rapid activation during cell cycle re-entry. We have since identified separate RSC subcomplexes managing quiescence entry and exit. Together, these results describe new roles for conserved chromatin remodelers in regulating global chromatin reactivation from a highly repressed state.

Towards a single-molecule perspective of lineage specification in the early mammalian embryo

S. Basu; University of Cambridge, Cambridge, United Kingdom

Revealing how pluripotent cells generate distinct cell lineages in the early mammalian embryo is central to uncovering the mechanisms that drive mammalian development and for unlocking the potential of pluripotent cells for regenerative medicine. The objective of my lab is to provide single-cell and single-molecule insights into nuclear protein complexes that influence the ability of pluripotent cells to differentiate. Although recent studies have characterised the enzymatic activities of some of these protein complexes at the nucleosome-scale, little is known about their intra-nuclear dynamics or how they influence spatiotemporal 3D enhancer-promoter relationships. To investigate these dynamics, we have established tools for live-cell 3D tracking of single HaloTag-tagged nuclear proteins and inactive dCas9-labelled genes. We have also developed machine-learning algorithms to infer properties about the resulting trajectories, properties that allow us to determine the chromatin binding kinetics of key nuclear protein complexes and also to determine how they control chromatin movement at specific

enhancers/promoters. Using these approaches, we reveal the chromatin binding kinetics of two major protein complexes that regulate differentiation - the chromatin remodeller NuRD and the histone methyltransferase KMT2B. Furthermore, we show that both NuRD and KMT2B influence the chromatin binding of specific transcription factors and the range that genes explore within the nucleus. We then use single-cell transcriptomics (scRNAseq) and chromosome conformation capture (scHi-C) to show that these changes in chromatin movement are linked to the length-scale over which enhancers activate transcription at nearby genes. We propose a model in which the movement of enhancers influence gene activation during pluripotent cell differentiation. Our results highlight the importance of making dynamic measurements at single-cell and single-molecule resolution to provide insight into transcriptional control during pluripotent cell differentiation. We are currently establishing these technologies within live mouse embryos and we believe this will help the field understand the underlying molecular mechanisms of cell fate decisions *in vivo*.

Post-transcriptional Gene Regulation

B314/P1995

Post-transcriptional regulation of the copper transporter ATP7A via the 3' untranslated region

N. J. Ferguson, T. J. Whitlow, Y. Zhang, K. E. Vest; Molecular Genetics, Biochemistry, and Microbiology, University of Cincinnati, Cincinnati, OH.

Copper (Cu) is an important trace nutrient that requires tight regulation due to its potential for toxicity. Impaired Cu regulation leads to a variety of disease states. Regulation of Cu is accomplished through a series of Cu transporter proteins connected through an intricate network of protein and small molecule chaperones. ATP7A is an Cu transporter that functions as the primary Cu detoxification pathway for most mammalian cells. This highly conserved P-type ATPase is a dual function transporter that incorporates Cu into secreted cuproproteins and also directly exports Cu from the cell when levels are high. Although ATP7A regulation is well studied at the transcriptional and post-translational level, post-transcriptional regulation remains understudied. Post-transcriptional regulation of gene expression is critical for normal tissue development and regeneration, so this lack of understanding represents a major gap in knowledge. The objective of our study is to elucidate the mechanisms mediating regulation of ATP7A using skeletal muscle cell differentiation as a model system. Skeletal muscle stores about a quarter of total systemic Cu and has a well characterized regenerative pathway that can be used to model dynamic metabolic states including fluctuating Cu needs. We previously discovered that muscle cell differentiation requires Cu and ATP7A. Using this model we found that Atp7a mRNA is readily degraded in proliferating myoblasts and is stabilized as these cells differentiate into myotubes. Closer examination of the Atp7a transcript revealed a long 3' untranslated region (UTR) with multiple conserved regulatory elements. We discovered that the 3' UTR mediates differentiation-dependent regulation in the context of a luciferase reporter. Through literature review and CLIP-seq data, we have identified the RNA-binding protein HuR as a candidate for regulating Atp7a mRNA via the 3' UTR. Our RNA-IP data suggests HuR binds Atp7a transcript in proliferating myoblasts but not in myotubes. Additionally, siRNA knockdown of HuR leads to an increase in Atp7a mRNA and altered Cu metabolism in myoblasts.These results suggest that HuR is involved in the dynamic, post-transcriptional regulation of Atp7a and provide the foundation for future studies to decipher the integrated regulation of ATP7A at all levels.

B315/P1996

Long Read Analysis Pipeline Predicts RBPs with Isoform-specific Functions

S. H. Park[1,2], M. Schertzer[2,3], D. A. Knowles[2,3,4]; [1]Department of Biomedical Engineering, Columbia University, New York, NY, [2]New York Genome Center, New York, NY, [3]Department of Computer Science, Columbia University, New York, NY, [4]Department of Systems Biology, Columbia University, New York, NY.

Alternative splicing (AS) plays a critical role in gene regulation and protein expression by generating different messenger RNA (mRNA) isoforms from the same pre-mRNA. AS is tightly associated with RNA binding proteins (RBPs), as RBPs bind to genetic sequences and regulate RNA processing. Importantly, RBPs often regulate AS of their own transcript and the pre-mRNA of other RBPs, so that the majority of RBPs are expressed as more than one isoform. Because AS typically results in different protein products, it is very likely to affect the downstream function of RBPs, but studies of isoform-specific RBP functions are limited. Here, we aim to identify annotated and novel RBP isoforms across different tissues, predict downstream functional effects based on amino acid sequence, and test them in human cells. To identify high-confidence isoforms, we analyzed 96 PacBio long-read RNA-seq datasets from the ENCODE consortium using a customized FLAIR pipeline. First, similar to the standard FLAIR pipeline, we aligned and corrected reads, then grouped them by their splice junctions to return credible isoforms. However, our analysis differs in that we filtered reads more stringently and ignored the 5' and 3' untranslated regions (UTRs). Next, we used NCBI's ORFfinder to identify the amino acid sequence of each isoform. We identified a total of 22,723 annotated and novel RBP isoforms, with an average of 14 isoforms per RBP. For example, we identified 5 annotated and 40 novel isoforms of RBFOX2, which is a well-studied splicing factor. Approximately two-thirds of the RBFOX2 isoforms lacked both the N and C terminal nuclear localization signals, which we predict will affect protein localization, and thus have downstream consequences for genes with RBFOX2-dependent splicing. Additionally, two RBFOX2 isoforms differed in the highly conserved RNA binding domain, which we expect to affect RNA recognition and affinity. To test downstream functions of these isoforms, we will express six FLAG-tagged RBFOX2 isoforms in human stem cells. We will use a FLAG antibody to perform isoform-specific RNA-immunoprecipitation, IP-mass spectrometry, and western blot to investigate differences in RNA binding, co-factor binding, and protein localization, respectively. Overall, our method provides a reliable strategy to identify and mechanistically investigate isoform-specific functions of RBPs.

B316/P1997

Identification of exon definitive regions for *MPC1* microexon splicing and its usage for splicing-mediated gene correction

E. Koh, D. Shin, K. Kim; Yonsei University, Seoul, KOREA, REPUBLIC OF.

Alternative splicing of microexons (3-30 bp) is involved in important biological processes in brain development and human cancers. Although there are many non-3x bp (not in-frame) microexons, understanding their splicing process is only the beginning. Based on our studies with endogenous mRNA analysis and minigene constructs, we showed that a 4 bp microexon of *mitochondrial pyruvate carrier1* (*MPC1*) is constitutively included in mRNA despite the short proximity between the 3' splice site (3'ss) and 5' splice site (5'ss) across the microexon. We also elucidated that there is a strong exon definition region in the proximal flanking introns of *MPC1* microexon, which is sufficient to facilitate the inclusion of *MPC1* microexons as well as artificially reconstituted microexons residing in different genomic

contexts. Ultimately, we defined a nucleotide fragment from the upstream 67 bp of *MPC1* microexon to the downstream 6 bp, as a core exon island, which has a strong exon definition to concatenate its microexon and neighboring exons by splicing. Furthermore, we showed that insertion of the core exon island into a target exon or intron induced to skip the target exon or to enhance the splicing of an adjacent exon, respectively. Collectively, we suggest that the exon island derived from *MPC1* microexon modify genuine splicing patterns depending on its position, thereby providing insights on strategies for splicing-mediated gene correction.

B317/P1998

A Kinetic Proofreading Model of Splice Site Selection

B. Donovan, D. Larson; National Cancer Institute, NIH, Bethesda, MD.

The U2AF heterodimer is an essential splicing factor that binds tightly to 3' splice sites to nucleate formation of the spliceosome E-complex. However, recent work from the Larson Lab establishes that an intron may contain dozens of U2AF binding sites, each with some probability of promoting spliceosome assembly at that specific location. Considering this pervasive U2AF binding, we seek to understand the characteristics of binding events that support spliceosome assembly. We approached this problem using single-molecule imaging of U2AF binding both *in vitro* and *in vivo.* In live-cell single-molecule tracking (SMT) experiments, we observe a broad distribution of U2AF dwell times that best follows a power-law distribution with timescales ranging from 1 s to > 100s. In contrast, when measuring purified recombinant U2AF binding to surface-tethered RNAs containing a consensus 3' splice site, the dwell time distribution is exponential, with a dominant characteristic dwell time of 18 ± 2 s. Importantly, we observe essentially no events longer than 100 seconds in this *in vitro* assay, suggesting that the long-lived U2AF dwell-times observed *in vivo* may be involved in splicing. To test this hypothesis, we monitored U2AF colocalization to an endogenous pre-mRNA (visualized using MS2-stem loops integrated ~4000 nt upstream of the 3' SS within the intron) in live cells using 3D orbital tracking spectroscopy. Indeed, we observe that U2AF binds for 100s of seconds to a pre-mRNA undergoing the splicing reaction. Taken together, this data supports a kinetic proofreading model where the vast majority of U2AF binding events are unproductive and transient. However, in certain circumstances (likely in coordination with other early-spliceosome associated proteins) stable association of U2AF to its pre-mRNA substrate dramatically increases the probability of spliceosome assembly.

B318/P1999

Paired mutational analyses of RNA-binding proteins-interactome and overall survival in cancer patients

E. Zheng[1], A. Saxena[2]; [1]Biology, Brooklyn Technical High School and Brookly College, The City University of New York, Brooklyn, New York, NY, [2]Biology, Brookly College, The City University of New York, Brooklyn, New York, NY.

Cancer is a disease of many altered molecular traits. The cancer disparity amongst ethnic groups is further distinguished using the -omics (genomics, transcriptomics, and proteomics) data. The database suggests that RNA binding proteins (RBPs) are key players in the process of tumorigenesis. Nucleolin (NCL) is one of the most abundant nucleolar proteins that is over-expressed in cancer. NCL plays a pivotal role in a vast variety of cellular processes. There are, however, limited data on how RBP-interactome provides cellular homeostasis during stress responses. In this project, we focused on

understanding the interplay between NCL and 11 other RBPs it interacts with (NPM1, PABPC1, TARBP2, FMR1, YBX1, HNRNPD, HNRNPU, PARP1, ELAVL1, ZFP36, & HNRNPA1). We decipher mutational analyses in these selective sets of RBPs and their impact on the patients' overall survival. We used "The Cancer Genome Atlas" PanCancer studies and cBioPortal to perform paired mutational analyses of NCL with its RBP-interactors. Samples with mutations in both NCL and 10 other RBP-interactors (excluding ZFP36) indicated an overall better prognosis. Subsequently, all samples in the pairs with both genes mutated showed a higher tumor mutational burden. Most of these mutations were also in the RNA-binding domains of the genes. This suggests that mapping mutations in the RNA-binding domains of genes can provide an advantage for a patient's survival. These paired mutational analyses can help inform the pathways affected during the progress of tumorigenesis and assist in identifying potential prognostic biomarkers.

Polyadenosine promotes complex formation between LARP4a and PABPC1

L. Pitman[1], E. Valkov[1], R. Maraia[2]; [1]National Cancer Institute, NIH, Frederick, MD, [2]Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, Bethesda, MD

La-related protein 4a (LARP4) is an RNA-binding protein involved in regulating the stability and translatability of messenger RNAs (mRNAs) at the transcriptome level. LARP4 regulates stabilization and protection of the polyadenosine [poly(A)] tail at the 3' ends of mRNAs; however, how LARP4 mechanistically contributes to poly(A) tail regulation is not well understood. Previous studies indicate that LARP4-mediated poly(A) tail regulation involves binding both to the poly(A) substrate and cytoplasmic polyadenosine-binding protein 1 (PABPC1). Using in vitro pull-down assays, we show that recombinant full-length LARP4 most stably interacts with PABPC1 only in the presence of a poly(A) substrate. Mass photometry data further validate the results of pull-down assays, suggesting that stable interaction between LARP4 and PABPC1 is mediated by a poly(A) substrate. Using our established in vitro biochemical system, we will map the exact interacting interface between LARP4 and PABPC1 and subsequently characterize the LARP4/PABPC1/poly(A) complex using cryo-electron microscopy.

Studying the impact of Diamond-Blackfan anemia associated mutations on Ribosome Structure and Function

S. Parveen, A. Rai Chowdhury, D. Girodat; University of Arkansas, Fayetteville, Fayetteville, AR

An essential process of gene expression that is poorly understood is how protein and RNA constituents assemble to form a ribosome, the catalytic component responsible for synthesizing proteins in all cells. In eukaryotes, the ribosome is comprised of four ribosomal RNA segments and seventy-nine ribosomal proteins all of which need to come together during ribosome biogenesis. Ribosomal proteins are essential for proper ribosome structure and function. Variation of ribosomal proteins by site specific mutations results in human diseases known as ribosomopathies. Ribosomopathy variant ribosomes are hallmarked by defects in ribosome assembly and translational output. The resulting heterogenous pool of ribosomopathy variant ribosome structures is unclear. Additionally, to understand these diseases it is imperative to identify which genes are actively translated into proteins by these ribosomes. Diamond-Blackfan anemia (DBA) is among the most well-studied ribosomopathy, making it a model disease to study the pathologies. To explore the impact of DBA causing variant ribosome structure and

translational output, we generated ribosomal protein variants in *Saccharomyces cerevisiae*. Using cryo-electron microscopy, mass spectrometry and next-generation sequencing we are performing structure-function analysis of 10 variants of the ribosomal protein, L5 which is located at the central protuberance of the large ribosomal subunit, a core functional region of the ribosome. We expect that these variants will perturb ribosome structure through deviations in ribosomal protein abundance. Furthermore, these studies will allow us to investigate if DBA ribosomal protein variants affect protein synthesis and gene expression. These experiments will be critical towards understanding the pathology of DBA and ribosomopathies.

Post-transcriptional control of mating-type genes in*Saccharomyces cerevisiae* spores

R. Yeager, M. McMurray; University of Colorado Sch Med, Aurora, CO

Abstract: Gametogenesis in diploid cells of the budding yeast *Saccharomyces cerevisiae* produces four haploid meiotic products called spores. Spores are dormant until nutrients trigger germination, when they bud asexually or mate to return to the diploid state. Each sporulating diploid produces a mix of spores of two haploid mating types, **a** and **α**. In asexually dividing haploids, the mating types result from distinct, mutually exclusive gene expression programs responsible for production of mating pheromones and the receptors, all of which are silent in diploids. It was assumed that spores only transcribe haploid- and mating-type-specific genes upon germination. Using RNA-seq on spore populations of each mating-type, we find that dormant spores harbor transcripts representing all these genes regardless of their mating-type, with the exception of Mata1, which we found enriched in Mat**a** spores. Of particular interest to our group are the mating pheromones and receptors, due to their cell-type specific roles in mating. Seemingly produced in an unbiased fashion during meiosis, and found equally in spore populations of both mating-types, these transcripts appear to be subject to multiple levels of translational regulation leading to high fidelity expression in only the appropriate mating-type upon germination. The protein products of these transcripts are not seen until germination, and are also regulated such that upon germination, each receptor protein is only present in spores of the appropriate mating-type. We find that antisense transcripts to the Ste3 mating-type receptor are present in all spores and may be responsible for the translational silencing of the Ste3 transcripts found inappropriately in Mat**a** cells. We also find evidence of 5'UTRs in meiotic Ste2 and Ste3 transcripts containing multiple uORFs that may translationally regulate these transcripts. Further, we note that a cryptic poly-A signal leading to short Ste2 transcripts may explain the presence and subsequent translational regulation of the Ste2 transcripts found inappropriately in Mat**α** spore populations. These findings add to the growing number of examples of post-transcriptional regulation of gene expression during gametogenesis and explain tightly regulated expression of key mating-type related proteins, despite a broad transcriptome found present in the early spore life.

Nuclear Morphology and Positioning

B323/P2003

A mechanical signal on the prophase nucleus contributes to mitotic entry

M. Dantas, A. Oliveira, P. Aguiar, H. Maiato, **J. Ferreira**; i3S - UP, Porto, PORTUGAL.

As cell prepare to divide, they must ensure that enough space is available to assemble the mitotic machinery without perturbing tissue homeostasis. To do so, cells undergo a series of biochemical reactions regulated by cyclin B1-CDK1 that trigger a reorganization of the actomyosin cytoskeleton and ensure the coordination of cytoplasmic and nuclear events.
Along with the biochemical events that control mitotic entry, mechanical forces have recently emerged as important players in the regulation of cell cycle events. However, the exact link between mechanical forces and the biochemical pathways that control mitotic progression remains to be established.
Here, using a combination of micromanipulation techniques with high resolution live cell imaging, we identify a mechanical signal on the nucleus that helps set the time for nuclear envelope permeabilization (NEP) and mitotic entry. This signal relies on actomyosin contractility, which leads to nuclear unfolding during the G2-M transition, activating the stretch-sensitive cPLA2 on the nuclear envelope and contributing to the spatiotemporal translocation of cyclin B1 to the nucleus. Our data demonstrate how nuclear mechanics during the G2-M transition contribute to timely and efficient mitotic spindle assembly and prevents chromosomal instability.

B324/P2004

The nuclear cargo adaptor KASH protein UNC-83 regulates the choice of dynein vs. kinesin-1 motor activity to move nuclei in opposite directions during C. elegans development

S. Gumusderelioglu[1], K. Chiba[2], E. Gregory[1], N. Sahabandu[1], S. Niwa[2], G. Luxton[1], R. McKenney[1], D. Starr[1]; [1]University California-Davis, Davis, CA, [2]Tohoku University, Sendai, JAPAN.

Nuclear movements driven by dynein and kinesin are important for developmental events including pronuclear migration during fertilization and vertebrate central nervous system development. Like most cargo, nuclei are simultaneously bound to both dynein and kinesin, resulting in their bi-directional movement along a microtubule with a net directionality towards one end. However, how nuclei bias their direction is poorly understood. We address this problem by studying bidirectional nuclear movement during C. elegans development. In this model, the outer nuclear membrane KASH protein UNC-83 serves as a cargo adaptor to recruit both dynein and kinesin-1 to nuclei. While dynein is the major force producer for larval P-cell nuclear migration, kinesin-1 drives nuclear migration in embryonic hypodermal precursors. It is unknown how UNC-83 regulates the choice of motors at different times in development. We hypothesize that the net directionality of nuclear movement in C. elegans is determined by the developmentally regulated expression of alternative isoforms of UNC-83. Using C. elegans genetics, we showed that mutations affecting the long UNC-83a/b isoform disrupts dynein-dependent movements, while disrupting all isoforms affects both nuclear migrations. Residues 58-233 specific to the long UNC-83a/b isoform are necessary for dynein-dependent nuclear migration. Moreover, we found that a line expressing the long isoform under control of the short isoform's promoter disrupted nuclear migration in embryonic hypodermal precursors, indicating that the UNC-83a/b-specific domain was sufficient to disrupt kinesin-1 mediated nuclear migration. We tested if the short isoform UNC-83c directly activates kinesin-1 motor activity using single molecule TIRF microscopy

assays. The presence of UNC-83c increased kinesin-1 binding to microtubules and stimulated processive movements. In contrast, UNC-83a/b did neither. These results support our current model where UNC-83c directly activates kinesin-1 to move nuclei in embryonic hypodermal precursors, while UNC-83a/b counteracts UNC-83c's ability to activate kinesin-1, causing dynein to become the dominant motor during larval P-cell nuclear migration. This work is an important step towards understanding how nuclei coordinate bidirectional microtubule-dependent transport during development.

B325/P2005

Control of nuclear size by osmotic forces in*Schizosaccharomyces pombe*

J. LEMIÈRE[1], P. REAL-CALDERON[1], F. CHANG[1], L. J. HOLT[2], T. G. FAI[3]; [1]Cell & Tissue Biology, University of California, San Francisco, San Francisco, CA, [2]Institute for Systems Genetics, New York University Langone Health, New York, NY, [3]Mathematics and Volen Center for Complex Systems, Brandeis University, Waltham, MA.

The size of the nucleus scales consistently with cell size so that the nuclear-to-cell volume ratio (N/C ratio) is maintained during cell growth in many cell types. Despite this simple and longstanding observation, the mechanism responsible for this scaling is still mysterious. The N/C ratio is not determined merely by DNA amount, but is influenced by factors such as properties of the nuclear envelope and nuclear transport. Here, we developed a physical-based model for nuclear size control based upon osmotic pressure. The nuclear envelope can be regarded as a semi-permeable barrier that allows water and small ions to pass, but is relatively impermeable to large macromolecules. These macromolecules generate colloid osmotic pressure differences between the compartments that inflate the nucleus. Nuclear size may arise as a passive outcome of the numbers of osmotically-active macromolecules in the nucleus and cytoplasm. We analyze N/C ratio regulation in fission yeast using quantitative tools and find that the fission yeast nucleus, in contrast to the more complex mammalian one, behaves as an ideal osmometer, whose volume is determined in a linear relationship by its osmotic environment following the Van't Hoff law. We also propose a theoretical model to explain homeostasis behavior that maintains both the N/C ratio during cell growth and the behavior by which cells born with an aberrant N/C ratio correct it over time. We show that the N/C ratio correction rate is the additive inverse of cell's growth rates. These studies support a quantitative model explaining how nuclear size is determined by physical mechanisms that integrates osmotic forces and biosynthesis of macromolecules. Importantly, this model does not call for a complex feedback regulatory mechanism to explain N/C ratio robustness. Abnormal nuclear size and shape are a hallmark of many cancer cells and has been used as a phenomenological diagnostic criterion; our results begin to shed light onto mechanisms for how N/C ratio changes during diseases and development.

B326/P2006

Branched actin CDC-42 networks function with a LINC and dynein pathway to move nuclei through constricted spaces in *C. elegans* development

J. Ho[1], L. Ma[1], L. Gurerro[1], D. Libuda[2], D. Starr[1]; [1]University California, Davis, CA, [2]University Oregon, Eugene, OR.

Cell migration through narrow spaces is critical for many developmental and disease processes, including immune cell intravasation and cancer metastasis. Some cells can squeeze through openings about 5% the resting diameter of the nucleus. Nuclear deformability appears to be the limiting step for

cell migration through constrictions. However, the mechanisms that facilitate nuclear movement through narrow spaces are unclear. We established a model in larval C. elegans using P-cell nuclei which migrate through a narrow constriction as a normal part of development. First, the linker of the nucleoskeleton and cytoskeleton (LINC) pathway recruits microtubule motors, primarily dynein, to the nuclear envelope. Knockdown of dynein heavy chain leads to a P-cell nuclear migration defect. Second, we identified components of a branched actin network using a forward genetics screen, including CGEF-1, a predicted CDC-42 GEF, that enhanced the nuclear migration defect in LINC complex mutants. Knockdown of CDC-42, ARP2/3, and non-muscle myosin-1 using the auxin-inducible degradation system leads to a P-cell nuclear migration defect, indicating that branched actin networks are necessary for nuclear migration. In our branched actin model, CGEF-1 activates CDC-42, which goes on to activate branched actin nucleators such as ARP2/3. Myosin-1 is also required to organize the actin networks. In our working model, dynein is recruited to the surface of nuclei to provide a pulling force on the nucleus while branched actin helps to deform the nucleus. Myosin-1 could act by providing a pushing force on the nucleus from behind to help move the nucleus through the constriction.

B327/P2007

Deforming safely: nuclear envelop folds define two regimes of nuclear volume, pressure and tension

A. Williart[1], R. Rollin[2], G. P. F. Nader[3], J. Joanny[2], P. Sens[2], N. Manel[4], M. Piel[5]; [1]UMR144, Institut Curie, Paris, FRANCE, [2]UMR168, Institut Curie, Paris, FRANCE, [3]Division of Cell Pathology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, [4]U932, Institut Curie, Paris, FRANCE, [5]Cancer Cell Biology Department, Institut Curie, Paris, FRANCE.

In the body, cells are often subjected to mechanical constraints and can undergo large deformations. This can occur when cells move through dense tissues or capillaries, or often during tumor development. When the cell deforms, its nucleus, as its largest and stiffest organelle, is also subjected to deformation, up until loss of nuclear envelope integrity and rupture. Using a 2D confinement device, we can *in vitro* impose a range of controlled heights to the cells, alter their mechanical state and that of their nucleus, and study the consequences of deformations. The mechanical deformation of the nucleus is associated with changes in the state of the nuclear envelope. Non-adhered, non-confined cells have nuclei which display large folds that gradually open upon confinement. This is associated with a decrease of NE fluctuations, which we interpret as an increase in NE tension (Lomakin et al., 2020). We show in three different cell lines that the nucleus follows two regimes depending on the deformation magnitude. Under mild confinement, the nucleus deforms at constant volume, with a low NE tension and a low internal pressure. In this regime, nuclear deformation is fully translated into NE unfolding. Because the NE contains a stiff lamina layer, when deformation reaches a threshold of full NE unfolding, the NE abruptly tenses, defining a precise deformation threshold and a switch to a deformation regime with volume loss up to 50%, high NE tension and high internal nuclear pressure, leading to the formation of nuclear blebs. We propose that the first regime defines a “safe” deformation range with a sharp threshold, defined by the amount of NE folds, below which a regime begins with altered volume, chromatin density and NE integrity. Combining a physical model for the nuclear volume and for the nuclear envelope mechanics, and using mechanical measures obtained with a wedged cantilever, and detailed quantitative imaging, we explain the origin of nuclear envelope folds, the mechanical response of the nucleus to deformation, with the two different regimes and the sharp transition, the onset of NE tension, nuclear internal pressure and appearance of nuclear blebs. We believe that our work provides a physically sound explanation for these phenomena which have recently proven to be responsible for

specific cellular responses to mechanical constraints. p { line-height: 115%; margin-bottom: 0.25cm; background: transparent }

Nuclear deformation and dispersion pathways cooperate to drive epithelial plasticity

R. Budhathoki, N. de Leeuw, J. T. Blankenship, D. Loerke; UNIVERSITY OF DENVER, DEPARTMENT OF BIOLOGICAL SCIENCES, Denver, CO.

Planar polarized cell intercalation is a local event that brings tissue-scale changes for convergent extension movements during embryonic development in *Drosophila*. The nucleus, being the largest organelle in a cell, may pose a significant mechanical barrier to cells attempting to adopt extreme shapes and intercalate to achieve optimal body-axis elongation. How this largest organelle allows cells to remodel for better packing, a crucial step for this developmental process, has been largely unstudied. Here, we examine how the nucleus responds to mechanical forces imposed by the contractile forces during the rapid phase of germband extension in *Drosophila*. We find that two central mechanisms allow nuclei to respond to these stresses: 1) nuclear deformation, and 2) the dispersion of nuclei to alternate planes along the apical-basal axis. First, we tested whether cortical cell deforming forces are necessary drivers for the shaping of nuclear dimensions, as well as whether nuclear redistribution along the apical-basal axis is responsive to these actomyosin forces. Disrupting cortical force generating machinery showed that nuclei no longer deformed and had a limited redistribution along the apical-basal axis. Interestingly, however, nuclei lost their ability to re-center themselves in cells. We next tested the effects of restricting nuclear deformability through the use of kugelkern disruptions. Embryos with “non-deformable” nuclei displayed a major shift towards the second mechanism, i.e., a more dynamic redistribution in the apical-basal axis. Although this redistribution allowed cells to change shape and still participate in cell intercalation, epithelial regularity was deeply compromised. We next tested embryos that possessed “non-dispersible” nuclei by inhibiting microtubule polymerization. Interestingly, this caused a jamming phenotype in which nuclei became locked in the same apical-basal plane and cell intercalation was completely halted. Lastly, we asked what would happen in epithelia in which nuclei are both non-deformable and non-dispersible. In these circumstances, nuclei engaged in a tug-of-war to occupy the same z-plane and cell intercalation was completely disrupted. This suggests the existence of an active force-sensing process that keeps nuclei in the same plane unless internuclear tensions engage the re-distribution mechanism that regulates apical-basal nuclear densities. Altogether, our results uncover a critical role for the nucleus in epithelial remodeling that demonstrates how local level effects on nuclear positioning and deformability are necessary to achieve tissue-level elongation.

Nuclear F-actin and Lamin A antagonistically regulate nuclear shape

S. Mishra, D. Levy; University of Wyoming, Laramie, WY.

Nuclear shape influences various cellular processes such as gene expression, cell cycle progression, and cell migration. Abnormal nuclear shape is a hallmark of diseased states like cancer and laminopathies. Two important regulators of nuclear shape in mammalian cells are the nuclear lamina and perinuclear cytoplasmic actin cap. Although cytoplasmic F-actin is known to regulate nuclear shape, open questions remain about the role of nuclear F-actin in regulating nuclear shape as well as possible interactions between nuclear F-actin and Lamin A/C. To address these questions, we assembled nuclei in F-actin

intact *Xenopus* egg extract, a simplified cell-free system lacking endogenous Lamin A/C. While nuclei were roughly round when F-actin was depolymerized, nuclei were bilobed in shape in the presence of F-actin, exhibiting nucleoplasmic and nuclear rim-localized actin filaments. This result suggested a role for nuclear F-actin in regulating nuclear shape. The composition of the two lobes was heterogeneous, with the larger lobe having more F-actin but less DNA, nuclear pores, and lamin B3. Interestingly, addition of recombinant Lamin A partially rescued the bilobed nuclear morphology, suggesting that Lamin A and F-actin have opposing roles in regulating nuclear shape. This hypothesis was further tested in mammalian cells. When nuclear-targeted actin was overexpressed in Lamin A knockdown HeLa cells, the nuclei were misshapen with some of the nuclei becoming multilobed. In some cells, nucleoplasmic and rim-localized F-actin were observed, coinciding with nuclear domains having less DNA, Lamin B1, and nuclear pores, similar to *Xenopus* extract. Nuclear-targeted polymerization-defective actin did not cause nuclear lobulation, showing that dynamic nuclear F-actin is responsible for altering nuclear shape as opposed to nuclear G-actin. Inducing nuclear export of actin by overexpression of exportin-6 rescued the shape defect caused by Lamin A knockdown, further supporting the idea that Lamin A/C and nuclear F-actin antagonistically modulate nuclear shape. Using small molecule inhibitors in *Xenopus* extracts and HeLa cells, we found that formins are responsible for inducing nuclear lobulation and not myosin or Arp2/3. Future studies will focus on how formins and nuclear actin dynamics regulate nuclear shape in laminopathies and cancers.

SUN1-mediated nucleus-cytoskeletal tension determines progerin-induced nuclear deformation

J. Jo, **D. Kim**; KU-KIST Graduate School of Converging Science and Technology, Korea University, Seoul, KOREA, REPUBLIC OF.

Hutchinson-Gilford progeria syndrome (HGPS) caused by mutation in the LMNA, leading to increased production of truncated prelamin A, progerin. As the HGPS cells display accumulated progerin at nuclear envelope that results in nuclear deformation. Accumulation of progerin induces the increased level of the inner nuclear membrane protein SUN1, which alters nucleus-cytoskeletal connections. While SUN1 overexpression in HGPS cells correlated with nuclear defects, however, how the molecular mechanism of progerin-induced SUN1 accumulation deforms the nuclear morphology remains unclear. Here, we introduce doxycycline-inducible progerin expression system in HeLa cells to precisely control the progerin expression-induced nuclear deformation. To generate stable cell lines for doxycycline-inducible progerin expression, PiggyBac transposon containing blasticidin resistant gene was co-transfected with the plasmids (Δ50 LMNA, mCherry-Δ50 LMNA) into HeLa cells. We showed that doxycycline-induced progerin expression reduced the nuclear tension by SUN1-dependent molecular connections with LMNA, which in turn resulted in NE wrinkling. As determined by quantitative analysis of immunofluorescence microscopy, progerin expression accumulates the phosphorylated myosin along with the F-actins, which dictates that progerin expression could enhance the cytoskeletal tension. Moreover, the specific inhibition of myosin activity without sacrificing F-actin organization restored the nuclear tension and ultimately, reduced the NE wrinkling. We demonstrated that progerin-induced nuclear deformation by progerin expression was mediated by the reduced nuclear tension, which was accompanied by SUN1 overexpression-dependent myosin tension rather than F-actin connectivity through SUN1-nesprin 2 bridging. Reconfirmed by siRNA-mediated SUN1-depleted Tet-On HeLa cells, we concluded that progerin-induced nuclear deformation was determined by SUN1 dependent nuclear tension. This work unveils the mechanism of nuclear deformation by progerin expression, which could

fill in the missing link between myosin activity-dependent cytoskeletal tension and SUN1-mediated nuclear tension. We further expect that progerin-inducible Tet-On system will provide a new approach to investigate how the progerin expression alter the nucleus-cytoskeletal connection, which is critical to find important role of nuclear lamina mediating mechanotransduction in biological aging process.

B331/P2011

Emerin dysregulation compromises nuclear integrity during metastatic transformation

E. Hansen, J. M. Holaska; Biomedical Sciences, Cooper Medical School At Rowan, Camden, NJ.

Breast cancer metastasis causes a majority of breast cancer-related deaths. In metastasis, cancerous tumor cells spread through the body by moving into and out of nearby blood vessels by squeezing through gaps in the endothelium. Nuclei in cancer cells are often smaller and more malleable, allowing for easier metastasis. We showed both invasive breast cancer cell lines and patient samples have less emerin expression, misshapen nuclei, and higher metastasis rates than non-cancerous controls. We hypothesize emerin reduction causes compromised nuclear integrity during metastatic transformation. The mechanism by which emerin modulates nuclear stiffness is not well understood. Increasing stiffness of the tumor microenvironment (TME) was shown to increase nuclear softening, suggesting emerin may respond to changes in TME. Interestingly, this increased stiffness in the TME and subsequent nuclear softening correlates with increased metastasis. Thus, we predict that increased extracellular matrix (ECM) stiffening decreases emerin protein expression to cause nuclear softening. Supporting this hypothesis, we show ECM stiffening decreased emerin expression and altered nuclear integrity. We posit that emerin is acting as a mechanosensor that responds to extracellular stimuli through the linker of nucleoskeleton and cytoskeleton (LINC) complex by modulating structural and/or transcriptional outcomes to cause nuclear softening and drive metastasis in triple negative breast cancer (TNBC). How emerin transduces these signals and how the loss of emerin causes dysfunctional mechanotransduction during cancer progression has yet to be elucidated. Previous work showed substrate stiffness causes LINC-dependent changes in nuclear F-actin and altered the transcriptional activity of the pro-migratory protein MKL1, both of which are affected by emerin. We overexpressed nuclear actin and actin polymerization mutants in TNBC cells and showed that increasing nuclear actin polymers rescued nuclear structure. We also tested whether transcriptional activity of MKL1 contributes to nuclear softening upon ECM stiffening. How emerin senses ECM changes via the LINC complex to modulate nuclear actin polymerization and/or transcription is also being tested. This analysis will provide key mechanistic insight into how changes in ECM stiffness cause nuclear softening during metastatic transformation.

Measurement of Mechanical Strain on Lamin A/C and Vimentin Intermediate Filaments using FRET-force Biosensors

B. E. Danielsson[1], B. G. Abraham[2], E. Mäntylä[2], D. E. Conway[3], T. O. Ihalainen[2]; [1]Virginia Commonwealth University, Richmond, VA, [2]Tampere University, Tampere, FINLAND, [3]Ohio State University, Columbus, OH.

Intermediate filament proteins provide mechanical rigidity both in the form of cytoskeletal networks as well as the nuclear lamina. However, to date there is not yet a technical approach to directly measure mechanical forces on intermediate filament proteins at the protein level. To further study these

structures, we developed two FRET based force biosensors that can be used to observe the mechanical state of either Lamin A or vimentin network. A novel strategy of indirectly tagging the target protein using nanobodies was used to avoid disruption of filamentous lamin or vimentin. Using the lamin A biosensor in MDCK epithelial cells, we were able to show that the nuclear lamina is subjected to significant force. These forces are dependent on nuclear volume, actomyosin contractility, functional LINC complex, chromatin condensation state, cell cycle, and EMT. Interestingly, large forces were also present on nucleoplasmic lamins. Additionally, using the vimentin biosensor in NIH3T3 fibroblasts we observed that the vimentin network experiences significant strain. Vimentin strain is dependent on actomyosin contractility and the LINC complex. Overall we demonstrate that nanobody-based biosensors can be utilized to study the mechanobiology of complex protein networks, including intermediate filaments.

Linker Cell-type Death in C. elegans: a Physiological Model for Nuclear and Chromatin Aberrations

O. Yarychkivska, Y. Lu, S. Shaham; Laboratory of Developmental Genetics, The Rockefeller University, New York, NY.

Changes in nuclear morphology and chromatin organization are commonly observed in physiological and pathological conditions such as developmental cell death, aging, progeria, and aggressive cancers. However, the precise consequences, implications and molecular nature of these changes for disease progression are not well understood. We focus on Linker Cell-type Death (LCD) as a physiological model to understand the contributions of nuclear and chromatin changes to developmental cell death. LCD refers to the programmed death of the *C. elegans* linker cell (LC), which dies using a caspase-independent, non-apoptotic, morphologically-conserved process. The LC is a sex-specific migrating leader cell that transitions from having an oval nucleus to one with a nuclear envelope (NE) bearing striking indentations as LCD takes place. We have discovered dynamic changes in nuclear morphology and chromatin in our *in vivo* LCD setting over time. We used endogenously-tagged fluorescent lamin to show that the nuclear lamina acquires unusual ring formations that precede onset of visible NE deformations. The LC then undergoes stereotypic events of competitive phagocytosis, splitting (small cytoplasmic fragment buds off), and engulfment resulting in a refractile cell morphology. Using animals staged at different times, as well as long-term live imaging of individual animals, we discovered that the nuclear lamina dissociates as the LC splits. Simultaneously, linker histone H1 and nucleosome-associated histone H2B staining transitions from nuclear puncta to a cell-wide diffuse distribution. Surprisingly, following LC budding, the lamina fully reassembles with the unusual ring formations resembling metastatic cancer cells, and histones are re-incorporated into chromatin puncta. EM studies demonstrate that as LCD progresses, LC acquires various NE defects and forms novel nuclear/cytoplasmic vesicles. To decipher the molecular mechanism behind these unusual nuclear dynamics, we are conducting a whole-genome LC-specific RNAi screen for animals exhibiting defects in lamina dynamics. We are specifically interested in identifying genes involved in nuclear disassembly and re-formation. Because nuclear changes are prominent in a host of pathological settings in humans, we believe that our studies may identify factors relevant for these conditions as well.

B334/P2014

The Nucleus Bypasses Obstacles by Deforming Like a Drop with Surface Tension Mediated by Lamin A/C

A. Katiyar[1], J. Zhang[2], J. Antani[1], Y. Yu[3], K. Scott[4], P. P. Lele[1], C. Reinhart-King[5], N. Sniadecki[6], K. Roux[7], R. Dickinson[3], T. P. Lele[1]; [1]Texas A&M University, College Station, TX, [2]University of Arkansas, Fayetteville, AR, [3]University of Florida, Gainesville, FL, [4]Sanford research, Sioux Falls, SD, [5]Vanderbilt University, Nashville, TN, [6]University of Washington, Seattle, WA, [7]Sanford Research, Sioux Falls, SD.

Migrating cells must deform their stiff cell nucleus to move through pores and fibers in tissue. Lamin A/C is known to hinder cell migration by limiting nuclear deformation and passage through confining channels, but its role in nuclear deformation and passage through fibrous environments is less clear. Here we studied cell and nuclear migration through discrete, closely spaced, slender obstacles which mimic the mechanical properties of collagen fibers. Nuclei bypassed slender obstacles while preserving their overall morphology by deforming around them with deep local invaginations of little resisting force. The obstacles did not impede the nuclear trajectory and did not rupture the nuclear envelope. Nuclei likewise deformed around single collagen fibers in cells migrating in 3D collagen gels. In contrast to its limiting role in nuclear passage through confining channels, lamin A/C facilitated nuclear deformation and passage through fibrous environments; nuclei in lamin-null (*Lmna−/−*) cells lost their overall morphology and became entangled on the obstacles. Analogous to surface tension-mediated deformation of a liquid drop, lamin A/C imparts a surface tension on the nucleus that allows nuclear invaginations with little mechanical resistance, preventing nuclear entanglement and allowing nuclear passage through fibrous environments.

B335/P2015

The farnesyltransferase inhibitor lonafarnib improves nuclear morphology in ZMPSTE24-deficient patient cells with the progeroid disorder MAD-B.

K. Odinammadu, K. Shilagardi, S. Michaelis; The Johns Hopkins School of Medicine, Baltimore, MD

Several related progeroid disorders are due to defective post-translational processing of prelamin A, the precursor of the nuclear scaffold protein lamin A, encoded by *LMNA*. Prelamin A is first farnesylated at its C-terminus and subsequently this farnesylated C-terminal segment is cleaved off by the zinc metalloprotease ZMPSTE24. The premature aging disorder Hutchinson Gilford progeria syndrome (HGPS) and a related progeroid disease, mandibuloacral dysplasia (MAD-B), are due to mutations in *LMNA* and *ZMPSTE24*, respectively, that result in failure to process and accumulate permanently farnesylated prelamin A. The farnesyl transferase inhibitor (FTI) lonafarnib is known to correct the aberrant nuclear morphology of HGPS patient cells and improves the health-span and life-span in children with HGPS. Importantly, and in contrast to a previous report, we show here that FTI treatment also improves the aberrant nuclear phenotypes in MAD-B patient cells with a mutation in *ZMPSTE24*. We also present evidence that, as expected, patient cells with *LMNA* mutations that alter residues at a distance from the ZMPSTE24 cleavage site are proficient in prelamin A processing, and their nuclear morphology defects do not improve with FTI treatment. Additionally, we examine for the first time, prelamin A processing in fibroblasts from two patients with the laminopathy mutation *LMNA-R644C*. Despite the proximity of residue R644 to the prelamin A cleavage site between Y646 and L647, neither patient cell line shows a prelamin A processing defect, and both have normal nuclear morphology. This work clarifies the processing status in a variety of laminopathy patient cells and supports the hypothesis

that MAD-B patients that are prelamin A processing-deficient due to a *ZMPSTE24* mutation may benefit from FTI treatment.

Nuclear growth links chromatin state to lamina organization in micronuclei

M. Zych[1,2], A. Mammel[1], E. Hatch[1]; [1]Fred Hutchinson Cancer Research Center, Seattle, WA, [2]University of Washington, Seattle, WA

Micronuclei form when missegregated chromosomes recruit their own nuclear envelope and have been commonly used as a marker of chromosome instability. Micronuclei frequently rupture, which results in genome instability, upregulation of metastatic genes, and increased immune signaling. Our lab found that gaps in the lamin meshwork are correlated with micronucleus rupture frequency but how lamina gaps form in micronuclei remains a critical, unanswered question. We found that micronuclei containing gene dense chromosomes are less likely to contain lamina gaps and are more stable. For individual chromosomes we see a correlation between micronucleus size and lamina gap number, suggesting that nuclear growth drives gap formation and that growth is delayed in gene dense micronuclei. Live-cell imaging supports a link between growth and lamina gap formation. Nuclear import is a key determinant of nucleus expansion, and we find a correlation between decreased Ran and the Ran GEF RCC1 and slower post-mitotic expansion in micronuclei compared to the main nucleus. Further supporting this model of lamina gap formation, we find that RCC1 is especially depleted from gene dense micronuclei, consistent with previous data that RCC1 is enriched on heterochromatin. We find that increasing histone methylation on gene dense micronuclei with methylstat increases lamina gaps, RCC1 recruitment, and micronucleus rupture. We also find that increasing histone acetylation on gene poor micronuclei decreases rupture. These treatments have significantly stronger effects than disrupting transcription, support the importance of histone modifications in micronucleus stability. We are currently working to further define the role of RCC1 in this connection between chromatin state and lamina gaps to outline how nucleus growth is regulated in micronuclei. Ultimately this work will enable new insight into how nucleus size is regulated and identify a new function for chromatin in this regulation.

Nuclear Pore Complexes

B337/P2017

The role of O-GlcNAcylation in mRNA nuclear export studied by single-molecule super-resolution microscopy

S. L. Junod, W. Yang; Temple University, Philadelphia, PA

Characterizing the relationship between the nuclear export of mRNA and the O-GlcNAcylation of nuclear pore proteins is a critical process for understanding the dynamic effects of post-translational modifications on gene expression. Specifically, it was reported that the concentration of O-GlcNAcylated nucleoporins (Nups) in the nuclear pore complexes (NPCs) could be significantly altered by O-GlcNAc transferase (OGT) and O-GlcNAcase (OGA) inhibitor drugs. Combining two single-molecule super-resolution microscopy methods, STORM and SPEED microscopy, we found that the amount of messenger ribonucleoprotein particles (mRNPs) that successfully export through the NPC is approximately doubled when increasing the O-GlcNAcylation in the NPC. Reversely, five-fold fewer mRNPs can exit the nucleus to reach the cytoplasm with the decreased O-GlcNAcylation of Nups.

Moreover, a virtual 3D imaging by SPEED microscopy revealed that the spatial distributions of these altered O-GlcNAcylated Nups colocalized well with the locations of Nups that are rich in phenylalanine-glycine (FG) repeats, suggesting the passage of mRNPs through the selective permeability barrier in the NPC is regulated by the amount of O-GlcNAcylated FG-Nups.

B338/P2018

The linker-scaffold architecture enables dilation and constriction of the nuclear pore complex

S. Petrovic, A. Hoelz; California Institute of Technology, Pasadena, CA.

Eukaryotic cells selectively transport macromolecules in and out of the nucleus through the nuclear pore complex (NPC). In humans, the NPC is a ~110 MDa assembly of ~1,000 copies of 34 different proteins, collectively termed nucleoporins. NPCs are built on an evolutionarily conserved core that presents eightfold and pseudo-twofold rotational symmetry along the nucleocytoplasmic axis and axes coplanar with the nuclear envelope, respectively. This symmetric core consists of two opposing outer rings anchored atop each of the two nuclear membranes and an interposed inner ring that encircles the central transport channel. Within it, natively unfolded nucleoporin regions rich in phenylalanine-glycine motifs emanate from the inner ring to form the diffusion barrier. Outer rings are decorated by cytoplasmic filament and nuclear basket nucleoporins that break the pseudo-twofold symmetry.Though the arrangement of most “scaffold” folded nucleoporins in the NPC’s symmetric core was previously determined, the topology and molecular details of the multivalent natively unfolded “linker” nucleoporins that hold the scaffolds together remained uncharted. Combining biochemical reconstitution, mutational analysis, crystal and single-particle cryo-electron microscopy structure determination, docking into cryo-ET maps, and cell-based assay validation, we elucidated the molecular architecture and evolutionary conservation of the linker-scaffold network that mediates the rubber band-like cohesion of the NPC’s building blocks. Linkers insert short defined motifs into scaffold surface pockets, with flanking regions reinforcing the binding through disperse fuzzy interactions.The mechanical tethering of the nucleus to the cytoskeleton imparts membrane tension that dilates nuclear pores by at least ~20 nm. We show how the linker-scaffold coalesces the inner ring protomers into eight flexibly connected rigid spokes that translate along with the dilating pore to produce lateral gaps for the transport of membrane proteins, without disrupting the NPC’s structural integrity. Moreover, our near-atomic composite structures of the yeast and human NPCs in dilated and constricted states are roadmaps for the mechanistic dissection of NPC (dis)assembly, NPC-associated diseases, the directional anchoring of asymmetric nucleoporins, and the role of the NPC’s mechanosensation in nucleocytoplasmic transport.

B339/P2019

TorsinA is essential for the timing and localization of neuronal nuclear pore biogenesis

S. Kim[1], S. Phan[2], D. Boassa[2], T. R. Shaw[3], S. S. Pappas[4], M. H. Ellisman[2], S. L. Veatch[3], S. J. Barmada[5], W. T. Dauer[4]; [1]Cellular and Molecular Biology Graduate Program, University of Michigan Medical School, Ann Arbor, MI, [2]National Center for Microscopy and Imaging Research, Department of Neurosciences, University of California San Diego, San Diego, CA, [3]Department of Biophysics, University of Michigan, Ann Arbor, MI, [4]Peter O’Donnell Jr. Brain Institute, UT Southwestern, Dallas, TX, [5]Department of Neurology, University of Michigan Medical School, Ann Arbor, MI.

Nuclear pore complexes (NPCs) are large protein complexes composed of hundreds of nucleoporins that mediate nucleocytoplasmic transport of protein and RNA. NPC abnormalities are implicated in DYT1 dystonia, a neurodevelopmental movement disorder caused by a loss-of-function mutation in the gene encoding torsinA, a AAA+ protein localized to the endoplasmic reticular (ER)/nuclear envelope (NE) endomembrane space. Despite increasing evidence implicating NPC dysfunction in DYT1 and other neurological diseases, NPC biogenesis in neurons remains poorly understood. Furthermore, the biological function of torsinA and the molecular defects underlying DYT1 dystonia remain largely unknown. In mouse primary neurons, we observed a striking upregulation in NPC biogenesis during neuronal maturation. While NPCs are uniformly distributed in wild-type (WT) neurons, torsinA-knockout (KO) neurons develop severe clusters of NPCs. Despite abnormal localization, NPC density is normal in torsinA-KO neurons, suggesting that torsinA is essential for NPC spatial organization, but not number. TorsinA-KO neurons develop abnormal evaginations of the inner nuclear membrane (NE blebs) that coincide with the formation of abnormal NPC clusters. Using scanning transmission electron microscopy tomography, we find that clusters of NE blebs connect to the inner nuclear membrane via NPC-like pore structures. This finding establishes a spatial link between NPC clusters and NE blebs and is consistent with a model in which loss of torsinA causes halted NPC assembly and NE bleb formation at sites of new NPCs. However, while NPC clusters persist, NE blebs resolve as neurons continue to mature, allowing NPC assembly to proceed albeit with a delay compared to WT NPC formation. These data demonstrate that torsinA is dispensable for interphase NPC assembly and that its loss causes delayed, rather than permanently halted, NPC biogenesis. Taken together, our data suggest that torsinA is essential for proper spatial and temporal organization of NPCs during a key period of neuronal development and implicate delayed NPC biogenesis in the pathogenesis of DYT1 dystonia.

B340/P2020

Nucleoporins are degraded via upregulation of nuclear ESCRT-III/Vps4 complex in *Drosophila* models of C9-ALS/FTD

S. DUBEY, K. Maulding, H. Sung, T. Lloyd; Johns Hopkins University School of Medicine, Baltimore, MD

Disruption of nucleocytoplasmic transport (NCT) has been implicated in Amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). The mechanisms by which expansion of GGGGCC in C9orf72 disrupts NCT is poorly defined. In this study, we find that the expression of GGGGCC repeat induces proteasome-mediated degradation of select nucleoporins of the NPC in *Drosophila* adult brain. In addition, we show that Vps4 ATPase and the endosomal-sorting complex required for transport complex-III (ESCRT-III) are required for degradation of nucleoporins through proteasomal degradation pathway. Knockdown of ESCRT-III/Vps4 complex in GGGGCC expressing neuron restores nucleoporin levels. Reducing ESCRT-III/Vps4 complex also rescues nucleocytoplasmic transport and suppresses repeat toxicity. GGGGCC expression upregulates nuclear ESCRT-III/Vps4 expression, and expansion microscopy demonstrates that the nucleoporins are translocated into the cytoplasm before undergoing proteasome-mediated degradation. These findings demonstrate a mechanism for nucleoporin degradation and NPC dysfunction in neurodegenerative disease.

ER and Golgi Transport

B342/P2021

SURF4-induced tubular ERGIC selectively accelerates ER-to-Golgi transport kinetics

R. Yan[1,2], K. Chen[2], B. Wang[2], K. Xu[2]; [1]Department of Genetics, Harvard Medical School, Boston, MA, [2]Department of Chemistry, University of California, Berkeley, Berkeley, CA.

The endoplasmic reticulum (ER)-to-Golgi transport is the first and a critical step of protein secretion and intracellular sorting. Although the protein components of this pathway have been characterized in detail, we know relatively little about the cell biological basis of ER-to-Golgi transport, such as how morphologically diverse cargo carriers are shaped and their structure-function relationships. Combining fast multiplexed live imaging, super-resolution microscopy, and genetic perturbations, we identified a highly elongated tubular ER-Golgi intermediate compartment (t-ERGIC) that selectively expedites the ER-to-Golgi transport for soluble cargoes of the receptor SURF4. Lacking the canonical ERGIC marker ERGIC-53 yet positive for the small GTPases Rab1A/B, the t-ERGIC is further marked by its extraordinarily elongated and thinned shape. With its large surface-to-volume ratio, high intracellular traveling speeds, and ER-Golgi recycling capabilities, the t-ERGIC selectively accelerates the trafficking of SURF4-bound cargoes. The biogenesis and cargo selectivity of t-ERGIC both depend on SURF4, which recognizes the N-terminus of soluble cargoes and co-clusters with the selected cargoes to expand the ER-exit site. Knockdown of SURF4 precludes the formation of t-ERGIC, yet intriguingly, its cargoes can still be transported at a significantly slower rate, indicating a role of the SURF4/t-ERGIC axis in modulating cargo transport kinetics. Furthermore, we showed that in the steady state, the t-ERGIC-mediated fast ER-to-Golgi transport is antagonized by the KDEL-mediated ER retrieval, which may be harnessed to enrich specific proteins to the ERGIC. Together, our results suggest that specific cargo-receptor interactions give rise to distinct transport carriers that regulate the trafficking kinetics. Given the early embryonic lethality of SURF4 knockout in mice and the emerging results of SURF4 modulation in metabolic diseases, we speculate that the t-ERGIC-dependent cargo transport plays an essential role in embryonic development and tissue homeostasis through its regulation of cargo trafficking kinetics and thus the spatiotemporal dynamics of the secretome.

B343/P2022

Molecular mechanisms of SURF4-mediated protein secretion

J. Maldutyte, N. Gomez-Navarro, S. Peak-Chew, E. A. Miller; Cell Biology, MRC Laboratory of Molecular Biology, Cambridge, UNITED KINGDOM.

Protein secretion is an essential process that drives organelle biogenesis, cell growth and communication. Once synthesised and processed in the Endoplasmic Reticulum (ER), secretory proteins are incorporated into transport carriers that are generated by the COPII coat. Efficiency and accuracy of cargo incorporation into ER-derived carriers is considerably enhanced by transmembrane cargo receptors. ER export receptors are especially important for secretion of soluble cargo as they provide a transmembrane bridge to the cytosolic COPII coat. In this study, we focus on SURF4, a receptor for soluble secreted and lysosomal cargo. We characterised the spectrum of SURF4 clients in HEK-293TREx and HuH7 cell lineages using mass spectrometry. Amongst the top hits, we identified many oligomeric Ca^{2+}-binding proteins, including Cab45 and NUCB1. Using *in vitro* translation and site-specific photo-crosslinking, we show direct co-translational SURF4 engagement with the cargo via the N-terminal ER-

ESCAPE motif. This result supports a fast-export mechanism for preventing cargo oligomerization in an unwanted organelle and for the first time shows a cargo receptor is able to start interacting with an unfolded and not fully translated client. Additionally, with the aid of structural prediction-guided mutagenesis and site-specific cross-linking, we map a putative cargo interaction surface on SURF4 which comprises acidic residues in SURF4 luminal loops and a hydrophobic pocket. Altogether, these data define the SURF4 cargo repertoire and describe the biochemical basis for cargo recruitment into COPII vesicles.

B344/P2023

Cell cycle-dependent regulation of a COPII subunit by post-translational modification

G. Georgiou[1], B. Bisnett[2], B. Condon[3], S. Rodriguez[4], J. Maiwald[5], M. Boyce[1]; [1]Biochemistry, Duke University, Durham, NC, [2]Boston Consulting Group, Minneapolis, MN, [3]Drexel University, Philadelphia, PA, [4]Duke University, Durham, NC, [5]Haverford College, Haverford, PA.

Coat protein II (COPII) vesicles are responsible for faithfully packaging and trafficking one-third of the human proteome from the ER towards its final intra- or extracellular destinations. The coat is composed of a minimum of five subunits, including Sec24C, one of four human Sec24 paralogs, which forms heterodimers with Sec23 to assemble the COPII inner coat. Despite the biological significance of intracellular trafficking, the mechanisms by which COPII subunits, such as Sec24C, adapt to cellular and environmental cues that promote changes in ER behavior and protein flux remain mostly unknown. Previous work from our lab identified that Sec24C is post-translationally modified by the addition and removal of O-linked β-N-acetylglucosamine (O-GlcNAc), an intracellular form of glycosylation, on at least seven discrete residues. Though the purpose of these modifications on Sec24C remains incompletely understood, O-GlcNAcylation has previously been demonstrated to regulate several cellular processes, including cell death, cell cycle progression, and cytoskeleton assembly. Here, we examined the role of Sec24C glycosylation in the regulation of COPII trafficking through different stages of the cell cycle because trafficking burdens and COPII assembly have been shown to vary dramatically by cell cycle phase. We found that Sec24C directly interacts with Aurora A, a mitotic kinase, and phosphorylation of Sec24C by Aurora A may influence its glycosylation, and vice-versa. Sec24C demonstrates both increased glycosylation and phosphorylation in G_2/M-phase, relative to G_1. Additionally, preliminary data indicate that inhibition of Aurora A by the small molecule alisertib leads to an increase in Sec24C glycosylation. Therefore, cross-talk between O-GlcNAcylation and O-phosphorylation by Aurora A and/or other kinases may regulate Sec24C and COPII function during mitosis. Ongoing work is focused on identifying site-specific changes to Sec24C phosphorylation and glycosylation and their functions throughout the cell cycle by mass spectrometry and trafficking assays.

B345/P2024

Two O-GlcNAcylation Sites in the Disordered Region of Sec24D are Critical for Collagen Trafficking*in vivo*

T. Hirata[1], D. Choudhary[2], B. Bisnett[1], N. Linhart[1], E. Knapik[2], M. Boyce[1]; [1]Duke University, Durham, NC, [2]Vanderbilt University Medical Center, Nashville, TN.

Protein transport from the endoplasmic reticulum (ER) to the ER-Golgi intermediate compartment (ERGIC) or the Golgi is achieved by coat protein II (COPII)-coated vesicles. The COPII coat is comprised of inner and outer coat protein complexes and assembled at ER exit sites (ERES). The inner COPII coat is

composed of Sec23-Sec24 heterodimers, and Sec13-Sec31 heterotetramers form the outer coat. COPII-dependent transport of proteins is known to be regulated by post-translational modifications, such as phosphorylation and O-GlcNAcylation. O-GlcNAcylation is a reversible form of glycosylation found on many nuclear and cytosolic proteins in many organisms. OGT transfers GlcNAc residues on the Ser/Thr residues of substrate proteins, whereas OGA removes GlcNAc from the substrate proteins. Recently, we identified multiple O-GlcNAcylated sites on several COPII components, including Sec24D, one of the four Sec24 isoforms in vertebrates. However, how O-GlcNAcylation regulates the functions of COPII is largely unknown.In this study, we aimed to uncover the function of O-GlcNAcylation on Sec24D. We mutated two glycosites on human Sec24D (T9 and S13) and analyzed their function by taking advantage of the Sec24D-mutant zebrafish line, *bulldog*, which accumulates intracellular collagen due to trafficking defects. We first examined Sec24D O-GlcNAc levels in human cells and confirmed significant reductions in glycosylation in both the T9A and S13A mutants. Next, we expressed either human Sec24D wild type or mutants in *bulldog* zebrafish embryos and examined the intracellular accumulation of collagen in chondrocytes. Expression of wild type human Sec24D in *bulldog* zebrafish restored normal collagen trafficking, whereas the T9A and S13A mutants did not, indicating that O-GlcNAcylation on these sites is critical for collagen trafficking. To better understand the molecular mechanisms behind these observations, we purified proteins interacting with wild type or mutant Sec24D, with or without OGA inhibition. Preliminary data indicate that some proteins interact with mutant, but not wild type, Sec24D, and these interactions are reduced by OGA inhibition, suggesting that O-GlcNAcylation on these sites may prevent protein binding. Therefore, O-GlcNAcylation on human Sec24D may facilitate COPII-dependent collagen trafficking by regulating protein-protein interactions.

Non-degradative Ubiquitin Signals are the Key Regulators of COPI-mediated ER-Golgi Homeostasis

S. S. Date, 1, T. R. Graham; Vanderbilt University, Nashville, TN

The ER and the Golgi play a central role in protein processing and sorting. As proteins move constantly between these organelles and Golgi compartments, proper retrieval, sorting, and localization of resident proteins, chaperones, and coat components becomes increasingly important to maintain functional ER-Golgi dynamics. Perturbations in retrieval, sorting and localization of ER-Golgi proteins are associated with neurodegenerative diseases, autoimmune disorders, and congenital diseases. COPI plays a critical role in retrieval and retrograde trafficking of proteins between the Golgi compartments and from Golgi to ER. The prevailing notion in the trafficking field is that COPI recognition of dilysine motifs is the primary mechanism for COPI to recognize and retrieve cargo. However, this notion does not explain the dependence of cargoes that do not have dilysine motifs on COPI, or why cells grow normally when both dilysine-binding sites in COPI are mutated. These observations indicate additional mechanisms for COPI to recognize, bind, and sort cargoes. We previously demonstrated that the WD repeat domains of alpha and beta'-COP bind polyubiquitin chains. Several COPI subunits, cargos, and ArfGAP Glo3 are ubiquitinated under physiological conditions with non-degradative ubiquitin linkages. Detailed analysis of COPI-dependent cargo localization and coat-cargo interactions using live-cell imaging, SILAC mass spectrometric analysis, and biochemical studies provide compelling evidence that the ability of COPI to bind ubiquitin, but not dilysine motifs, is critical for the proper localization of several important COPI cargoes such as the SNAREs Snc1, Gos1, Bet1, and Sec22. Additionally, we also show the dependence of some key Golgi-ER chaperones on the ability of COPI to recognize ubiquitin. Altogether our results help

redefine the fundamental mechanisms associated with cargo recognition by COPI and provide novel insights into how non-degradative ubiquitination plays a key role in ER-Golgi homeostasis.

Acute COG inactivation unveiled its immediate impact on Golgi & illuminated the nature of intra-Golgi recycling vesicles

F. Sumya, I. Pokrovskaya, Z. D'Souza, V. Lupashin; UAMS, Little Rock, AR.

Conserved Oligomeric Golgi (COG) complex orchestrates intra-Golgi retrograde trafficking and glycosylation of macromolecules, but the detailed mechanism of COG action is unknown. The auxin-inducible degradation system was employed to investigate initial defects resulting from COG dysfunction. This approach allows a speedy and efficient depletion of COG4, which provides the ability to accumulate COG complex-dependent (CCD) vesicles and investigate primary cellular defects associated with the acute depletion of COG. The results revealed that upon COG4 depletion, both lobe A and lobe B COG subcomplexes were mislocated from Golgi. As predicted, v-SNAREs (GS15, GS28) were relocalized into CCD vesicles, while t-SNAREs (STX5, YKT6) remained attached to the Golgi membrane. Coiled-coil tethers also demonstrated differential response: t-tethers GM130 and P115 remained associated with Golgi, while the v-tethers (giantin and golgin-84) show off-Golgi patterns in COG4 depleted cells. Surprisingly, the majority of COG complex-interacting Golgi Rab-GTPases (Rab2a, Rab6a, Rab30a) did not relocate to CCD vesicles after acute COG4 depletion. These results indicate that COG interacting Rabs are primarily acting from the acceptor Golgi membrane during the intra-Golgi vesicle recycling process. Importantly, all tested Golgi enzymes (B4GalT1, MGAT1, GalNT2, FUT 8) and Golgi resident proteins (GPP130, TMEM165, SDF4, TGN46) were significantly relocalized from Golgi into CCD vesicles. Accumulated CCD vesicles were relatively stable - partial degradation of vesicle content was observed only after prolonged (24-48 hours) COG depletion. Superresolution microscopy analysis of CCD vesicles indicated that medial and trans-Golgi enzymes MGAT1 and B4GalT1 recycle in different populations of CCD vesicles. Native IP was used to separate and characterize different classes of CCD vesicular carriers. Moreover, acute COG depletion significantly affected three Golgi-based vesicular coats- COPI, AP1, and GGA, suggesting that COG uniquely orchestrates tethering of multiple types of intra-Golgi CCD vesicles produced by different types of coat machinery. In summary, the study provided a first detailed view of primary cellular defects associated with COG complex dysfunction and uncovered heterogeneous nature of vesicular intermediates that recycle Golgi enzymes and other resident Golgi proteins in human cells.

Two Model Secretory Cargoes Show Different Kinetics of Golgi Export

F. M. Valbuena, B. S. Glick; The University of Chicago, Chicago, IL

The Golgi apparatus processes and sorts biosynthetic cargo proteins, but there are still questions about the basic pathways of cargo transit through the Golgi. *Saccharomyces cerevisiae* contains non-stacked Golgi cisternae, and cargoes are continuously present within these cisternae, which mature over time by means of retrograde vesicles that recycle resident Golgi proteins. A similar cisternal maturation process is thought to operate in mammalian cells, in which Golgi stacks are laterally connected to form a Golgi ribbon. The implication is that cisternae progress through each Golgi stack in a conveyor belt-like fashion while carrying the cargoes forward. However, the existence of cisternal maturation in mammalian cells

has been challenged based on two findings. First, the kinetics of cargo export from the Golgi were reportedly exponential-like, in disagreement with the expectation that a conveyor belt-like mechanism would yield linear kinetics. Second, cargoes reportedly exchanged between Golgi ribbons in fused cells, in disagreement with the expectation that cargoes would remain within the cisternae. We have now revisited both issues using inverse fluorescence recovery after photobleaching (iFRAP). Our analysis took advantage of "mini-ribbons", which are small Golgi elements separate from the main ribbon. Mini-ribbons receive and export secretory cargoes, and they exchange resident Golgi proteins with the main ribbon. One set of experiments employed the transmembrane secretory cargo VSVG. We find that VSVG departs from Golgi mini-ribbons with linear kinetics. These results support the cisternal maturation model. A second set of experiments employed the soluble secretory cargo ESCargo. Interestingly, when iFRAP is performed using the main Golgi ribbon, ESCargo departs with exponential-like kinetics, but when iFRAP is performed using mini-ribbons, ESCargo departs with linear kinetics. These results can be explained by the observation that ESCargo moves between Golgi stacks, as detected by exchange between the main ribbon and mini-ribbons. We postulate that ESCargo recycles at some frequency within the Golgi, probably by partitioning into retrograde vesicular carriers. Our data point toward a unified picture of intra-Golgi transport in diverse eukaryotes.

B349/P2028

Filling in the GAPs- Spatiotemporal analysis of Arf1 regulation at the Golgi

K. Manzer, C. Fromme; Cornell University, Ithaca, NY.

The Golgi serves as the cellular hub for intracellular membrane trafficking. Golgi trafficking is orchestrated by the small GTPase Arf1, which recruits several effector proteins to the Golgi membrane at precise points in cisternal maturation to facilitate vesicle formation. To achieve this, Arf1 is tightly controlled by GEFs and GAPs, which reside on specific compartments to activate and inactivate Arf1, respectively. The differential localization of GEFs and GAPs is essential for maintaining proper Arf1 function. While the spatiotemporal dynamics of the GEFs are well-characterized, they were unknown for the Arf GAPs. Through the use of live-cell time-lapse fluorescence microscopy, we established the timing of each of the yeast Golgi-localized Arf GAPs relative to the major Golgi trafficking pathways. We found that a distinct GAP is present at each stage of Golgi maturation, with Glo3 functioning at the early Golgi, Gcs1 at the medial Golgi, and Age2 at the late Golgi. To further understand how the differential localization of the GAPs is achieved, we are investigating the mechanism of localization of the particularly unstudied Arf GAP, Age2. We identified a highly conserved sequence in Age2 that may comprise an amphipathic helix and is essential for membrane binding. Interestingly, we also found that the interaction between the catalytic GAP domain and its substrate, Arf1, is required for Age2 recruitment. Lastly, despite the role of Age2 in clathrin-dependent trafficking, we did not observe a role for clathrin or its adaptors in Age2 localization. This ongoing work establishes a timeline for Arf1 regulation at the Golgi and provides mechanistic insight into how this timeline is achieved.

SARS-CoV-2 Envelope hijacks an ARFRP1-AP1-AP1AR *trans*-Golgi network-to-endolysosome trafficking pathway to drive lysosomal deacidification

G. Pearson, M. Broncel, A. Snijders, J. Carlton; Francis Crick Institute, London, United Kingdom

The SARS-CoV-2 structural proteins Membrane(M), Envelope (E), Nucleocapsid (N), and Spike (S), assemble into nascentvirions at the ER-Golgi-Intermediate Compartment (ERGIC) and bud into thesecretory pathway lumen to allow viral egress. Recent work has described anatypical secretion route for coronaviruses involving delivery to deacidifiedlysosomes and subsequent release through lysosome-plasma membrane fusion. Here,by developing inert tagging strategies for SARS-COV-2 E, we identifytrafficking motifs and host cell interaction partners required for itsER-export, its delivery to the ERGIC and its forward traffic from the *trans*-GolgiNetwork (TGN) to endolysosomes. We show that SARS-CoV-2 is oligomeric inendolysosomes and contributes to pH neutralisation in these organelles. ACRISPR-knockout screen based on our TurboID proximity-ome reveals roles for theARF1-related GTPase, ARFRP1, in controlling Golgi-to-endolysosome traffickingof SARS-CoV-2 E. We identify an interaction between SARS-CoV-2 E's cytoplasmicdomain and the beta-adaptin subunit of AP1 and show that both GGA1 and AP1 andthe microtubule adaptor for AP1 cargo, AP1AR, are necessary for delivery ofSARS-CoV-2 E from the Golgi to endolysosomes. Given the recent evidence thatAP1 is an essential host-factor for for SARS-CoV-2 replication, we suggest thatE-driven lysosomal deacidification may contribute to a favourable replicationenvironment for this virus.

Altered secretory trafficking and processing of amyloid precursor protein variants associated with familial Alzheimer's disease

J. Wang, L. Fourriere, P. A. Gleeson; Bio21 Institute, University of Melbourne, Melbourne, Australia

Alzheimer's disease (AD) is characterized by high levels of neurotoxic amyloid beta peptides (Aβ) which are generated by the cleavage of amyloid precursor protein (APP) by proteolytic secretases. The intracellular processing of APP, and secretion of Aβ, is regulated by the trafficking itineraries of APP and its secretases. However, the relative contribution of APP processing in the secretory and the endocytic pathways in AD is poorly defined. Here, we employ the Retention Using Selective Hooks (RUSH) technique to track the anterograde trafficking and processing of newly synthesized APP. We define the anterograde trafficking, and temporal and spatial regulation of cleavage events, of wild-type APP (APPwt), as well as the disease-causing Swedish APP variant (APPswe), and the disease-protective Icelandic APP variant (APPice). Interestingly, we find that both APP variants displayed altered trafficking and processing along the secretory pathway compared with APPwt. We show that newly synthesized APPswe is transported through the Golgi less efficiently compared with APPwt, and is associated with enhanced amyloidogenic APP processing and Aβ production. In contrast, APPice is transported more rapidly through the Golgi apparatus to the endosomal compartments, and is associated with lower Aβ production through the secretory pathway. These data reveal that APP and the familial APP variants differ in the kinetics of transport through the Golgi to the endocytic pathway, findings relevant for understanding the molecular mechanisms associated with AD susceptibility of the familial APP mutations, and the design of therapeutics to reduce Aβ production.

B352/P2031

***TRAPPC6B* Biallelic Variants are Associated with TRAPP II-Specific Defects and Cause Neurodevelopmental Disorder and Microcephaly in Humans**

H. Almousa[1], S. Lewis[2], R. Maroofian[3], M. Kreuer[2], M. Sacher[1]; [1]Department of Biology, University Concordia, Montreal, QC, CANADA, [2]Department of Child Health and Neurogenetics, University of Arizona, Arizona, AZ, [3]Department of Neuromuscular Disorders, Queen Square Institute of Neurology, London, UNITED KINGDOM.

Background The transport protein particle (TRAPP) complexes play essential roles in vesicular trafficking pathways that are crucial for proper cell functioning. Defects in some TRAPP subunits are associated with neurodevelopmental disorders in humans. **Methods** Through Genematcher, we gathered multiple patients with biallelic mutations in the *TRAPPC6B* gene and conducted detailed clinical and neuroradiologic assessments. We then performed functional studies to assess the effect of the identified variants on Golgi integrity and membrane trafficking. **Results** We identified 7 homozygous nonsense (n=12 patients) and 7 canonical splice site mutations (n=13 patients). In addition, we identified a single patient with a compound heterozygous mutation (one nonsense allele and one amino acid substitution allele) with a milder phenotype. All individuals suffer from microcephalic neurodevelopmental disorder, speech impairment and movement disorder. MRI imaging revealed reductions in several brain regions (cortex, cerebellum, and corpus callosum) with frequent white matter hyperintensity. *Drosophila* locomotor studies supported a role of the *TRAPPC6B* ortholog in neuromotor function. We focused our functional studies on two individuals with the following homozygous variants: c.454C>T, p.Q152* (individuals S1 and S2) and c.149+2T>A, predicted splice variant (individuals S3 and S4). Molecular studies revealed a weakened interaction between mutant TRAPPC6B (c.454C>T, p.Q152*) and its TRAPP binding partner TRAPPC3. Patient-derived fibroblasts from S1 and S2 have reduced levels of TRAPPC6B as well as TRAPP II complex-specific members (TRAPPC2L, TRAPPC9 and TRAPPC10) Interestingly, the levels of the TRAPPC6B homologue TRAPPC6A were found to be elevated. The reduction in TRAPPC6B affects Golgi integrity and trafficking into the Golgi in both S1 and S2, as well as in S3 and S4-derived fibroblasts. These defects were rescued by wild type TRAPPC6B. Interestingly, treatment of S2 fibroblasts with Ataluren, a small molecule that reads through premature stop codons, also rescued the trafficking defect, suggesting a possible therapeutic approach. **Conclusion** Our data provide additional support for TRAPPC6B biallelic variants association with neurodevelopmental disorder, microcephaly, language impairments and movement disorder in humans. These phenotypes overlap with alterations in other TRAPP subunits, mainly components of the TRAPP II complex. This suggest that TRAPPC6B is essential for brain development through its role in the TRAPP II complex.

B353/P2032

Steady-state Regulation of Secretory Cargo Export by Inositol Trisphosphate Receptors and Penta EF Hand Proteins

A. J. Held[1], J. R. Sargeant[1], J. Hojanazarova[1], C. Madreiter-Sokolowski[2], R. Malli[2], W. F. Graier[2], J. C. Hay[1]; [1]University of Montana, Missoula, MT, [2]Medical University of Graz, Graz, AUSTRIA.

Ca^{2+} release by inositol trisphosphate receptors (IP3Rs) regulates diverse physiological processes in many cell types. Notably, agonist-stimulated Ca^{2+} signaling involving IP3Rs can modulate ER export rates through activation of the Ca^{2+}-dependent COPII coat adaptor, ALG-2. It is unknown, however, whether

IP3Rs and ALG-2 regulate ER export rates at steady state. Here we report that partial depletion of IP3Rs from normal rat kidney (NRK) epithelial cells caused a marked increase of ER export of the transmembrane cargo VSV-G. Depletion of IP3R-3, the major IP3R isoform in NRK cells, had a larger impact on secretion than the other extant isoform, IP3R-1. Under standard growth conditions, spontaneous cytosolic Ca^{2+} oscillations usually occurred simultaneously in successive groups of contiguous cells, generating intercellular Ca^{2+} waves (ICWs) that moved across the monolayer. Unexpectedly, IP3R-3-depleted cells exhibited increased cell participation in this spontaneous signaling. IP3R-3-depleted cells also exhibited increased agonist-dependent Ca^{2+} signaling, suggesting a general potentiation of the remaining IP3R-1 channels. Increased spontaneous signaling was accompanied by increased ALG-2 and decreased peflin at ER exit sites (ERES), resulting in increased targeting of Sec31 to ERES. Furthermore, the effects of IP3R depletion on the secretion rate required ALG-2. Kinetic colocalization analysis found that in IP3R-3 depleted cells, VSV-G was sequestered more quickly into ERES, suggesting that an early step in ER export, perhaps cargo sorting, was affected. In addition, while IP3R-3 depletion caused increased export of the COPII client cargo VSV-G, it caused decreased export of the bulk flow cargo construct GFP-F_M4-hGH, once again pointing to cargo sequestration or sorting as the functional locus of Ca^{2+} and ALG-2. We conclude that in NRK cells, IP3Rs regulate spontaneous Ca^{2+} signaling that helps determine the basal secretion rate by modulating early COPII-dependent steps through ALG-2. Furthermore, the IP3R channel density and/or isoform composition significantly impacts this phenomenon.

B354/P2033

An ERAD-independent role for rhomboid pseudoprotease Dfm1 in mediating sphingolipid homeostasis.

S. Bhaduri, S. E. Neal; UNIVERSITY OF CALIFORNIA San Diego, San Diego, CA.

Nearly a third of nascent proteins are targeted to the endoplasmic reticulum (ER) where they are correctly folded and assembled before being delivered to their final cellular destinations. To prevent the accumulation of toxic misfolded membrane proteins, ER-associated-degradation (ERAD) removes these clients from the ER membrane to the cytosol in a process known as retrotranslocation. Recent work from our lab demonstrated that rhomboid pseudoprotease Dfm1 is involved in the retrotranslocation of ubiquitinated integral membrane ERAD substrates. To survey for potential interaction partners of Dfm1 we performed protein-proximity labeling by BioID (proximity-dependent biotin identification) followed by mass spectrometry and identified several interacting proteins known to play a role in the sphingolipid biosynthesis pathway. Specifically we found that Dfm1 physically interacts with the SPOTS complex which is composed of serine palmitoyltransferase (SPT) enzymes and accessory components, critical for catalyzing the first rate-limiting step of the sphingolipid biosynthesis pathway. We demonstrate for the first time that Dfm1 has a role in ER-Golgi export, a function that is independent of Dfm1s canonical ERAD retrotranslocation function. Specifically, we show that loss of Dfm1 results in the accumulation of phosphorylated Orm2 (a negative regulator of SPT) at the ER, suggesting a novel role for Dfm1 in trafficking Orm2 from the ER and its subsequent degradation by EGAD (Endosome and Golgi associated degradation). Moreover recruitment of AAA ATPase Cdc48 by Dfm1 which is critical for its role in ERAD retrotranslocation is dispensable for Dfm1s role in ER export. Given that the accumulation of human Orm2 homologs ORMDLs are associated with many maladies our study serves as a molecular foothold for understanding how dysregulation of sphingolipid metabolism leads to various diseases.

B355/P2034

Topological Regulation of a Transmembrane Protein by Luminal-to-Cytosolic Retrotranslocation of Glycosylated Sequence

J. Wang*, S. Han*, J. Ye; Department of Molecular Genetics, UT Southwestern Medical Center, Dallas, TX.

* Co-first authors.

Transmembrane proteins must adopt proper topology to perform their functions. The topology of a membrane protein, which depicts the orientation of their soluble segments relative to the plane of membranes, are thought to be fixed and determined by their primary sequence. This assumption has been challenged by recent observations demonstrating that some transmembrane proteins can adopt more than one topology, and topological alteration has emerged as a mechanism to regulate transmembrane proteins.

We recently reported that in mammalian cells, ceramide can alter the topology of TM4SF20 (transmembrane 4 L6 family 20). In cells cultured under normal conditions, TM4SF20 primarily exists with the C-terminus in the lumen. This form of TM4SF20 inhibits proteolytic activation of CREB3L1 (cAMP response element binding protein 3-like 1). In cells treated with doxorubicin, a chemotherapeutic reagent, the accumulation of ceramide results in production another form of TM4SF20 with a cytosolic C-terminus. This form of the protein stimulates proteolytic activation of CREB3L1, allowing the transcription factor to active expression of genes that inhibit cancer cell proliferation. Thus, the topology of TM4SF20 is regulated by ceramide level, but the mechanism for topological regulation of TM4SF20 was obscure.

In the current study, unexpectedly, we uncovered a retrotranslocation process that plays an important role in the topology regulation. We demonstrated that TM4SF20 is synthesized in the endoplasmic reticulum (ER) with a cytosolic C-terminus and a luminal loop before the last transmembrane helix where N132, N148 and N163 are glycosylated. In the absence of ceramide, trafficking of TM4SF20 from ER to Golgi allows complete retrotranslocation of the sequence surrounding glycosylated N163 but not N132 from lumen to cytosol. Accompanying this retrotranslocation, the C-terminus of the protein is relocated from cytosol to lumen. Ceramide inhibits the retrotranslocation process by delaying the ER-to-Golgi traffic of TM4SF20, thereby causing accumulation of the ER form of the protein. The retrotranslocation event was revealed by a novel method we developed to determine the localization of N-linked glycosylation sites by PNGase F treatment on sealed microsomes: N-Glycans in the cytosol are trimmed without detergent, while those in the lumen require detergent to be accessible by PNGase F. Our observations suggest that topology of a transmembrane protein may not be fixed once the protein is synthesized, and it can be altered through retrotranslocation. Thus, in addition to ER-associated degradation (ERAD) of transmembrane proteins, retrotranslocation may also play a critical role in regulating the topology of these proteins.

B356/P2035

Endoplasmic reticulum is involved in cell membrane repair

Y. Hirose[1], R. Yamanaka[2], **K. Miyake**[3]; [1]Sch. Med., Int. Univ. Health & Welfare, Narita, JAPAN, [2]Sch. Health Sci. Narita, Int. Univ. Health & Welfare, Narita, JAPAN, [3]Cent. Basic Med. Res. Narita, Int. Univ. Health & Welfare, Narita, JAPAN.

Plasma membrane disruption is repaired by mechanism involving Ca^{2+}-regulated exocytosis, but the origin of these vesicles is unknown. Using the super-resolution system Zeiss Airyscan (Airyscan), we have successfully imaged the dynamics of Sec61βGFP-expressing ER during the repair of two-photon laser-induced membrane damage in BS-C-1 cells. The tubular endoplasmic reticulum collapsed instantly, and numerous ER vesicles were formed near the damaged membrane site. However, in the presence of extracellular calcium, these segmented vesicles did not fuse to the plasma membrane and slowly fused each other to form the original tubular ER. On the other hand, staining of unfixed damaged membranes with calnexin antibody resulted in staining, strongly supporting the fusion of the ER with the damaged area. Furthermore, Airyscan observation with Brefeldin A (BFA), which inhibits retrograde transport from the ER to the Golgi sac, revealed tubes extending from the ER to the plasma membrane during membrane repair and subsequent vesicle columns. Those segmented vesicles were observed to slowly fuse into the damaged membrane like a meteor shower. This suggests that the BFA is putting a brake on the fusion of vesicles that would normally fuse to the damaged membrane at high speed. Finally, a plasma membrane repair assay labeled for ATP leakage showed that BFA clearly inhibits plasma membrane repair. This suggests that plasma membrane repair requires calcium influx and that the necessary speed at which vesicles fuse to the damaged membrane is not captured by our conventional microscopy techniques. In contrast, we did not observe BFA-induced membrane fusion of Sec61β-GFP in skeletal muscle fibers, nor did we observe any effect of Sec61β-GFP on membrane repair.

B357/P2036

IP6K1- a novel regulator of gastric chief cell secretion in mammalian digestion physiology

J. Sen, R. Bhandari; Laboratory of Cell Signalling, Centre for DNA Fingerprinting and Diagnostics, Hyderabad, INDIA.

Inositol hexakisphosphate kinases (IP6Ks) catalyse the synthesis of the inositol pyrophosphate 5-IP7 (5-diphosphoinositol pentakisphosphate) from IP6 (inositol hexakisphosphate). Mice lacking the IP6K1 enzyme show different physiological defects including male infertility, delay in blood clotting, reduced insulin levels, and lower body weight compared to wild type mice. The expression of IP6K1 is conserved throughout the gastrointestinal tract epithelium, including stomach, ileum, colon, and rectum. We have observed that IP6K1 is highly expressed in isolated mouse gastric glands. Chief cells of the stomach secrete enzymes like pepsin and gastric lipase that help in digestion of protein and lipid ingested in food. Immunofluorescence studies show that IP6K1 is localized to chief cells in the gastric gland. Pyloric ligation of the stomach followed by carbachol treatment revealed that gastric secretion from IP6K1 knockout mice has lower levels of pepsin and gastric lipase compared with wild type mice. IP6K1 knockout mice also display a reduced number of chief cells in their gastric glands. Chief cells lacking IP6K1 show a reduction in the number of secretory granules containing pepsinogen C and gastric lipase, and also show defective Golgi morphology. In the AGS gastric cancer cell line, CRISPR mediated knockout of IP6K1 led to reduced granular intensity of pepsinogen C, correlating with the phenotype observed in mouse gastric glands. Using mass spectrometry analysis, we have identified IP6K1 binding proteins in

AGS cells that are involved in vesicle formation and exocytosis. We propose that IP6K1 expression in gastric chief cells plays an important role in the regulation of secretory granule formation and digestion physiology in mammals.

B358/P2037

Jagn1 isoforms are tissue specific critical regulators of zebrafish development

H. M. Rosengrant, P. E. Vanwinkle, E. Sztul, E. J. Lee; Department of Cell, Developmental and Integrative Biology, University of Alabama At Birmingham, Birmingham, AL.

The Jagunal homolog 1 (Jagn1) protein is a transmembrane endoplasmic reticulum (ER) component that cycles at the ER-Golgi interface. Jagn1 is highly evolutionarily conserved from humans to plants, suggesting that it is essential to support one or more fundamental cellular process(es). Jagn1 was first identified in the fruit fly species D.melanogaster as an essential component for egg development, possibly playing a role in the trafficking of yolk proteins. Subsequent studies showed that humans with homozygous mutations in the Jagn1 gene exhibit Severe Congenital Neutropenia caused by impaired neutrophil maturation. Neutrophils obtained from these patients contain decreased numbers of secretory granules and enlarged ERs, suggesting a possible ER to Golgi traffic defect.The sequence of Jagn1 does not have any similarities to any other protein, but Jagn1 is a tetraspanin, and therefore belongs to a group of proteins known to “chaperone” cargo proteins during their trafficking between compartments. Consistent with that function, Jagn1 contains sorting motifs that may implicate it in trafficking cargo proteins in the anterograde and retrograde directions between the ER and the Golgi. To study the organismal functions of Jagn1, we have a developed a zebrafish D.rerio model system. Zebrafish have two JAGN genes: Jagn1a (expressed almost exclusively in the brain) and Jagn1b (expressed ubiquitously). We utilized the CRISPR/Cas9 system to generate fish deleted of either JAGN. We uncovered that the Jagn1a knockout zebrafish larvae display no obvious phenotypes and grow to adulthood, but exhibit a neuronal defect reflected in altered circadian rhythm. In contrast, Jagn1b knockout larvae die early in development, with none reaching adulthood. We are currently probing the physiological basis of larval death.To understand the molecular role that Jagn1 performs in cells, we aim to elucidate what other proteins Jagn1 interacts with in cells. We have generated Jagn1 constructs tagged with the BirA* biotin ligase at either the N or the C-terminus; that when supplemented with biotin will biotinylate proteins neighboring Jagn1. Such biotinylated proteins are then purified on streptavidin beads and identified via mass spectrometry. A number of putative interactors have been identified and will be tested for direct binding. Jagn1 has also been implicated in a cellular response to ER stress, and we are also investigating if and/or how the Jagn1 interactome changes during cellular stress. Together, our studies provide a fundamental new insight into the role of Jagn1 in cellular and organismal homeostasis.

B359/P2038

Tmed10 regulates the secretion of insulin like growth factor 2 for myoblast differentiation

F. Yang[1], **T. LI**[1], Y. Heng[1], S. Zhou[1], G. Wang[1], J. Wang[2], X. Chen[1], Z.-P. Yao[2], Z. Wu[1], Y. Guo[1]; [1]Hong Kong University Sci & Technol, Hong Kong, China, [2]The Hong Kong Polytechnic University, Hong Kong, China

The insulin-like growth factor 2 (IGF2) plays critical roles in cell proliferation, migration, differentiation, and survival. Despite its importance, the molecular mechanisms mediating the secretion of IGF2 remain unclear. Here we utilized a Retention Using Selective Hook (RUSH) system to analyze molecular

mechanisms that regulate the secretion of IGF2. We found that a type I transmembrane protein, TMED10, is essential for the secretion of IGF2 and for differentiation of mouse myoblast C2C12 cells. Further analyses indicate that the residues 112-140 in IGF2 are important for the secretion of IGF2 and these residues directly interact with the GOLD domain of TMED10. We then reconstituted the release of IGF2 into COPII vesicles. This assay suggests that TMED10 regulates the packaging of IGF2 into COPII vesicles to be efficiently delivered to the Golgi. Moreover, TMED10 also regulates ER export of newly synthesized TGN-localized cargo receptor, sortilin, which subsequently regulates TGN export of IGF2. These analyses indicate that TMED10 is critical for IGF2 secretion by directly regulating ER export and indirectly regulating TGN export of IGF2, providing novel insights into the trafficking of IGF2 for myoblast differentiation.

An in vitro vesicle formation assay to reveal novel cargo proteins that depends on AP-1 or AP-4 to be exported out of the trans Golgi network

Z. PENG, J. Fan, Y. GUO; Hong Kong University of Science and Technology, Hong Kong, China

The *trans*-Golgi network (TGN) is an essential station of protein sorting in the secretory transport pathway. The fidelity of protein transport depends on package of specific cargo proteins into transport vesicles, followed by delivery to their destinations. Adaptor protein (AP) complexes are key players that mediate protein sorting at the TGN. Although significant progresses have been achieved in understanding the underlying molecular mechanisms, the spectrum of cargo proteins that depends on a specific AP complex to be incorporated into transport vesicles remains largely unclear. Here, we performed an in vitro vesicle formation assay using wild type HeLa cells or HeLa cells knockout (KO) of the gamma subunit of AP-1 or the epsilon subunit of AP-4. Through this approach, we reconstituted the requirement of AP-1 or AP-4 to package their clients, Vangl2 and ATG9A, into transport vesicles. We then performed label-free quantitative mass spectrometry analyses of the isolated vesicles from wild type cell or KO cells. This quantitative analyses revealed specific clients of AP-1 and AP-4. Further analyses indicate that one of these identified cargo proteins, 45 kDa calcium-binding protein (Cab45), depends on AP-1 to be enriched into TGN-derived vesicles. Our study identified novel AP-1 and AP-4 clients and indicates that the vesicle formation assay is a powerful approach to reveal novel cargo clients of specific cargo adaptors.

Characterization of the Distribution and Kinetics of the Yeast Golgi Glycosylation Machinery

C. F. Lee-Smith, B. S. Glick; University of Chicago, Chicago, IL

A core function of the Golgi apparatus is the post-translational modification of secretory cargoes, primarily through N- and O-linked glycosylation. There is a long-standing assumption that Golgi glycosylation enzymes are arranged in a polarized distribution that matches the order of oligosaccharide processing. However, the distribution of yeast glycosylation enzymes has not been rigorously evaluated in the context of Golgi maturation. Here, we describe an optimized method for the fluorescent tagging and visualization of yeast glycosylation enzymes, and we outline steps for achieving a precise mechanistic understanding of the intra-Golgi distribution of the glycosylation machinery.
Functional tagging of yeast glycosylation enzymes is challenging. These enzymes are type II integral membrane proteins. The short N-termini are critical for Golgi localization, and the C-termini are exposed

to an oxidizing luminal environment that can cause misfolding of fluorescent tags. C-terminal tagging of certain glycosylation enzymes such as Och1, Kre2, and Mnn1 with an oxidation-resistant GFP variant results in missorting of the proteins to the vacuole, presumably due to recognition by a quality control system. We found that an internal truncation of the vacuolar hydrolase receptor Vps10 improves the localization of Golgi enzymes and reduces their missorting to the vacuole. The additional deletion of a Vps10 homolog, which we term Vth3, further enhances the Golgi localization of Och1.
This strain background will be critical for assessing the arrival and departure kinetics of yeast glycosylation enzymes. We will perform kinetic analyses of Och1 and Mnn1, which are the initiating and terminating enzymes for N-linked glycosylation, respectively, and also of Kre2 and other enzymes involved in glycosylation. Kinetic data will enable us to determine when each enzyme is present during Golgi maturation, and which membrane traffic pathway each enzyme follows to recycle within the Golgi. The results will provide the first comprehensive map of Golgi glycosylation enzyme distribution in any organism.

Auto-inhibitory interactions of Sec7, master regulator of the Golgi complex

B. Brownfield, J. Fromme; Cornell University, ITHACA, NY

In eukaryotes, protein and lipid secretory trafficking is orchestrated by the Golgi apparatus where proteins are modified and sorted in a cascade of functionally distinct compartments. The composition of these compartments is maintained primarily by vesicular traffic facilitated by Arf and Rab GTPases. These GTPases are regulated by a GTP/GDP cycle facilitated by Guanine Nucleotide Exchange factors (GEFs) and GTPase Activating Proteins (GAPs) to induce GDP/GTP exchange and GTP hydrolysis respectively. Arf1 and its close paralogs are required for virtually all vesicle biogenesis events at the Golgi complex. At the final compartment, the *trans*-Golgi network, these vesiculation events are tightly regulated to balance membrane flux through endosomal and secretory pathways. In budding yeast, Arf1 is activated at the *trans*-Golgi network by the Arf GEF Sec7, the homolog of the human ARFGEF/BIG proteins. Previous work has determined that Sec7 is regulated by autoinhibition, positive feedback, and GTPase crosstalk, yet the mechanistic basis for these regulatory features is unknown. To understand how Sec7 is regulated, I have determined the structure of the flexible Sec7 dimer by cryoEM at 4.9 Å resolution. Focused refinements on individual monomer subunits improved resolution to 3.8 Å, sufficient for molecular model building. This structure reveals the mechanism for Sec7 autoinhibition: an interaction between the catalytic GEF domain and the HDS domains occlude the catalytic surface. AlphaFold modeling predicts the putative active conformation, with the GEF domain positioned near the putative membrane binding site. Functional studies are currently underway to determine the physiological relevance of our structural findings.

Selective ER-Golgi traffic of G protein-coupled receptors: role of the ER-localized C1orf27-UFSP2 complex

X. Xu, H. Li, G. Wu; Augusta University, Augusta, GA

G protein-coupled receptors (GPCRs) regulate a wide variety of cell functions under physiological and pathological conditions; however the molecular mechanisms underlying their anterograde surface transport after synthesis in the endoplasmic reticulum (ER) are not well defined. In *C. elegans*, ER-

localized odr-4 and its partner protein odr-8 have been implicated in the delivery of olfactory GPCRs to the cilia of chemosensory neurons, and we have recently shown that C1orf27, human homolog of odr-4, controls the ER export of GPCRs in mammalian cells. Here, we demonstrate that C1orf27 forms a stable complex with Ufm1-specific protease 2 (UFSP2), human homolog of odr-8, leading to the recruitment of UFSP2 to the ER membrane in mammalian cells. We also show that, similar to C1orf27, UFSP2 knockout significantly impedes the ER-to-Golgi export kinetics of a group of GPCRs, without affecting the transport of non-GPCR plasma membrane proteins. More intriguingly, simultaneous depletion of C1orf27 and UFSP2 does not cause more deleterious effects on receptor transport, suggesting that they act functionally as one unit. Furthermore, C1orf27, but not UFSP2, directly associates with some GPCRs the complex regulates, such as α_2-adrenergic receptors. Taken together, these data demonstrate an important role for the C1orf27-UFSP2 complex formed at the ER membrane in the ER-Golgi traffic of nascent GPCRs by virtue of its ability to interact directly.

Exploring alternative secretion pathways of proteins involved in *C. elegans* eggshell formation

L. M. Kulber, S. Olson; Molecular Biology, Pomona College, Claremont, CA.

In eukaryotes, protein trafficking is a ubiquitous process in which proteins are distributed to organelles throughout the cell and secreted to the extracellular space. The vast majority of secreted proteins encode signal peptides which direct them through a canonical secretory pathway mediated by COPII-coated vesicles. In metazoans, certain proteins are secreted to form an extracellular matrix around oocytes and embryos (known as the eggshell in *Caenorhabditis elegans*). Previously, we identified three eggshell proteins, PERM-2, PERM-4, and CBD-1, whose secretion was unaffected by the RNAi depletion of SEC-16A.1, an essential protein of the COPII coat. This was a surprising finding since all structural proteins of the *C. elegans* eggshell contain signal peptides that should direct them through the canonical secretory pathway. We are exploring three hypotheses that could explain this finding. (1) SEC-16A.2 (a homolog of SEC-16A.1) compensates for SEC-16A.1 depletion. We deleted *sec-16A.2* via CRISPR-Cas9. PERM-2, PERM-4, or CBD-1 secretion was unaffected in these strains. (2) COPII coat formation is only partially dependent on SEC-16A.1. We knocked down other COPII coat proteins such as SEC-23. Previous *sec-23(RNAi)* experiments led to the deterioration of the gonad, resulting in ambiguous data. Next steps include *sec-24a(RNAi)* and *sec-23* feeding RNAi which should result in a less severe phenotype. (3) PERM-2, PERM-4, and CBD-1 are secreted via unconventional protein secretion (UPS). If the first two hypotheses fail to explain the differential secretion phenotypes, we will conduct a high-throughput RNAi screen to identify proteins implicated in unconventional secretion. With over 30% of human genes encoding a signal peptide sequence, it is important to comprehensively understand the mechanisms by which proteins are variably trafficked and secreted in a cargo-specific manner.

Extracellular Vesicles and Unconventional Secretion

The Exocyst Complex Directs the Exocytic Trafficking of Multivesicular Endosomes for Exosome Secretion

D. Liu[1], K. Tao[2], B. Wu[1], M. Szczpaniak[2], M. Rames[3], C. Yang[1], T. Svitkina[1], Y. Zhu[1,4], Z. Yu[1], X. Nan[2,3], W. Guo[1]; [1]Department of Biology, School of Arts & Sciences, University of Pennsylvania, Philadelphia, PA, [2]Program in Quantitative and Systems Biology, Department of Biomedical Engineering, Oregon Health and Science University, Portland, OR, [3]Cancer Early Detection Advanced Research Center, Knight Cancer Institute, Oregon Health and Science University, Portland, OR, [4]Department of Pathology & Laboratory Medicine, Children's Hospital of Philadelphia Research Institute, Philadelphia, PA.

Introduction: Exosomes are secreted to the extracellular milieu when multivesicular endosomes (MVEs) dock and fuse with the plasma membrane. However, MVEs can also fuse with lysosomes for degradation. How MVEs are directed to the plasma membrane rather than to lysosomes is unclear. Here we aim to study whether the exocyst, an octameric protein complex consisting of Sec3, Sec5, Sec6, Sec8, Sec10, Sec15, Exo70 and Exo84, mediates MVE trafficking to the plasma membrane for exosome secretion. **Methods**: shRNAs that target members in the exocyst complex were used to construct the stable exocyst subunit knockdown cell lines. Exosome secretion from these cell lines was measured by Nanoparticle Tracking Analysis (NTA). Exosomes were then collected by ultracentrifugation and examined for the levels of exosomal markers such as CD63 and Tsg101. MVEs along with exocyst subunits were analyzed using the above cell lines by live-cell microscopic imaging, electron microscopy, and DNA-PAINT super resolution imaging. Moreover, ectopic expression of Sec3 on mitochondria membrane was used to monitor whether MVEs are targeted to mitochondria rather than the plasma membrane. **Results**: Knockdown of subunits the exocyst complex led to intracellular accumulation of MVEs and reduced the secretion of exosomes into the culture media. Chemical inhibition of the exocyst subunit Exo70 also led to defects in exosome secretion and MVE trafficking. Exocyst partially co-localize with MVEs in cells. Ectopic targeting of the exocyst subunit Sec3 to mitochondria directed members of the exocyst and MVEs to the mitochondria rather than the plasma membrane. **Summary/Conclusion**: The exocyst complex mediates the targeting of the MVEs to the plasma membrane for exosome secretion. **Funding**: NIH grants R35 GM141832 to W.G.

B366/P2045

Biogenesis of neuronal exosomes via ESCRT machinery

E. C. Dresselhaus, M. Rozencwaig, R. Soslowsky, M. F. Pescosolido, B. Ermanoska, A. A. Rodal; Brandeis University, Waltham, MA.

Exosomes arise from fusion of endosomal multivesicular bodies (MVB) with the plasma membrane, releasing their intraluminal vesicles (ILVs) into the extracellular space. These vesicles can serve degradative or signaling functions in the brain and are implicated in the spread and clearance of neuropathological proteins. At present, the mechanisms by which cells determine whether an MVB fuses with the plasma membrane, rather than canonical fusion with lysosomes, are poorly understood. This is particularly true in neurons, where these organelles form and mature differently in the somatodendritic compartment compared to synapses. The *Drosophila* larval NM serves as a powerful model synapse for the study of the trafficking and function of exosome cargoes. Here, we show for the

first time that exosome release at this synapse requires a canonical pathway for ILV formation mediated by the Endosomal Sorting Complex Required for Transport (ESCRT) proteins. Presynaptic knockdown of the ESCRT components *tsg101*, *shrub,* and *vps4* leads to a postsynaptic loss of a variety of exosome cargoes as well as a presynaptic buildup of these cargoes within intracellular compartments. This finding provides the opportunity to investigate how ILV formation controls the trafficking and function of neuronal exosome cargoes. We found by live imaging that neuronal loss of *tsg101* also impacts axonal trafficking of APP, leading to accumulation along the axon and impaired retrograde trafficking, without affecting trafficking of mitochondria. Remarkably, the signaling activities of the exosome cargoes Synaptotagmin-4 and Evi/Wingless are preserved upon loss of ESCRT machinery, despite being trapped in presynaptic terminals, suggesting that these cargoes function cell autonomously in the neuron, and do not require transsynaptic transfer. Our results indicate that exosome release depends on ESCRT machinery and may serve primarily as a proteostatic rather than intercellular signaling mechanism for some cargoes at this synapse.

B367/P2046

Alpha-Synuclein Regulates the Release of Extracellular Vesicles in Human Cutaneous Melanoma Cells

N. Aloy[1], M. W. Graner[2], C. Coughlan[2], S. N. Witt[1]; [1]Biochemistry & Molecular Biology, Louisiana State University Hlth Sci Ctr, Shreveport, LA, [2]University of Colorado Anschutz Medical Campus, Denver, CO.

Alpha-Synuclein **(**α-syn) is a small, intrinsically disordered protein of the synuclein family, which has multiple functions in cells. In neuronal cells, α-syn localizes to the nucleus, synaptic terminal, binds to the plasma membrane and has a role in both endocytosis and exocytosis. α-syn has a known role in promotion of Parkinson's disease (PD), and emerging evidence suggests that α-syn is one of the key proteins that is correlated to an increased incidence of melanoma in PD patients. The role of α-syn in melanoma progression is poorly understood. α-Syn was reported to colocalize to the multivesicular bodies (MVBs) and plasma membrane in both melanoma and neuronal cells but the physiological function of α-syn in melanoma cells remains a mystery. α-Syn is found in exosomes of PD patients and in the serum of melanoma patients. α-syn is also involved in the assembly of SNARE proteins and dilation of fusion pore in neuronal cells. We hypothesized that α-syn regulates the trafficking and secretion of modulators of melanoma progression through extracellular vesicles. We found a significant decrease in the release of extracellular vesicles (EVs) in *SNCA*-knock out (*SNCA*-KO) cells compared to control SK-MEL-28 melanoma cells, and EV release was restored upon re-expression of α-syn using lentivirus (in one of the two knock-out clones). One of the knock-in (KI) clones did not rescue the EV-release and work is going on to validate that. We further found that the level of the protein CD81, one of the most common EV markers, was significantly decreased in *SNCA*-KO clones, and the expression of CD81 was rescued upon lentiviral re-expression of α-syn. Interestingly, the level of the protein CD63 was increased in *SNCA*-KO cells compared to the control and *SNCA*-KI SK-MEL-28 cells. Based on these findings, we suggest that α-syn functions in the pathway that releases EVs, perhaps by modulating the levels of CD63 and CD81.

B368/P2047

Ubiquitination of FMR1 by Trim25 determines miRNA selectivity

K. E. King, P. Ghosh, **A. L. Wozniak**; University of Kansas Medical Center, Kansas City, KS.

Background: The mechanisms by which exosomal cargo loading occurs are not fully understood. We previously showed that inflammasome activation results in the exosomal loading of the RNA binding protein FMR1 and its associated microRNA, mir-155-5p. The mechanism by which this occurs is dependent on cleavage of RILP (Rab interacting lysosomal protein). RILP is a Rab7 effector that directs trafficking through the endo-lysosomal pathway. It undergoes caspase-1 dependent cleavage during inflammation, resulting in altered trafficking of intracellular vesicles including the multivesicular body, the site of exosome biogenesis. Interestingly, the cleavage status of RILP directly influences which cargo are put into the exosome suggesting the existence of distinct RILP-mediated sorting mechanisms. The **aim** of this study is to determine the mechanism by which FMR1 and cleaved RILP (cRILP) cooperate to selectively load specific exosomal cargo. **Results**: The Endosomal Sorting Complex Required for Transport (ESCRT) consists of four distinct complexes and exosome cargo sorting involves a ubiquitinated protein being recognized by the ESCRT-0 complex. To determine if FMR1 loading is ESCRT-dependent, we first examined its ubiquitination status. We found that after inflammasome activation, FMR1 is K63-ubiquitinated and expression of the cRILP alone is sufficient to promote this ubiquitination. Expression of a non-cleavable RILP did not promote the K63-ubiquitination of FMR1. We further found that the E3 ligase TRIM25 is responsible for not only ubiquitinating FMR1 but also inducing its loading into the exosome by promoting an interaction with the Hrs component of the ESCRT-0 complex. Interactions between FMR1 and Hrs are lost when TRIM25 is knocked down. The loss of TRIM25 prevents the exosomal enrichment of FMR1 as well as its associated miRNA, mir-155-5p without affecting the ability of FMR1 to bind miR-155-5p. **Conclusion**: Altogether, the results suggest that inflammation-mediated loading of FMR1 and its associated microRNAs are dependent on cRILP-mediated recruitment of TRIM25 and eventual recognition by the exosome biogenesis machinery. This study provides insight into the mechanism behind inflammation-mediated selective exosome loading and enhances our general understanding of exosome cargo loading.

Secretion of DNA and nuclear envelope-derived exosomes from the back of actively migrating neutrophils

S. B. Arya[1,2], S. P. Collie[3], C. A. Parent[1,2,4]; [1]Department of Pharmacology, University of Michigan, Ann Arbor, MI, [2]Life Sciences Institute, Ann Arbor, MI, [3]Cellular and Molecular Biology Graduate Program, University of Michigan, Ann Arbor, MI, [4]Department of Cell and Developmental Biology, Ann Arbor, MI.

Neutrophils are the first line of defense in response to injury or infection. Once neutrophils reach affected sites, they contain the area by phagocytosing pathogens and releasing powerful proteases from cytoplasmic granules. In addition, neutrophils release their genomic DNA, studded with toxic enzymes, which ensnare and kill microbes in neutrophil extracellular traps (NETs). Excessive NET release aggravates inflammation, delays resolution, and subsequently leads to host tissue injury during various autoimmune diseases, and infections. Neutrophils migrating towards shallow chemoattractant gradients emanating from injured/infected tissues amplify their recruitment range by releasing the secondary chemoattractant leukotriene B_4 (LTB_4). LTB_4 is synthesized from arachidonic acid through the action of the cytosolic enzyme 5-lipoxygenase (5-LO), the endoplasmic reticulum/nuclear envelope-resident

protein 5-lipoxygenase activating protein (FLAP), and leukotriene A_4 hydrolase. The LTB_4 synthesizing enzymes and LTB_4 are packaged in and released from extracellular vesicles called exosomes. We recently showed that the biogenesis of LTB_4-containing exosomes originates at the nuclear envelope (NE) of activated neutrophils. We found that the neutral Sphingomyelinase 1 (nSMase1)-dependent generation of ceramide-rich lipid-ordered membrane microdomains is required for FLAP and 5-LO clustering at the NE, and subsequent NE-budding. With nano-scale microscopic resolution achieved by 4x isotopic expansion of samples, we found 5-LO-positive intraluminal vesicles within NE-resident Lamin B Receptor (LBR)-positive limiting membranes, generating NE-derived multivesicular bodies (NE-MVBs). Interestingly, we discovered that both NE-derived MVBs and exosomes are distinct from conventional plasma membrane-derived CD63-positive MVB/exosomes. We also observed the presence of DNA in the lumen of the NE-MVBs. Using SYTOXgreen, a membrane-impermeable DNA-binding dye, we visualized in real time the secretion of DNA from the back of chemotaxing neutrophils - a process that was dependent on nSMase1 activity and on the presence of LBR, which is known to bind DNA. We further determined that decondensed chromatin is present in the lumen of NE-MVBs and found that increasing chromatin decondensation, by inhibiting histone deacetylases (HDAC), increases NET secretion. Finally, we determined that hexadecenal, the end metabolite of the sphingomyelin pathway and a known inhibitor of HDAC, promotes DNA packaging in NE-MVBs, thereby providing a physiological pathway in the regulation of NET release. Taken together, our study provides novel mechanistic insights into an inside-out pathway of DNA and exosome secretion originating from the NE of activated neutrophils.

B370/P2049

Spatiotemporal Imaging Tools for Studying The Role of Exosomes in Migrating Cancer Cells

B. Sung, A. Weaver; Vanderbilt University, Nashville, TN.

Exosomes are a type of small extracellular vesicle (EV) that are actively secreted from cells and originate from multivesicular endosomes. Recently, the mechanisms by which exosomes mediate cell-cell communication and regulate cellular physiology and behavior have been investigated using live imaging techniques visualizing the spatial and temporal dynamics of exosome secretion and interactions with cells. Here, we introduce several spatiotemporal imaging tools for studying the function and secretion of exosomes, and demonstrate their utility in visualization of secreted exosomes in 3D culture and in vivo. Using a pH-sensitive, stable live cell reporter of exosome secretion, pHluorin_M153R-CD63, we identify a key role for exosomes in promoting leader-follower behavior during cancer cell migration in 2D and 3D environments. These findings are complemented by experiments showing that exosome secretion drives directionally persistent migration of cancer cells in a topologically defined electrospun fiber environment. Finally, using a combination of pH-sensitive and non-pH-sensitive fluorescent tags, we visualize multiple steps of exosome secretion and uptake in migrating cancer cells. Overall, we find that dynamic exosome secretion drives directionally persistent migration and quorum sensing behavior.

B371/P2050

Annexin A6 mediates calcium-dependent exocytosis of multivesicular bodies in intact and streptolysin O-permeabilized cells

J. M. Ngo, J. K. Williams, R. Schekman; Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA.

Exosomes are an extracellular vesicle (EV) subtype that is exported to the extracellular milieu upon fusion of multivesicular bodies (MVBs) with the plasma membrane. Exosomes have elicited broad interest due to their utility as disease biomarkers and potential role in intercellular communication. Despite this interest, the molecular mechanisms underpinning exosome secretion are incompletely understood. To assess the molecular determinants underlying exosome secretion, we developed sensitive and robust cellular and *in vitro* biochemical assays to measure exosome secretion. Our results demonstrate that exosome secretion is coupled to Ca^{2+}-dependent plasma membrane repair elicited by treatment with either a bacterial pore-forming toxin or mechanical stress. Using a targeted proteomics approach, we identify Annexin A6 (ANXA6), a well-known plasma membrane repair protein, as a MVB binding protein and demonstrate that it is required for Ca^{2+}-dependent exosome secretion both in cells and *in vitro*. Overall, our results suggest that cells employ MVBs as a membrane source for plasma membrane lesion repair during physiological mechanical stress or bacterial infection, and that this repair process results in the coincident egress of exosomes into the extracellular space. We propose that this unconventional secretion process may contribute significantly to the heterogeneity of EVs in biological fluids.

B372/P2051

Endolysosomal fusion attenuates extracellular vesicle biogenesis

G. V. Shelke, C. D. Williamson, M. Jarnik, J. S. Bonifacino; NIH, Bethesda, MD

Intercellular crosstalk is critical for the maintenance of cellular homeostasis and it is partly mediated by secreted factors including extracellular vesicles (EVs). EVs are membrane-bound, nano-sized particles that carry bioactive molecules such as proteins, lipids and nucleic acids. EVs are widely used as biomarkers and potential therapeutic agents. A subset of small EVs (sEVs) known as exosomes are released from the cell by fusion of multivesicular bodies (MVBs) with the plasma membrane. This process is alternative to the more extensively characterized fusion of MVBs with lysosomes. However, the conditions and protein machinery that control the fusion of MVBs with the plasma membrane versus lysosomes are poorly understood. Our work addresses the role of endolysosomal fusion and positioning in the regulation of exosome biogenesis and release. The BLOC-1-related complex (BORC) and Arf-like GTPase-8 (ARL8) are two components of the machinery that regulates both endolysosomal fusion through recruitment of the homotypic fusion and vacuole protein sorting (HOPS) complex, and endolysosomal positioning through recruitment of the kinesins KIF1B and KIF5B. We used various biochemical and microscopic approaches to examine exosome biogenesis and release in cells with knock out (KO) or knock down (KD) of BORC, ARL8, HOPS or KIF1B-KIF5B. We found that BORC-, ARL8-, and HOPS-KO cells displayed enhanced exosome secretion. In contrast, exosome secretion was unaffected by KIF1B-KIF5B KO under basal conditions. These findings indicated that HOPS-mediated fusion of MVBs with lysosomes decreases the pool of exosomes available for extracellular release. In contrast, anterograde transport of MVBs toward the cell periphery did not influence exosome release. Further analyses by transmission electron microscopy showed that BORC- and ARL8-KO cells loaded with

horseradish peroxidase exhibited enlarged MVBs full of intraluminal vesicles (precursors of exosomes). Additionally, BORC- and ARL8-KO cells exhibited reduced transport of internalized EGF, EGF-receptor and dextran, as well as newly-synthesized cathepsins, to lysosomes, all consistent with a block in endolysosomal fusion. In summary, our studies have identified a key regulatory step for exosome biogenesis, by demonstrating that HOPS-mediated fusion of MVBs with lysosomes attenuates exosome formation and ensuing release

B373/P2052
Identification of autophagy-related genes regulating unconventional secretion of amyloid-β
J. Kim, T. Kim, S. Lee; INHA UNIVERSITY, Incheon, Korea, Republic of

It has recently been reported that unconventional protein secretion of leaderless cytosolic proteins is important for various cellular functions such as inflammation, cell signaling and neurodegeneration. Some inflammatory cytokines, such as IL-1β, IL-18 and HMGB1, are known to be secreted by unconventional protein secretion called secretory autophagy. Latest studies have shown that neurotoxic proteins, such as α-synuclein, DJ-1 and amyloid-β, are secreted by unconventional protein secretion. Extracellular accumulation of amyloid-β is a prominent pathological hallmark of AD, but the secretion of amyloid-β has not been studied much. While the canonical degradative autophagy pathway is well established, it is unclear as to whether the players in degradative autophagy pathway also participate in the secretory autophagy pathway. In this study, we investigated the role of secretory autophagy machinery in secretion of neurotoxic proteins, such as amyloid-β and DJ-1. We found secretion of neurotoxic proteins was reduced in cells lacking a specific set of autophagy-related genes. A detailed mechanism will be shown in the presentation.

Rab GTPases

B374/P2053
An InR-Vps34/PI3P-Kinesin-2 axis accelerates the anterograde axonal transport of a subset of Rab4-associated vesicles in*Drosophila*
K. Singh, A. Sarkar, S. Das, K. Ray; Department of Biological Sciences, Tata Institute of Fundamental Research, Mumbai, INDIA.

Rab4 GTPase organizes endosomal sorting essential for maintaining the balance between recycling and degradative pathways. Elevated Rab4 levels in the CNS have been associated with synaptic atrophy and neurodegeneration in *Drosophila* and humans. Insulin signaling, which activates Rab4-associated membrane trafficking in adipocytes, regulates synaptic plasticity in the CNS. In addition, a reduction in insulin signaling can ameliorate symptoms associated with neurodegeneration and aging. However, the underlying mechanism(s) remain unclear. Using *in vivo* time-lapse imaging of *Drosophila* larvae, we show that insulin signaling in neurons increases the anterograde speed of a subset of Rab4 vesicles through a novel InR-Vps34/PI3P-Kinesin-2 axis, which elevates the overall anterograde flux of these vesicles in the segmental-nerve axons. Further, we find that synaptic influx of Rab4 in CNS of *Drosophila* larvae is periodically altered during development, and is inversely correlated with the synaptic density in this region. Together, these observations delineate a potentially unique role of insulin signaling in stimulating the movement of a subset of Rab4-associated vesicles through the ESCRT complex in axons and its impact on synaptic stability.

B375/P2054

DENND2B functions as an activator of Rab35 to regulate cytokinesis

R. Kumar, V. Francis, M. Ioannou, G. Kulasekaran, E. Banks, A. Córdova, M. Khan, P. McPherson; Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, QC, CANADA.

Cytokinesis is the final stage of cell division. Successful cytokinesis depends on coordinated membrane trafficking pathways regulated by small GTPases including Rabs, molecular switches activated by guanine nucleotide exchange factors (GEFs). Cytokinesis requires the formation of an intercellular cytokinetic bridge (ICB) connecting the two daughter cells that then undergoes abscission, a step that relies on depolymerization of actin. Rab35 recruits MICAL1 to oxidate and depolymerize actin filaments but the activation and recruitment of Rab35 for cytokinesis is not understood. Here we report that DENND2B, a protein previously implicated in cancer and a multiple congenital disorder is required to recruit and activate Rab35 at the ICB for successful abscission. Knockdown (KD) of DENND2B delays abscission timing and results in increased multinucleated cells. Biochemical analysis unexpectedly reveals that the DENN domain of DENND2B interacts with an inactive mutant of Rab35 and functions as a Rab35 GEF whereas the N-terminus of DENND2B interacts with an active mutant of Rab35, suggesting an effector relationship. Functionally, loss of DENND2B causes significant reduction of Rab35 enrichment and overaccumulation of F-actin at the ICB and leads to lagging chromatin at the ICB region. The presence of lagging chromatin is known to activate the NoCut/abscission checkpoint delaying abscission and we discover that DENND2B regulates the abscission checkpoint. Our work thus identifies DENND2B as a crucial player in cytokinetic abscission and provides insight into the multisystem disorder associated with DENND2B mutation.

B376/P2055

The small GTPase *RAB35* coordinates epithelial polarization and cell survival in a human model of epiblast formation

A. Rengarajan, K. Taniguchi; Medical College of Wisconsin, Wauwatosa, WI

The formation of a central lumen in the developing human epiblast is a critical step that occurs during implantation. However, there is a significant knowledge gap in the mechanistic understanding by which epiblast cells initiate polarization and form a central lumen. To uncover key molecular players involved in this process, we recently employed a spatial proteomics approach to profile apical and basolateral membrane territory proteomes of a previously established human pluripotent stem cell-derived model of epiblast formation (hPSC-epiblast model), and identified a cohort of proteins enriched in the polarized membrane territories (Wang *et al.*, *Science Advances* 2021). In particular, using loss- and gain-of function analyses, we revealed a role of RAB35 in regulating apical membrane morphogenesis of developing hPSC-epiblast model. This present study investigates the molecular and cellular mechanisms by which RAB35 controls lumenogenesis of the human epiblast model. Detailed characterizations of the *RAB35*-KO epiblast models showed additional novel defects: *RAB35*-KO epiblast models 1) form ectopic satellite lumens, and 2) are significantly smaller in size. These defects can be rescued through an inducible expression of a wild-type RAB35-GFP fusion construct throughout hPSC-epiblast model development (for 4 days (D4)). Interestingly, a similar rescue is observed when RAB35-GFP is induced during the initial 48 hours (D0-D2), but not when RAB35-GFP is induced at later time points. In controls,

by D1, hPSC form an apicosome, an apically charged membrane bound structure, and, once the apicosomes are formed, cells initiate radial organization, and the apicosomes fuse at the radial center to give rise to a lumen by D2. Intriguingly, *RAB35*-KO hPSC display formation of multiple apicosomes, instead of a singular apicosome as seen in controls. Furthermore, while a central lumen is formed, *RAB35*-KO epiblast models at D2 display an increased number of unfused apicosomes and satellite lumens, suggesting that apicosome fusion event is delayed in the absence of RAB35. Surprisingly, while proliferation rate in *RAB35*-KO epiblast model is comparable to controls, apoptosis rate is significantly higher in the KO background, a likely cause of the reduced size in the *RAB35*-KO epiblast models. Finally, an ectopic expression of a wild-type form of CDC42 Rho GTPase, a known downstream RAB35 effector, leads to a partial restoration of apical membrane defects as well as the increased apoptosis. Taken together, these results reveal previously unrecognized roles of RAB35 in apical membrane formation likely through CDC42, as well as in promoting cell survival.

B377/P2056

Structural basis for specific activation of the Rab11 GTPase by the TRAPPII complex

S. Bagde, J. Fromme; Cornell University, Ithaca, NY

Secretion and endocytic recycling are essential eukaryotic processes that involve transport of protein cargoes to the plasma membrane in membrane-bound vesicles. The formation of these vesicles is regulated by activation of the Rab GTPase Rab11. The activation of GTPases at membrane compartments is dependent on the localization of their specific guanosine exchange factors (GEFs), which catalyze the exchange of GDP with GTP and stabilize the active GTPase on the membrane. The multisubunit TRAPPII complex acts as Rab11 GEF and recruits it to the *trans*-Golgi network (TGN) and recycling endosome (RE) membranes. More than 60 different Rabs are present in mammals and the budding yeast model has 11 different Rabs. Specific localization of each of these Rabs to different membrane compartments is important for determining organelle identity and membrane organization of these compartments. While multiple GTPases and GEFs localize at the TGN, the mechanistic details of how TRAPPII specifically activates Rab11 are unknown. Moreover, another related GEF, the TRAPPIII complex, shares the same catalytic subunits with TRAPPII and yet activates another GTPase, Rab1. A steric gating mechanism has been proposed in which TRAPPII selects against Rab1 based on the length of the C-terminal hypervariable domain. We determined the cryo-EM structure of yeast TRAPPII bound to its substrate Rab11 at an overall resolution of 3.7Å. Analysis of the atomic structure revealed specific interactions between Rab11 and the TRAPPII complex, and how TRAPPII interacts with the membrane. We tested the physiological relevance of these observed interactions using *in vivo* functional studies. We determined that the TRAPPII subunit Trs130 provides a ‘leg’ that lifts the TRAPP catalytic site above the membrane, thereby preventing access to the catalytic site by Rab1. We find that the TRAPPIII complex selects against Rab11 based on repulsive interactions with the catalytic subunits. TRAPPII surmounts these repulsive interactions using subunit Trs120 as a ‘lid’ to enclose the active site. We also observed an alternative conformation of the TRAPPII complex which may facilitate access of Rab11 to the TRAPP catalytic site. Taken together, these experiments reveal the mechanism of specific activation of Rab11 on the membrane by TRAPPII, a key step for initiation of secretory vesicle formation. As Rab11 and the TRAPPII complex are conserved throughout eukaryotes, this mechanism may be widely conserved across all eukaryotic secretory systems.

Structures of full-length LRRK1 and mechanisms of autoinhibition

R. G. Abrisch[1], J. M. Reimer[1], A. Dickey[1], Y. Lin[1], S. Mathea[2], D. Chatterjee[2], D. Alessi[3], S. Knapp[2], M. Daugherty[1], A. E. Leschziner[1], S. Reck-Peterson[1]; [1]University of California San Diego, San Diego, CA, [2]Goethe-Universität, Frankfurt, Germany, [3]University of Dundee, Dundee, United Kingdom

Leucine Rich Repeat Kinase 1 and 2 (LRRK1 and LRRK2) are homologs in the ROCO family of proteins in humans. Despite their shared domain architecture and involvement in intracellular trafficking through phosphorylation of Rab proteins, their disease associations are strikingly different: mutations in LRRK2 are linked to Parkinson's Disease (PD), while those in LRRK1 are linked to osteopetrosis and osteosclerotic metaphyseal dysplasia. Furthermore, all PD-linked mutations in LRRK2 increase kinase activity and are autosomal dominant gain-of-function, while disease-linked mutations in LRRK1 lead to loss of kinase activity and are autosomal recessive loss-of-function. To understand these differences, we solved cryo-EM structures of LRRK1 in its monomeric and dimeric forms. Both differ from the corresponding LRRK2 structures, and the dimer is particularly dissimilar; unlike LRRK2, which is sterically autoinhibited as a monomer, LRRK1 is sterically autoinhibited in a dimer-dependent manner, a state stabilized by two disordered regions of the structure. Strikingly, there is a second level of autoinhibition that only occurs in LRRK1, where the DYG motif in its kinase is prevented from assuming an active conformation. Indeed, LRRK1 phosphorylation of Rab7a in human cells is markedly increased by mutations in LRRK1 that disrupt either autoinhibition mode and further enhanced by disrupting both modes. Our work suggests that LRRK1 has added layers of regulation that are not present in LRRK2. We also discuss our results in the context of the evolution of the LRRK family of proteins.

B379/P2058

Role of Rab4A on intracellular iron transport in MDA-MB-231 breast cancer cells

P. Pampa Mandal, I. Crosbourne, R. Abini-Agbomson, J. Barra, **M. Barroso**; Albany Medical College, Albany, NY

Iron is an essential element for several cell functions and tumor cells demand high amounts of iron for support their cell growth and proliferation. Iron-bound transferrin (Tf) binds to the transferrin receptor (TfR) at the plasma membrane and TfR-Tf complexes are internalized into endosomes, where iron dissociates and is transported into mitochondria for use in heme synthesis and iron-sulfur cluster (Fe-S) biogenesis. Rab4, a marker of early endosome, is responsible for proper sorting and recycling of Tf-TfR complex to plasma membrane. To understand the role of Rab4A isoform in intracellular iron transport in MDA-MB-231 breast cancer cells, we generated stable cells displaying Rab4A knockdown using shRNA or Rab4A knock-out cells using CRISPR. The level of knockdown was assessed by qPCR and immunoblotting and showed significant decrease in Rab4A mRNA and protein expression, respectively. As expected, Rab4A knockdown slows down Tf-TfR recycling. The mitochondrial iron biosensor, RDA, red-fluorescence undergoes rapid quenching upon iron translocation into the mitochondria. Interestingly, Rab4A knockdown in MDA-MB-231 led to increased RDA quenching levels, suggesting elevated mitochondrial iron translocation. Next, we assessed the effect of Rab4A on labile iron pool by conducting Ferro-orange imaging assay. The result demonstrates that Rab4A knockdown lowers the labile iron pool (LIP) in MDAMB231 cells. Therefore, our results indicate that Rab4A knockdown leads to the accumulation of mitochondrial iron and reduced LIP levels. Altered iron acquisition and utilization lead to metabolic

changes which are a hallmark of cancer. Therefore, elucidating the role of Rab4A in intracellular iron transport should further our understanding of the role of mitochondrial iron in breast cancer.

B380/P2059

Dynamics of the Rab11-Rabin8-Rab8 cascade in membrane tubulation and ciliogenesis

I. Saha, Q. Lu, C. J. Westlake; National Cancer Institute, NIH, Frederick, MD

Rabs, a family of GTPases, which function as molecular switches by alternating between a GTP-bound active state and GDP-bound inactive state, play a major role in membrane trafficking that coordinate biogenesis, transport, tethering and fusion of membrane associated structures in cells. Guanine nucleotide exchange factors (GEF) promote GTP binding while GTPase-activating proteins (GAP) stimulate GTP hydrolysis to the GDP bound state. Several Rab cascades have been described wherein a GTP bound Rab recruits a GEF to activate another Rab needed to organize cellular membrane compartments. The Rab8 GEF Rabin8 functions in a Rab11-Rab8 cascade important for primary cilium assembly and neurite outgrowth. However, the precise mechanism of this cascade is poorly understood. In this study, we set out to characterize the membrane dynamics of Rab11-Rabin8-Rab8 cascade. To show Rab8 activation on Rab11-Rabin8 membranes we performed live cell imaging and observed accumulation of newly translated tRFP-Rab8, following doxycycline inducible expression, on SNAP-Rab11a/GFP-Rabin8 vesicles. We thereby demonstrate that the Rab11-Rabin8-Rab8 cascade is required for Rab8 membrane tubule formation stimulated by Cytochalasin D treatment in RPE-1 cells. Moreover, we find that other trafficking regulators linked to this Rab ciliogenesis cascade are important for Rab8 tubulation in these cells suggesting a conservation in function for these membrane assembly processes. Strikingly, by live cell imaging with a super resolution Elyra7 microscope we could visualize the interplay of GFP-Rab11a and tRFP-Rab8a during membrane tubule assembly. Subsequently, we evaluate Rab11-Rab8 membrane dynamics during ciliogenesis. Notably we show that GFP-Rab11 is observed in the cilium more prominently with tRFP-Rab8a expression. Furthermore, tRFP-Rab8a ciliary transport is enhanced by Rab11 and/or Rabin8 as determined by FRAP studies. Together these studies indicate Rab8 is activated on Rab11-Rabin8 membranes during membrane tubulation and ciliary membrane assembly. Ongoing work will be described aimed at determining where Rab8 activation occurs during ciliary membrane assembly and the association of the Rab11-Rabin8-Rab8 cascade with the ciliary pocket membrane.

B381/P2060

Identification of paralog-specific Rab27 GTPase effectors

I. M. Lehman, J. M. Ngo, J. K. Williams, R. W. Schekman; Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA.

Extracellular vesicles (EVs) are membrane-bound compartments that are exported to the extracellular environment after fusion of multivesicular bodies with the plasma membrane. Exosomes are an EV subpopulation that have garnered particular interest in the scientific community due to recent studies suggesting a role for exosomes in intercellular communication in both normal and disease states. Despite broad interest in exosomes, little is known about how their release is regulated. Rab27a and Rab27b are two Rab GTPase paralogs (71% amino-acid identity) that regulate different steps of the exosome secretion pathway. To address how these proteins control separate steps of exosome secretion, we utilized both biochemical and cellular approaches to identify Rab27 paralog-specific

interactors and visualize their subcellular localization. We purified recombinant Halo-tagged Rab27a and Rab27b and utilized them as bait for SILAC-based quantitative proteomics. We then determined that TBC1D2B and CCDC186 are unique interactors of Rab27b, whereas Melanophilin preferentially binds to Rab27a. Next, we demonstrated that these three interactors bind specifically to the GTP-bound state of their respective Rab27 paralog, indicating that they are indeed Rab27 effector proteins. Finally, we generated stable cell lines expressing fluorescent Rab27a and Rab27b fusion proteins under the control of the low expression L30 promoter, and show that they localize to peripheral vesicles and the Golgi apparatus, respectively. Overall, we have identified unique and preferential effectors of Rab27b and Rab27a, respectively. Future work will focus on delineating the relationship between these unique effectors on Rab27 subcellular localization and exosome secretion.

B382/P2061

Targeting of the Tail-Anchored Rab GAP (GTPase Accelerating Protein) Gyp8 to Peroxisomes Is Regulated by the AAA ATPase Msp1

D. P. Nickerson, M. A. Quinn, A. Lin, C. Vuong, A. Mora, S. Connolly, J. T. Maddox; Dept of Biology, California State University San Bernardino, San Bernardino, CA.

Rab GTPase signaling proteins (Rabs) are key regulators of vesicular transport, controlling where and when membranes dock and fuse, ensuring lipid and protein cargoes are delivered to appropriate destinations. Rabs depend upon GTPase accelerating proteins (GAPs) to trigger GTP hydrolysis and return the signaling active, GTP-bound Rab to its inactive, GDP-bound state. Rab GAPs contribute to the efficiency and fidelity of transport pathways, and defective Rab GAPs are implicated in a variety of human diseases. Rab GAPs tend to be cytosolic proteins that transiently localize at membranes to survey for their client Rab. Since its initial discovery, the cellular localization and functions of the yeast (*S. cerevisiae*) Rab GAP Gyp8 have remained essentially uncharacterized. We report that Gyp8 is an atypical transmembrane (TM) GAP whose association with peroxisomes and mitochondria is regulated by the AAA ATPase Msp1, a chaperone that functions to remove tail-anchored proteins from peroxisomes and mitochondria. Computational analysis of Gyp8 predicted a single-pass TM domain near the carboxy terminus, characteristic of a tail-anchored (TA) protein. Subcellular fractionation demonstrated that Gyp8 localized exclusively to a membrane fraction and was resistant to chemical membrane extraction. Fluorescence microscopy indicated that GFP-tagged Gyp8 co-localized with peroxisome, endoplasmic reticulum (ER) and mitochondrion markers in wild type cells. In the absence of peroxisomes, GFP-Gyp8 redistributed to the ER. Loss of machineries regulating membrane insertion or extraction of TA proteins resulted in redistribution of GFP-Gyp8 to mitochondrial membranes. Truncation analyses of Gyp8 indicated that the TM and luminal domains are necessary and sufficient to direct localization to peroxisomes. Growth experiments of cells lacking specific Rab GAPs indicate a peroxisome-related carbon utilization defect in cells lacking Gyp8. Many Rab GAPs enforce spatiotemporal boundraries for activities of their cognate Rab GTPases. We report that Gyp8 spatially restricts localization of the secretory Rab Ypt1. Our results demonstrate regulatory mechanisms to control localization of a transmembrane Rab GAP at multiple organelles, a novel alternative to strategies of transient membrane association and dissociation used by soluble Rab GAPs.

B383/P2062

Structural basis for Rab6 GTPase activation by the Ric1/Rgp1 complex

R. Feathers; Cornell University, Ithaca, NY

Membrane trafficking is a highly coordinated process in eukaryotes essential for maintaining lipid homeostasis and sorting proteins to the proper location inside cells. The Golgi complex serves as the hub of this dynamic set of pathways where it directs cargo sorting through vesicle mediated transport. Vesicles of varying lipid composition loaded with different protein cargo are in constant flux through the Golgi and precise spatial and temporal regulation of these processes requires communication between compartments. Rab GTPases are small signaling proteins that act as molecular switches to regulate vesicular trafficking. Rab6 functions at the Golgi where it is important for endosome to Golgi retrograde transport in both yeast and metazoans and for anterograde exit from the TGN in metazoans. The Ric1/Rgp1 protein complex is a conserved guanine nucleotide exchange factor (GEF) required for activation of Rab6. In mammalian cells Ric1/Rgp1 is known to be regulated by the Rab33 GTPase, but it remains unresolved how the activity of the complex is regulated and the mechanism by which it catalyzes Rab6 nucleotide exchange. Furthermore, little is known about the structure and domain organization of Ric1/Rgp1. We have used cryo-EM to determine the structure of the yeast Ric1/Rgp1-Rab6(Ypt6) complex, representing the key intermediate of the nucleotide exchange reaction. This structure reveals the overall architecture of the complex and has enabled us to identify the specific interactions that govern the recognition and activation of Rab6. Ongoing studies aim to test the physiological significance of these interactions as well as a proposed mechanism for localization of the complex on the Golgi membrane surface.

Polarity in Development

B385/P2063

Understanding the role of Dishevelled in establishing epidermal planar cell polarity

P. Sil, D. Devenport; Molecular Biology, Princeton University, Princeton, NJ.

Planar cell polarity (PCP) pathway directs the coordinated alignment of cell polarity across the plane of a tissue and guides morphogenesis in a range of organisms from planaria to mammals. A hallmark of the PCP pathway in epithelia is the asymmetric distribution of its components along cell-cell junctions, with the seven-pass transmembrane cadherin Celsr1 partnering with atypical GPCR Frizzled (Fz) and cytoplasmic Dishevelled (Dvl) on one side and four-pass transmembrane Vangl and cytoplasmic Prickle(Pk) on the opposite side of the cell. The cytoplasmic adaptors, Dvl and Pk, are essential for the asymmetric distribution of their transmembrane counterparts, but the molecular mechanisms by which they help to organize asymmetric PCP complexes are poorly understood. PCP proteins exhibit signalosome-like properties, where they assemble into relatively stable, asymmetric clusters along cell junctions. We hypothesize that Dvl promotes the formation of junctional PCP clusters, given the well-documented ability of Dvl proteins to oligomerize. In this study, we have determined the distribution and function of Dvl2 and Dvl3 in the mouse embryonic epidermis and tested if and how Dvl organizes and stabilizes Fz-containing complexes along cell junctions to asymmetrically partition PCP components. Additionally, using a structure-function approach in primary mouse keratinocytes in vitro we have investigated how Dvl-Fz interactions impact the enrichment, dynamics and organization of Fz along cell junctions.

Kinase Signaling Regulates Hair Cell Planar Polarity and Establishes a Line of Polarity Reversal in the Mouse Inner Ear

S. Jia, E. M. Ratzan, R. Abrar, E. J. Goodrich, L. Heiland, **M. R. Deans**; University of Utah School of Medicine, Salt Lake City, UT.

Planar polarity is the polarized organization of cells and cellular structures within the plane of an epithelium and underlies organ and tissue function. Core planar cell polarity (PCP) signaling coordinates the orientation of cells along a common axis, however it remains unclear is how PCP signaling is interpreted by individual cells during differentiation. We are addressing this using the utricle and saccule of the mouse inner ear which contain the sensory receptor hair cells that detect motion and gravity. Hair cells function via the deflection of a planar-polarized bundle of stereocilia located on the apical cell surface, and the orientation of the bundle determines the direction of motion that an individual hair cell can detect. Although the planar polarity of vestibular hair cells resembles *Drosophila* wing hairs, they also exhibit planar bipolarity because they are divided between two groups with oppositely oriented bundles. The two groups are adjacent and meet at a cellular boundary called the Line of Polarity Reversal (LPR), and due to the orientation of their bundles, these hair cells detect and respond to motion in opposite directions. We identified a serine-threonine kinase that functions as a planar polarity effector within one group of hair cells in the utricle or saccule, and therefore is required to establish planar bipolarity and position the LPR. Following gene deletion in mice, the intrinsic polarity of the bundle is no longer aligned with the polarized distribution of core PCP proteins. Kinase expression is restricted to hair cells on one side of the LPR in utricles and saccules, and bundle orientation in these regions is randomized in knockouts. This pattern of expression is complementary to the transcription factor Emx2 which is expressed on the other side of the LPR and is also required for its formation. We find that Emx2 represses kinase gene transcription, but kinase overexpression is sufficient to reorient stereociliary bundles when delivered to Emx2-expressing hair cells using AAV. We propose a model in which planar bipolarity of the utricle and saccule is established by parallel functions Emx2 and kinase signaling, each acting in hair cells located on opposite sides of the LPR. In this model the position of the LPR is determined by the boundary of Emx2 since it actively represses the alternative kinase-mediated polarity pathway.

B387/P2065

Identifying mechanisms underlying Orb2-dependent regulation of neural stem cell centrosome asymmetry

J. Buehler, D. A. Lerit; Department of Cell Biology, Emory University School of Medicine, Atlanta, GA.

Neural stem cells (NSCs) orchestrate repeated rounds of asymmetric cell division designed to pattern the developing brain with neurons and glia. During each round, the centrosomes facilitate the segregation cell fate determinants that predispose each daughter cell to a different fate. Drosophila Orb2 is a cytoplasmic polyadenylation element binding protein (CPEB) ortholog involved in the post-transcriptional regulation of diverse mRNAs across multiple tissues. Our lab recently reported that loss of orb2 results in NSC centrosome maturation defects and microcephaly, but the mechanisms and cell types behind these phenotypes are unknown. To begin to dissect the role of Orb2 in neurodevelopment, we are testing whether Orb2 regulates centrosome activity or brain volume via its conserved RNA-

binding domain. Our preliminary data suggest a functional Orb2 RNA-binding domain is required for centrosome asymmetry. However, localization experiments revealed that Orb2-GFP does not localize to centrosomes, but rather is diffusely distributed within the NSC cytoplasm. Taken together, these data suggest Orb2 functions indirectly, likely through one or more mRNA targets, to instruct centrosome activity. Consistent with this idea, an in-silico analysis of crosslinking immunoprecipitation and sequencing data (CLIP-seq) of Orb2 targets within Drosophila S2 cells identified an enrichment of RNAs with centrosome ontologies. To identify mRNA targets involved in centrosome activity control, we are presently conducting CLIP RT-PCR to identify RNAs bound to Orb2 within the third instar larval brain. This work reinforces a model whereby Orb2 contributes to the posttranscriptional regulation of centrosome genes critical for NSC asymmetric centrosome maturation, guiding proper neurodevelopment.

B388/P2066

Soluble factors produced by the epithelial cell induce macrophages differentiation

A. Siqueira Berti, H. Carvalho; University of Estadual De Campinas-UNICAMP, Campinas, Brazil

Androgens are important for prostate gland development and homeostasis. Androgen deprivation leads to the influx of immune cells, in particular, of different populations of macrophages. We have shown that prostatic epithelial cells cultured in the absence of androgenic stimulus induced to the production of soluble factors that influence macrophage polarization and motility. Furthermore, LNCaP conditioned medium affects macrophages RAW 264.7 cells promoted prostate epithelial cell death (J Cell Physiol 2019).O objetivo deste trabalho foi analisar os fatores solúveis produzidos pela LNCaP ausência de andrógenos que induzem a diferenciação de macrófagos. O meio condicionado LNCaP foi analisado por espectrometria de massa para identificar todas as proteínas. A linhagem celular de macrófagos Raw 264,7 foi cultivada em meio completo, suplementado com 50% de meio condicionado LNCAP, na presença ou ausência de R1881 e recebeu tratamento com 1 µM de Granulina e após 24h imunocoloração para INOs. O meio condicionado LNCaP foi analisado por espectrometria de massa e a Granulina foi identificada após esta análise. Observamos que as células LNCaP liberam granulina e os macrófagos tratados com granulina aumentaram a expressão de INOs. Apesar da ausência de andrógenos nos macrófagos e cocultura da linha de células tumorais, resulta em uma frequência aumentada de Tunel (fragmentação de DNA) e células duplamente positivas de caspase 9 clivadas. Essas observações sugerem que a granulina liberada pelo LNCAP atua na diferenciação de macrófagos que leva à morte das células epiteliais. Este trabalho apoiado pela CAPES.

B389/P2067

Crawling under your skin: Understanding how planar cell polarity generates polarized cell movements during hair follicle morphogenesis

R. Sharan[1], L. Leybova[1], X. Du[2], M. Shelley[2], D. Devenport[1]; [1]Princeton University, Princeton, NJ, [2]Flatiron Institute, New York, NY

Breaking symmetry is essential for the development of complex structures at almost every scale, from macromolecular to cellular to organismal. One such symmetry breaking process is establishment of planar cell polarity (PCP), the coordinated orientation and alignment of cells within the plane of a tissue. This is through the asymmetric localization of the three transmembrane proteins, Frizzled-6, Vangl2, and Celsr1. PCP is required for collective cell behaviors such as alignment of single-cell protrusions of the

Drosophila wing to multicellular structures such as the mammalian hair follicle. However, while the components of the PCP pathway have largely been identified, how they regulate downstream cytoskeletal dynamics to generate collective cell movements in multicellular structures is not well understood. Our previous work has shown that PCP and downstream myosin is required for counter-rotational cell flows that drive polarized hair follicle morphogenesis. These cell flows are further required for organizing the cell fates of the hair placode by repositioning centrally-located to the anterior and sweeping peripheral cells to the posterior. Given these previous data, we hypothesized that PCP might polarize myosin or myosin activity at intercellular junctions to bias cell rearrangements. However, visualization of several myosin reporters in both live and fixed embryonic epidermal tissues, we did not find evidence of planar polarized myosin at junctions, nor did we observe a strong correlation between myosin and PCP protein localization. Rather, through 3D reconstruction of the hair follicle epithelium, we found that the basal surface of placode cells forms anterior-facing protrusions and that the basal surface precedes the apical surface, suggesting PCP may direct polarized cell crawling. In support of a mechanism involving crawling, Rac1 inhibition (NSC 23766) of embryonic skin explants lead to disrupted hair follicle polarization. Further, a continuum mechanics model *in silico* supported the idea that forces applied at the basal surface can drive movements at the apical surface.

B390/P2068

Biogenesis of lysosome-related organelles complex-1 (BLOC-1) Required for Planar Cell Polarity in the Inner Ear

C. Tower-Gilchrist; Emory University, School of Nursing, Atlanta, GA

Planar cell polarity (PCP) plays a critical role in embryonic development and in functioning of tissues. PCP is described as the distinct cell polarity exhibited among neighboring cells along an axis parallel to the plane of the sheet. More importantly, dysregulation of PCP results in neural tube closure defects including craniorachischisis, misorientation of stereociliary hair bundles in the cochlea, and deafness. One conserved feature of PCP is the asymmetric localization of core PCP proteins, Vangl2 and Frizzled, to opposing cell boundaries. We have previously characterized the role of Adaptor Protein Complex -3 (AP-3) in PCP and regulating the intracellular trafficking of Vangl2. Although studies have demonstrated the importance of protein trafficking in the asymmetrical sorting of PCP transmembrane proteins, the molecular mechanisms still remain poorly understood. One way to provide insight into these mechanisms is to identify additional Vangl2 binding partners. Previous studies have shown that BLOC-1 interacts with AP-3. In this study we use mouse cochlea to examine the role of BLOC-1 in planar cell polarity and Vangl2 localization. We first examined the localization of Vangl2 in the organ of Corti of the cochlea and posterior cristae obtained from loss of function BLOC-1 sandy mice ($Dtnbp1^{sdy/sdy}$) and pallid ($Pldn^{pa/pa}$). Within the organ of Corti of pallid ($Pldn^{pa/pa}$) mice, there were notable reduction in Vangl2 membrane localization. Furthermore, we observed misorientation of sterociliary hair cell bundles along with extra hair cell rows in the cochlea of sandy ($Dtnbp1^{sdy/sdy}$) mice. These findings suggest a new role for BLOC-1 in PCP and that it is important for the membrane targeting of Vangl2. Future studies will determine if BLOC-1 directly interacts with Vangl2.

Neuronal Degeneration and Regeneration

B391/P3111

Neurologic responses of the developing nervous system to arsenic exposure

T. H. Adebambo, A. R. Bharadwaj, D. A. Lerit; Emory University, Atlanta, GA

Neurodegenerative disorders including Alzheimer's disease (AD) and Parkinson's disease (PD) have been linked to environmental exposure to arsenic and other neurotoxins. The blood-brain barrier (BBB) is known to be permeable to arsenic, and there has recently been an increase in research into the potential health hazards of chronic exposure. Arsenic neurotoxic course in the central nervous system, however, is still poorly understood. Understanding how arsenic contributes to neurodevelopmental and neurodegenerative disorders may lend insight into novel therapeutics. We report here a chronic toxicity study of arsenic as well as the neurotoxic action on neurodevelopment in developing *Drosophila*. Age-matched newly emerged *wild-type* first instar larva were exposed to different concentration groups (50 µM, 100 µM, 250 µM, 500 µM and 1000 µM), and a control group fed an equal amount of yeast paste and bromophenol blue mixed in *Drosophila* meal. A dose-dependent relationship was evaluated by monitoring development through first instar larval stage, pupation, and fly eclosion. The effect of arsenic on *Drosophila* neurodevelopment was determined by measuring age-matched brain volumes from randomized images. Our preliminary data indicate arsenic administration results in a dose-dependent delay in larval pupation and adult eclosion relative to the mock-treated control. There was also a marked decrease in the number of pupa and eclosed arsenic-exposed flies, consistent with the idea that chronic exposure to elevated concentrations of arsenic is lethal. Unexpectedly, we noted brain volume was significantly increased in treated third instar larva compared the control group. In addition to laying precedence to the understanding of the mechanism of arsenic neurotoxicity in the *Drosophila* central nervous system, our findings suggest that arsenic affects fly eclosion by slowing down the rate of eclosion and reducing the number of eclosed flies.

B392/P2069

Pro- Inflammatory Factor and Beta- Amyloid Accumulation Pathology: Parkinson's Disease

S. E. Vendrell- Gonzalez[1], J. Roldan- Khan[2], A. De Freitas- Suarez[1], G. Jimenez-Jordan[1], F. Reyes-Ortiz[1], J. Alves[1], M. Inyushin[1]; [1]Universidad Central Del Caribe, Bayamon, PR, [2]University of Puerto Rico Medical Sciences Campus, Bayamon, PR

Neuroinflammation, more specifically the pro-inflammatory effect caused primarily by microglia activation, are crucial in understanding Parkinson's Disease (PD) progression. Studies show an expression of cytokines involved in neuroprotection and neurotoxicity throughout PD progression. Levels of neuroprotective cytokines, like TNF-a, IL-6, IL-1b and glutamate are seen increase throughout. Our study focuses on analyzing pro-inflammatory factors and AB accumulation to better understand the progression of PD and how that affects the neurovascular unit. To accomplish this*, Sprague Dawley* rats were injected with 6-Hydoxydopamine (6-OHDA) to induce dopaminergic neuron cell death and promote a similar inflammatory response in the CNS as seen in PD patients. Throughout the experiment, affected and unaffected brain tissue samples were compared using ELISA, Western Blot, Specific Cytokine Signaling and fluorescent Microscopy. Preliminary immunoassayed data showed AB 1-40 peptide accumulation inside the blood vessels and affected areas. Using this data as a base, Immunoassayed tissue sections were used to analyze the concentration of dopaminergic neurons,

showing a correlation between dopaminergic neurons reduction and AB accumulation. Secondly, a cytokine profile study was performed to compare and confirm pro-inflammatory cytokine commonly seen in PD patients. Protein quantification assays such as Western Blot and ELISA were used to corroborate cytokine and AB concentration in brain tissue samples. Western Blot Assay confirmed increased pro-inflammatory cytokine concentration for tissues treated with 6-OHDA. Meanwhile, ELISA assay confirmed AB accumulation was significantly greater in affected brain samples. Preliminary ELISA data was also used previously to confirm the immunoassayed AB accumulation. Improving our understanding of the effect pro-inflammatory factors have in the CNS and in the progression of PD puts us closer to be able to delay or reverse dementia symptoms so commonly seen in PD patients.

B393/P2070

LIF-mediated cell proliferation in rat fetus astrocyte and neuronal cell lines after exposure to HIV-gp120

F. Reyes-Ortiz[1], R. Vega-Román[1], S. E. Vendrell- Gonzalez[1], A. De Freitas-Suarez[1], G. Jiménez-Jordán[1], M. Inyushin[1], J. Alves[1], R. Noel, Jr.[2]; [1]University of Central Del Caribe, Bayamón, PR, [2]Ponce Health Sciences University, Ponce, PR

HIV-induced neurotoxicity remains an important, yet unmanageable, manifestation of the disease, despite effective pharmacological therapy in the control of viral replication. HIV-gp120 is associated to induce HIV-associated neurocognitive disorders (HANDs), affecting 20% to 50% of infected individuals, increasing with age. Hence, novel approaches are explored, necessary to prevent or alleviate CNS damage after HIV infection. Leukemia Inhibitory Factor (LIF) is a cytokine known for its protection of glial cells, inducing GFAP astrocyte differentiation, as well as increasing self-renewal of neuronal stem cells to promote proliferation and survival of neurons. Efficacy of LIF is evaluated, as it promotes neuronal cell survival and differentiation, by assessing inflammation and cell proliferation factors within an in vitro model of rat embryonic hippocampal astrocytes and cerebral cortex neurons exposed to HIV-gp120. Astrocytic and neuronal cells are extracted and later treated with LIF in a primary co-culture. Neuronal markers, MAP2 and NeuN, are used to determine neuronal differentiation of mature and young neurons, respectively. Confocal Microscopy preliminary results show an increase in the expression of NeuN and MAP2 in the presence of LIF, compared to cells treated with HIV-gp120, suggesting that LIF is promoting neuronal development. Changes in the expression of these proteins are determined by immunoblotting. GFAP levels show presence of inflammation in cells treated with HIV-gp120. Further studies are explored using BrdU and TUNEL assays as apoptosis and inflammation markers to determine the role of LIF in promoting cell proliferation, when exposed to HIV-gp120 and its associated neuronal and astrocyte cell death. BrdU immunoassays detect high levels of stained proliferated cells responding to LIF, resulting in low levels of inflammation and apoptosis, compared with cells exposed to HIV-gp120. TUNEL reagents are used to detect late stage apoptotic cells during inflammation when exposed HIV-gp120. Better understanding of these mechanisms require the replication of independent confocal microscopy experimentation, and evaluation of the expression of pro-inflammatory cytokines in neuronal cell death. Evidencing the neuroprotective function of LIF on HIV, in our model, has the potential to contribute as a future direction against neurodegenerative disorders underlying HIV-induced CNS damage.

B394/P2071

HIV-induced tension provoked by the homeostatic effects between neurotoxicity and the neuroprotection provided by LIF

J. Alves[1], A. De Freitas-Suarez[1], J. Roldán-Kalil[2], R. Vega-Román[1], S. Vendrell-Gonzalez[1], F. Reyes-Ortiz[1], G. Jimenez-Jordan[1], M. Inyushin[1]; [1]University of Central Del Caribe, Bayamon, PR, [2]University of Puerto Rico Medical Sciences Campus, San Juan, PR

Despite modern HIV therapies, it has not been sufficient to combat its neurotoxic proteins which are detrimental to the neurocognition of its subjects resulting in HIV-Associated Neurocognitive Disorders (HAND). Proteins such as HIV-gp120 and HIV-nef are responsible for the development of HANDs. Our project aims to study another approach to prevent or alleviate central nervous system damage after HIV infection by evaluating the protective effects of the Leukemia Inhibitor Factor (LIF). In addition, we seek to diminish or prevent acute HIV infection via immunization. For our first interest, neuronal and astrocytic cells are extracted from our embryonic rat model and later treated with LIF, a neuroprotective factor, in a primary co-culture. Neuronal markers are used to detect neuronal differentiation of mature and young neurons. Our preliminary results show an increase in the expression of NeuN and MAP2 in the presence of LIF indicating neuronal growth, compared to its counterparts treated with HIV-gp120. In order to analyze apoptosis and inflammation, we performed studies using BrdU and TUNEL assays. TUNEL reagents are applied to detect late-stage apoptotic cells during inflammation when exposed to HIV-gp120. BrdU immunoassay resulted in low levels of inflammation and apoptosis, compared with cells exposed to HIV-gp120. Another interesting approach is developing an effective HIV vaccine to diminish infection. By targeting dendritic cells (DC) we pre-activate in-vivo DC before HIV immunization using certain adjuvants that interact with DC in order to achieve rapid enhancement of immune response. To properly observe the effect of DC stimulation on the effectiveness of a Gag DNA vaccine in-vivo Imiquimod was employed as an adjuvant in concentrations of 25, 50, and 100nM. Low concentrations of Imiquimod were found to effectively stimulate Gag production by up to 25% as well as T-cells response.On the contrary, higher concentrations of Imiquimod reduced immunization effects by up to 55%. The aim of this study is to discuss the neuroprotective properties of LIF in order to develop a treatment for the affected population of HANDs. In addition, we discuss a possible alternative for an effective HIV vaccine as an agent to combat this unrelenting disease. These different goals each carry the weight of ensuring a better quality of life for the vulnerable population. **Acknowledgments:** Supported by Universidad Central Del Caribe (UCC) and the office of the Associate Dean for Research and Graduate Studies, The Alliance-NIMHD-NIH, Expanding Undergraduate Students Education, Opportunities and Options in Clinical and Translational Research Supported by the US Department of Education: Title V Grant Award #P031S160068 and MAC-FRED Program 2018.

Tau secretion by VAMP8 impacts its intra- and extracellular cleavage

J. Pilliod[1], M. Gélinas-Faucher[2], **N. Leclerc**[2]; [1]CRCHUM, Montréal, QC, Canada, [2]University of Montreal, Montréal, QC, Canada

In Alzheimer's disease, Tau, a microtubule-associated protein, becomes hyperphosphorylated, detaches from microtubules, and accumulates in the somato-dendritic compartment where it forms insoluble aggregates. Tau also accumulates in the CSF of patients indicating that it is released by neurons. Consistent with this, several laboratories including ours have shown that Tau is secreted by neurons through unconventional secretory pathways. Recently, we reported that VAMP8, an R-SNARE found on late endosomes, increased Tau secretion and that secreted Tau was cleaved at the C-terminal. In the present study, we examined whether the increase of Tau secretion by VAMP8 affected its intra- and extracellular cleavage. Upon VAMP8 overexpression, an increase of Tau cleaved by caspase-3 in the cell lysate and medium was observed. This was correlated to an increase of active caspase-3 in the cell lysate and medium. Using a Tau mutant not cleavable by caspase-3, we demonstrated that Tau cleavage by caspase-3 was not necessary for its secretion upon VAMP8 overexpression. By adding recombinant Tau to the culture medium, we demonstrated that extracellular Tau cleavage by caspase-3 could occur because of the release of active caspase-3, which was the highest when VAMP8 was overexpressed. When cleavage of Tau by caspase-3 was prevented by using a non-cleavable mutant, secreted Tau was still cleaved at the C-terminal, the asparagine N410 contributing to it. Lastly, we demonstrated that N-terminal of Tau regulated the secretion pattern of a Tau fragment containing the microtubule-binding domain and the C-terminal of Tau upon VAMP8 overexpression. Collectively, the above observations indicate that VAMP8 affects the intra- and extracellular cleavage pattern of Tau.

Dysregulated epidermal keratinocyte dynamics contribute to chronic damage signaling and impaired healing of thermal burn injury

A. Horn, A. Fister, J. Squirrell, A. Huttenlocher; University of Wisconsin, Madison, WI.

Repair of epithelial injury requires the coordinated activity of keratinocytes, the primary constituent of the epidermis. Directed migration of keratinocytes facilitates immediate wound closure, while production of signaling molecules such as reactive oxygen species (ROS) promotes long-term healing. While epithelial tissue is well-adapted to repair from mechanical trauma, thermal burn injuries heal poorly. To investigate whether dysregulated keratinocyte behavior contributes to wound healing defects in burned tissue, we used the larval zebrafish, which allows for real-time visualization of keratinocyte dynamics during tissue repair. In contrast to injury by mechanical tailfin transection, we find that burn injury induces excessive keratinocyte movement, reminiscent of collective migration. Disorganized keratinocyte movement immediately following injury results in accumulation of epithelial damage over time. Inhibiting keratinocyte movement by injuring in the presence of isotonic medium prevents long-term epithelial damage and suggests that keratinocytes respond to osmotic cues in the burn environment. While it is known that epithelial repair requires transient and wound-localized ROS production, we find that burn injury causes chronically-elevated ROS across the tissue-scale. However, blocking keratinocyte movement spatially restricts ROS production to the site of injury, suggesting regulated keratinocyte migration is a mechanism for localizing repair signaling. To determine whether excessive keratinocyte movement contributes to poor burn wound healing, we assessed the function of

peripheral sensory neurons. Clinical observations highlight that patients suffer from loss of sensory perception in burned tissue, and chronic ROS increase is linked to neurodegenerative disease. We find sensory neuron regeneration and function is compromised following burn injury compared to tailfin transection; however, preventing excessive keratinocyte movement and subsequent tissue damage through treatment with isotonic medium, or reducing ROS by antioxidant treatment, is sufficient to rescue sensory neuron function. These results demonstrate the requirement of tightly regulating keratinocyte dynamics following tissue injury. In the context of thermal burn injury, dysregulated keratinocyte function contributes to neuronal damage and loss of sensory perception in wounded tissue.

Keratinocyte-dependent oxidative stress impairs sensory neuron regeneration after tissue injury

A. Fister, A. Horn, J. Squirrell, A. Huttenlocher; Pediatrics, University of Wisconsin, Madison, WI.

Damage to the skin results in a cascade of wound healing and regenerative responses that mediate tissue repair. Sensory neuron function is also impaired by tissue damage, and reactive oxygen species (ROS) signaling is required for their recovery after mechanical injury. Clinical observations reveal that while sensory function is recovered after mechanical injury, thermal burn injury results in either chronic loss of touch sensation or pain and the underlying mechanisms of this defect remain unclear. To understand why this occurs, we took advantage of the optical transparency and simple epithelial structure of larval zebrafish to visualize the mechanical (transection) and burn wound environment *in vivo*. After transection, sensory neurons regenerate well and maintain sensory perception. After burn, sensory neurons regenerate poorly, and larvae display a prolonged loss of sensation in the wound area. Live imaging reveals that the early burn response, but not the mechanical response, is characterized by the uncoordinated and excessive movement of intertwined keratinocytes and sensory neurons. Real time analysis of neuronal damage and calcium flux shows prolonged neuronal damage in thermal injury that is not a direct result of tissue movement. In association with this this damage, there is dysregulated reactive oxygen species signaling that is restored after a tail transection following the burn. Reduced ROS induced by the tail transection or treatment with the antioxidant N-Acetyl Cysteine (NAC) rescued the defect in sensory neuron regeneration and function after thermal injury. Taken together, the findings suggest that a balance and spatiotemporal regulation of ROS signaling is necessary for sensory neuron regeneration and repair.

CHIP ameliorates neuronal damage in H_2O_2-induced oxidative stress in HT22 cells and gerbil ischemia

I. Hwang[1], K. Hahn[2], H. Kwon[3], Y. Yoon[1], D. Kim[4]; [1]Seoul National University College of Veterinary Medicine, and Research Institute for Veterinary Science, Seoul, KOREA, REPUBLIC OF, [2]Seoul National University College of Veterinary Medicine, Seoul, KOREA, REPUBLIC OF, [3]Gangneung-Wonju National University College of Dentistry, Gangneung, KOREA, REPUBLIC OF, [4]Gangneung-Wonju National University, Research Institute of Oral Sciences, College of Dentistry, Gangneung, KOREA, REPUBLIC OF.

Carboxyl terminus of Hsc70-interacting protein (CHIP) is highly conserved and is linked to the connection between molecular chaperones and proteasomes to degrade chaperone-bound proteins. In this study, we synthesized the transactivator of transcription (Tat)-CHIP fusion protein for effective delivery into the brain and examined the effects of CHIP against oxidative stress in HT22 cells induced by hydrogen

peroxide (H_2O_2) treatment and ischemic damage in gerbils by 5 min of occlusion of both common carotid arteries, to elucidate the possibility of using Tat-CHIP as a therapeutic agent against ischemic damage. Tat-CHIP was effectively delivered to HT22 hippocampal cells in a concentration- and time-dependent manner, and protein degradation was confirmed in HT22 cells. In addition, Tat-CHIP significantly ameliorated the oxidative damage induced by 200 μM H_2O_2 and decreased DNA fragmentation and reactive oxygen species formation. In addition, Tat-CHIP showed neuroprotective effects against ischemic damage in a dose-dependent manner and significant ameliorative effects against ischemia-induced glial activation, oxidative stress (hydroperoxide and malondialdehyde), pro-inflammatory cytokines (interleukin-1β, interleukin-6, and tumor necrosis factor-α) release, and glutathione and its redox enzymes (glutathione peroxidase and glutathione reductase) in the hippocampus. These results suggest that Tat-CHIP could be a therapeutic agent that can protect neurons from ischemic damage.

B399/P2076

Neuronal activity regulates matrin-3 in a calcium and calmodulin dependent manner

J. Wu, A. Malik, C. Gillies, Q. Doctrove, S. Barmada; University of Michigan, Ann Arbor, MI.

RNA binding protein (RBP) dysfunction and abnormal neuronal excitability are hallmarks of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Even so, it remains unclear if and how activity dependent processes regulate RBPs. In a subset of familial ALS cases, the mutations in the gene encoding the DNA-RNA binding protein matrin-3 (MATR3) causes familial ALS and FTD. MATR3 pathology, including cytoplasmic mislocalization and increased nuclear staining, also occurs in sporadic cases of ALS, suggesting a potentially important role for MATR3 in disease pathogenesis. Consistent with this, we demonstrated that both knockdown and overexpression of MATR3 results in neurotoxicity, indicating proper MATR3 homeostasis is essential for neuronal survival. Here, we show that neuronal activity regulates MATR3 abundance through a calcium-dependent mechanism, providing a crucial link between neuronal excitability and disease pathogenesis in ALS and FTD. Stimulation of neuronal activity with the glutamate receptor agonist NMDA leads to the rapid degradation of MATR3 in mature primary neurons. Both calcium and calpains—a family of calcium-sensitive cysteine proteases—are required for MATR3 degradation in response to NMDA. Furthermore, treatment with W-7, an inhibitor of the calcium signal transduction protein calmodulin (CaM), blocks MATR3 turnover. Previous studies hinted at a direct interaction between CaM and the RNA binding domain of MATR3, and we found that NMDA treatment rapidly inhibits MATR3's ability to bind its RNA targets. These observations suggest a model in which NMDA receptor activation results in calcium influx, CaM binding to MATR3 and release of its RNA substrates, and subsequent MATR3 degradation via calpains. This model may also help explain the toxicity of a newly-identified *MATR3* mutation affecting a conserved residue (F488L) adjacent to MATR3's RNA binding domains. Collectively, our data connect two conserved phenomena in ALS and FTD—neuronal hyperactivity and RNA binding protein pathology—and may have direct implications for the regulation of RBPs as well as disease pathogenesis.

Genetic Interaction between Protein Quality Control System and GSK3β Signaling Pathway in ALS Disease Models

H. Choi[1,2], J. Lee[3], K. Kim[4]; [1]Soonchunhyang Institute of Medi-bio Science, Soonchunhyang University, Cheonan, KOREA, REPUBLIC OF, [2]Department of Integrated Biomedical Science, Soonchunhyang University, Cheonan, KOREA, REPUBLIC OF, [3]Department of Medical Biotechnology, Soonchunhyang

University, Asan, KOREA, REPUBLIC OF, [4]Department of Medical Science, Soonchunhyang University, Asan, KOREA, REPUBLIC OF.

Fused in sarcoma (FUS) and TATA-box binding protein associated factor 15 (TAF15) belong to the FET family of structurally similar DNA/RNA-binding proteins involved in DNA repair and RNA processing. FUS/TAF15 are associated with neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Normally FUS/TAF15 resides primarily in neuronal nuclei whereas cytoplasmic mislocalized FUS/TAF15 accumulates, causing neuronal toxicity. However, the molecular mechanisms underlying FUS/TAF15 -mediated ALS pathogenesis are largely unknown. Here, we found that *Shaggy*, which is a *Drosophila* homolog of *GSK3β* is a potential modulator of FUS/TAF15 -induced neuronal toxicity. Moreover, shaggy enzyme activity was increased in the FUS/TAF15-induced ALS model. Knockdown of *Shaggy* in fly neurons attenuates neurodegenerative phenotypes, including motor neuron degeneration, and mitochondrial dysfunction. In addition, we demonstrated F-box protein Slimb controls the FUS/TAF15 protein levels, and SCF^{slimb} is a critical regulator for shaggy-mediated suppression of FUS/TAF15-induced toxicity in *Drosophila*. These findings revealed a novel mechanism of neuronal protective effect through SCF^{Slimb}-mediated FUS/TAF15 degradation via GSK3β inhibition.

PFOS exposure disrupts glutamate-dependent sensory behavior in C. elegans

K. Kessel, E. Luth; SIMMONS University, Boston, MA.

Perfluorooctanesulfonic acid (PFOS) is part of the polyfluoroalkyl substance (PFAS) family that were used industry and consumer products like cookware and clothing. The accumulation of PFAS in the brain has been proposed to lead to behavioral and cognitive disorders. However, the specific mechanisms underlying the effects of PFAS-induced neurotoxicity still need to be explored. Previous studies in the roundworm C. elegans have reported that PFOS affects the dopaminergic system, but its effects of glutamate signaling have not been explicitly explored. Here, we explore the effects of PFOS on glutamate-dependent sensory behavior in C. elegans. To test this we looked at the optogenetic activation of ASH sensory neurons in channelrhodopsin-expressing transgenic worms. This has been shown to trigger glutamate-dependent locomotor reversals. We exposed synchronized L1 worms to PFOS concentrations ranging from 0.001 ppm-10 ppm (0.0017 uM-17 uM) as well as a methanol control. We found that exposure to as little as 0.1 ppm PFOS significantly reduced the light-induced reversal response rate compared to the methanol control. Importantly, we only observed growth defects at concentrations above 10 ppm, suggesting that the impaired glutamate-dependent reversal response was independent of gross developmental delay. Our preliminary data indicated that channelrhodopsin::YFP expression in ASH neurons is not altered upon exposure to 1 ppm PFOS. This implies that the capacity for ASH depolarization is not affected by PFOS exposure and the source of the behavioral defect is downstream of sensory neuron activation. We conclude that 0.1-10 ppm PFOS impairs the function of glutamate neurons in C. elegans. Our results provide a benchmark for testing low concentrations of other PFAS on glutamate neurons. This will help us in the future identify how PFOS impacts the central nervous system, possibly affecting memory, cognition, mood and motor skills.

Role of Y-family polymerases in neuronal genome maintenance and aging

M. Abdelmageed[1], S. Paul[2], **A. Paul**[1]; [1]Neural Behavioral Sciences, Penn State College of Medicine, Hershey, PA, [2]Biochemistry and Molecular Biology, Penn State College of Medicine, Hershey, PA.

Genomic instability increases with age due to an accumulation of DNA damage and distinct DNA damage response pathways have evolved with a host of distinct polymerases that act via different pathways such as nucleotide excision repair, base excision repair to mend DNA lesions. In contrast, the relatively newly discovered Y-family DNA polymerases can bypass damaged DNA in dividing cells, however, their functions in enduring post-mitotic cell types like neurons are largely unknown, where the non-homologous end joining (NHEJ) pathway has been shown to repair double-stranded DNA breaks. To understand the biological role of Y-family polymerases in maintaining the central nervous system (CNS) genome we studied its expression as function of aging and neurodegeneration. We discovered that most Y-family polymerases are expressed extensively in the brain and its expression in sub-cellular compartments are significantly altered as a function of chronological age. We identify that such alterations in neurons are non-uniform across different brain areas perhaps reflecting metabolic demand and demonstrate interacting partners of one member of Y-family polymerase, Polymerase kappa (PolK) to be associated with a NHEJ pathway protein. We further identify the subcellular compartments of PolK sites within the neurons and explore the potential relationship of PolK with cytoplasmic DNA and immune activation.

Synaptojanin 2-mediated transport of mRNA maintains mitophagy and mitochondrial function in axons and synapses

W. S. Gibbs, PhD, T. L. Schwarz, PhD; Boston Children's Hospital, Boston, MA.

In neurons, maintaining healthy mitochondria is complicated by the need for delivery and clearance in long axons. Mitochondrial proteins require rejuvenation despite their distance from the nucleus. Moreover, proteins such as PINK1 have extremely short half-lives, suggesting the need for local translation. PINK1, a serine-threonine protein kinase, regulates mitochondrial function and quality control pathways, including mitophagy. Mutations in PINK1 cause autosomal recessive Parkinson's disease.We are studying the role of mRNA transport in preserving mitochondrial function and turnover. Harbauer et al, 2022 demonstrated the association and co-transport of PINK1 mRNA with axonal and dendritic mitochondria. Synaptojanin 2 (SYNJ2) tethers PINK1 mRNA to the outer mitochondrial membrane (OMM) through its interaction with OMP25. SYNJ2 has a predicted RNA Recognition Motif (RRM) that had not previously been studied, but is critical for PINK1 mRNA localization to mitochondria. This neuron-specific mechanism works in concert with the translation of the PINK1 transcript.We have now used UV-crosslinking of FLAG-tagged SYNJ2 expressed in rat cortical neurons for gel shift assays and demonstrated that SYNJ2 binds neuronal RNA and that this binding is prevented by introducing three alanine mutations in the SYNJ2 RRM ($SYNJ2^{AAA}$). We have also used CRISPR to introduce the AAA mutation into the endogenous SYNJ2 locus of mice and of human iPSCs. The mice are homozygous, viable and fertile and the iPSCS can be differentiated into iNeurons. We have used these systems to determine the functional significance of SYNJ2 RRM. In axons of $SYNJ2^{AAA}$ iNeurons, depolarization of mitochondria failed to induce the accumulation of PINK1 protein that occurred in isogenic control axons. Similarly, the induction of phospho-ubiquitination, a direct product of the PINK1/Parkin dependent

mitophagy pathway, was prevented in SYNJ2^{AAA} mouse primary cortical neurons. In addition, mitochondrial bioenergetics was impacted by the mutation of the RRM: under stress conditions, ATP levels were reduced in the mutants compared to WT mouse primary neurons. Our work demonstrates the functional importance of SYNJ2 in mitochondrial mRNA transport and translation for regulating mitochondrial health and will further our understanding of how distal mitochondrial mechanisms are compromised in neurodegeneration.

Evidence that autophagy plays roles in alzheimer's disease

M. Ranjbar[1], E. L. Bearer[2]; [1]University of New Mexico, Albuquerque, NM, [2]Department of Pathology, University of New Mexico Health Sciences Center, Albuquerque, NM.

Intro: Neurodegenerative diseases are tightly related to the process of Aging in the cells. Autophagy as a critical mechanism for the turnover of cell contents can be a key pathway in order to regulating aging. By the way, the whole genomic pathway of autophagy is not known clearly. With a holistic knowledge of genetic alterations in the autophagy genetic map, we may be able to have a more profound picture of the potential roles of genetic variations in autophagy genes and their relationship with neurodegenerative diseases such as Alzheimer's Disease (AD).Method: A comprehensive list of potential autophagy genes was prepared, using 5 different sources. As one of the references, a machine learning (ML) method was used to find so-called autophagy dark genes, which are genes that can be related to the enormous autophagy machine but are currently ignored by the autophagy database. After that, these genes were checked with previous studies on the genomics of AD to find their presence in the pathologic pathway of the disease. Single nucleotide polymorphisms (SNPs) of the discovered genes were observed from the previously collected sequencing data.Results and Discussion: More than 9800 gene names were found in the comprehensive list. Additionally, a list of the top 20 autophagy dark genes was prepared. Our further exploration showed strong connections of those genes to the autophagy system and AD. It suggests the potential roles of autophagy in neurodegenerative diseases such as AD. This project is supported by the National Center for Research Resources and the National Center for Advancing Translational Sciences of the National Institutes of Health through Grant Number UL1TR001449 and by NIH Common Fund U24 CA224370.

Microscoop, a discovery-based image-guided proteomics technology, reveals novel factors on amyloid-beta aggregates in differentiated SH-SY5Y cells

C. Huang, **W. Chong**, C. Huang, Y. Chen, C. Chung, H. Chang, J. Liao; Syncell Inc., Taipei, TAIWAN.

Aggregation of amyloid-β peptides (Aβ) is a hallmark of Alzheimer’s disease (AD). Subcellular distribution of Aβ is well recognized under a microscope, but its pathological and physiological functions remain unclear, partially due to our limited understanding of interacting proteins and corresponding signaling pathways associated with Aβ. Existing spatial proteomics technologies focus on mapping of known proteins using antibody panels/arrays, hindering hypothesis-free proteome discovery. In this study, we used Microscoop^{TM}, a fully-automated microscopy-guided subcellular photolabeling with a machine learning-based precision recognition to enable discovery-based image-guided proteomics. We applied Aβ1-42 deposition in human neuroblastoma, SH-SY5Y, differentiation cells as an AD model. Multiple images of Aβ1-42 aggregates were applied to segment to locations of specific Aβ1-42 aggregates of

interest using convolutional neural networks (CNN)-based deep learning. Microscoop was used to illuminate these segmented regions to induce photochemical reactions of proprietary photosensitive probes and trigger spatial covalent labeling of proteins adjacent to Aβ1-42 aggregates. This spatial-specific photochemical labeling process was repeated automatically on thousands of microscopic fields of view to accumulate enough Aβ1-42-associated proteins for LC/MS-MS-based proteome identification. A series of novel factors were discovered to be associated with Aβ aggregation in SH-SY5Y differentiated cells. We further validated these newly identified proteins using antibody staining and found that these proteins indeed colocalized with Aβ1-42. The finding of these novel factors opens a door to reveal associated signaling pathways related to AD. They may also serve as new diagnostics biomarkers or new AD drug target. Our study not only reveals the Aβ-associated spatial proteome, but also demonstrates its possible broad applications on discovery-based spatial proteomics in neuroscience.

Intricate viral proteins: A deathly hallow to affect the brain

D. Tiwari, H. C. Jha; Department of Biosciences and Biomedical Engineering, Indian Institute of Technology Indore, Madhya Pradesh, Indore, INDIA.

Historically, virus infections have been linked to neurodegenerative disorders. Members of the *Herpesviridae* family are the most well-known culprits for causing damage to the neurological milieu. Among them, Epstein-Barr virus (EBV) is one pathogen with high population penetrance. It infects >95% of the global population asymptomatically and establishes lifelong latency. In some cases, EBV infection could give rise to fatal consequences such as gastric cancer, blood cancer, and neurodegenerative disorders (NDs). However, what triggers the initiation of such grievous outcomes is still not clearly understood. Although, the clinical presence of EBV in CSF and tissue samples of patients suffering from NDs, along with its recently established neurotropic potential, strongly suggests its role in neurodegeneration. Further, various processes closely linked with NDs like Alzheimer's (AD) and Parkinson's disease (PD), such as neuroinflammation, cell-cycle disruption, and Reactive Oxygen Species (ROS) homeostasis, are shown to be affected by EBV. We hypothesize that EBV has the potential to modulate neuronal cellular processes, which are crucial for the development of neurodegenerative pathology, like in AD.The present study attempts to understand the mechanism underlying virus-mediated neurodegeneration that might lead to AD via malfunctioning protein metabolism. The formation of amyloid beta ($A\beta_{42}$) aggregates is a characteristic feature of AD, and previous reports have linked the members of the *Herpesviridae* family with proteinaceous aggregate formation. Therefore, in this study, we tried to determine the aggregate forming tendency of EBV proteins. We performed the *in-silico* analysis of various EBV proteins to evaluate their aggregation proclivity and found that a 12 amino acid long peptide derived from EBV glycoprotein-M (146-157) has a high aggregation tendency. Further, *in-vitro* analysis of the EBV-$gM_{146-157}$ peptide established the formation of aggregates in the solution by a process that followed time- and concentration-dependent kinetics. The viral protein aggregates formed were observed to have a secondary structure similar to $A\beta_{42}$ and were highly cytotoxic to neurons (IMR-32) even at a low concentration of 37μM. We have also observed the increased amyloid-beta aggregate seeding capability of the viral peptide with increasing concentration, corroborating the possibility of viral peptide-mediated aggregation cascade initiation. Our findings demonstrated a positive correlation between amyloid aggregate deposition and viral infection. The proposed hypothesis provides a possible mechanistic explanation of EBV's role in developing AD pathophysiology by initiating the proteinaceous aggregate deposition cascade that has been elusive to date.

TPPP Forms Liquid Condensates and Aggregates in Multiple Systems Atrophy

H. S. Richardson, S. Kemal, J. Nowacki, A. Kopach, M.-m. Fu; National Institute of Neurological Disease and Stroke, Bethesda, MD

Oligodendrocytes are glial cells that make myelin sheaths to increase the speed of neuronal electrical signals. They use radial and lamellar microtubules to seek out and wrap axons. An important protein in this process is tubulin polymerization promoting protein (TPPP), which our lab showed nucleates microtubules outside the cell body from satellite organelles called Golgi outposts. Previous papers noted that TPPP accumulates in oligodendrocytes in Multiple Systems Atrophy (MSA), a neurodegenerative disease characterized by aberrant aggregation of the protein alpha-synuclein (a-syn) in oligodendrocytes. However, the link between the function of TPPP in oligodendrocyte cell biology and its role in disease has yet to be uncovered. We now find that TPPP is a dynamic protein that forms liquid condensates in order to nucleate new microtubules. When using fluorescence recovery after photobleaching (FRAP) on oligodendrocyte cells, TPPP fluorescence recovery happens within a minute. However, TPPP is prone to aberrant aggregation and shaking for 1-2 days can induce recombinant TPPP to form long fibrils and chunks several μm in size. By FRAP, similar aggregates of TPPP can be seen on oligodendrocyte microtubules when TPPP is overexpressed. To see if these accumulations also occur in human samples, immunofluorescent staining was used on human MSA and control brains. When co-stained with myelin basic protein (MBP), fibrillar TPPP accumulations are colocalized with MBP sheaths. Yet, in MSA cases there were fibrillar TPPP accumulations without MBP, showing a possible breakdown of the myelin sheath. There was also an increased amount of perinuclear accumulations in the MSA cases. In MSA brains co-stained with a-syn and TPPP, many perinuclear aggregates had TPPP only (55%) while only 35% were colocalized and 10% were a-syn only. These results indicate that TPPP fibrillar accumulations may represent a precursor stage that begins in the myelin sheath, where Golgi outposts are normally found and where non-pathological TPPP performs important cellular functions. First, the TPPP may cause the myelin sheath to begin degrading. Then, the overabundant TPPP may find its way into the cell body and continue to accumulate. Finally, TPPP and a-syn co-aggregate in oligodendrocyte cell bodies. Ongoing studies will look at the effects of TPPP phosphorylation on its potential to form liquid condensates and aggregate in cells and disease.

Genetic validation of novel drug targets to prevent alpha-synuclein-induced dopaminergic degeneration

E. S. Luth[1], **R. Kienle**[1], E. San Andres[1], C. Beauvais[1], U. Dettmer[2], N. Ramalingam[2]; [1]Biology, Simmons University, Boston, MA, [2]Ann Romney Center for Neurologic Diseases, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

Parkinson’s disease (PD) is a neurodegenerative disease that causes a progressive loss of movement. Hallmarks of PD are the degeneration of dopamine-producing neurons in the substantia nigra and the formation of alpha-synuclein (aSyn) aggregates called Lewy bodies. Currently, there are only treatments for PD symptoms, none actually stop neurodegeneration. We recently identified the cytoskeleton-associated proteins myosin-V and spastin as potential modifiers of the toxicity induced by aSyn in a drug screen with neuroblastoma cells. To validate these potential therapeutic targets in an animal model that

undergoes age-related aSyn-induced neurodegeneration, we used transgenic *C. elegans* that overexpress aSyn and have fluorescently tagged dopamine neurons, allowing for visualization of dopaminergic degeneration. We crossed worms with deletions in either *hum-2* or *spas-1*, *C. elegans* homologs for myosin-V and spastin, respectively, into this transgenic strain. Using fluorescence microscopy, we found that 7-day adult mutant worms overexpressing aSyn had more visible head dopaminergic neurons than transgenic worms with wildtype copies of *hum-2* or *spas-1*. Also, a greater percentage of mutant worms had a complete set of anterior dopaminergic neurons compared to worms with only the aSyn transgene. Overall, our data suggest that the knockout of *hum-2* or *spas-1* prevents dopaminergic neuron degeneration caused by aSyn overexpression. These results support efforts to pursue myosin-V and spastin as novel drug targets to stop the dopaminergic neurodegeneration in PD. In the future, we plan to look at dopamine-mediated behavior in aSyn-overexpressing worms with *hum-2* or *spas-1* mutations to see if, in addition to protecting against their overt loss, disrupting *hum-2* or *spas-1* preserves dopaminergic neuron function.

B409/P2086

TMBIM6 prevents the apoptosis on in vitro and in vivomodels of Parkinson´s Disease

P. Ahumada-Montalva[1], W. Gómez[2], M. Calegaro-Nassif[2], M. Sanhueza[3], R. Vidal[4], D. Rojas-Rivera[1]; [1]Cell Death and Biomedicine Laboratory, Universidad Mayor, Santiago, CHILE, [2]2Autophagy and Neurodegeneration laboratory, Universidad Mayor, Santiago, CHILE, [3]Centro de resilencia, adaptación y mitigación, Universidad Mayor, Temuco, CHILE, [4]Center for Integrative Biology, Universidad Mayor, Santiago, CHILE.

Introduction: Parkinson´s disease (PD) is a common neurodegenerative syndrome characterized by dopaminergic (DAergic) neurons death, and consequent extrapyramidal movement disorder. Unfortunately, PD has no cure. Tmbim6 is an anti-apoptotic protein that integrates several key cellular processes. Tmbim6 arises as protective factor in other disorders, but its possible neuroprotective role in PD is unknown. Here, we hypothesize that Tmbim6 plays a neuroprotective role in PD, avoiding DAergic neurons death. **Methods:** We inhibited Tmbim6 on primary cortical neuron cells (CXNs) using small molecules and siRNA. Then, Additionally, we decreased Tmbim6 expression on whole brain- and DAergic neurons- of drosophila using siRNA and assessment locomotor and survival. Then, we injected small molecules inhibitor of Tmbim6 on substantia nigra of mouse and the motor skills and DAergic neurons was assessment. Also, we overexpressed Tmbim6 on CXNs genetic technique and then cell death was assessment by real-time cell death assays, meanwhile cleaved caspase 3 levels was assessment by western blotting. **Results:** In brief, we demonstrated *in vivo* that the loss of Tmbim6 in pan- and DAergic-neurons causes a rapid and significant deficit in locomotor ability on flies exposed to rotenone, in contrast to the control. Also, we had shown inhibition of Tmbim6 on substantia nigra causes a rapid and significant deficit in locomotor skills. Finally, we shown that overexpression of Tmbim6 decrease both cell death and levels of cleaved caspase 3 induced by 6-OHDA and rotenone on CXNs. **Discussion:** For first time, we demonstrated *in vitro* and *in viv*o the neuroprotective role of Tmbim6 in sporadic PD models. We demonstrated that inhibition of Tmbim6 on primary cortical neurons triggers the cell death, also we observed that lack of Tmbim6 on neurons cause decreased in life spam and locomotor ability in drosophila, principal features of PD-like neurodegeneration. We concluded that Tmbim6 is critical to neuronal survival. For last, the overexpression of human Tmbim6 result in decreased cell death caused by 6-OHDA and rotenone on cortical neurons. We conclude that overexpression of Tmbim6 is

neuroprotector on PD. Taken together, our work is the first to strongly suggest a possible neuroprotective role of Tmbim6 in PD.

B410/P2087

A novel neuroprotective role of Reelin signaling in a cellular model of NPC disease

C. Alarcon-Godoy, A. Pacheco, N. Sommer, M. Benitez, M. Marzolo; Dept. Cell and Molecular Biology, Pontificia University Catolica Chile, Santiago, CHILE.

Niemann-Pick type C (NPC) disease is a rare lipid-storage disorder mainly caused by mutations in the NPC1 transporter, which regulates the export of unesterified cholesterol from lysosomes. The accumulation of cholesterol and glycosphingolipids in endo-lysosomal compartments impairs lysosomal degradation functions and trafficking. In neurons, lysosomal impairment evokes oxidative stress and neuronal cell death, driving severe neurological symptoms in NPC patients. Reelin is a secreted glycoprotein with several functions in neurodevelopment and the adult brain that triggers a complex signaling pathway upon binding to ApoER2 or to VLDL, receptors belonging to the LDLR family. Reelin has protective effects in neurodegenerative disorders such as Alzheimer's disease and Parkinson's disease. To evaluate if Reelin has a neuroprotective effect in an NPC condition, we induced an NPC1-like phenotype using the U18666A inhibitor, which accumulates cholesterol in the lysosomes. Scholl's analyses showed that the addition of Reelin in primary hippocampal neurons treated with U18666A partially recovered dendritic arborization. Moreover, Reelin increased the survival of neurons treated with U18666A by MTT assay and reduced apoptotic nuclei. Interestingly, reelin effects were possibly associated with a reduction of the NPC1 phenotype induced by U18666A by decreasing the accumulation of cholesterol (determined by the intensity of filipin staining) compared to mock and causing a re-distribution of those endo-lysosomes to the cell periphery. The bioavailability of Reelin and its signaling components could modulate the pathology's essential traits, allowing some functional recovery of damaged organelles.

Blockade of endo-lysosomal pathway promotes progranulin-deficient microglial toxicity via proinflammatory lipids

K. Hashimoto, E. J. Huang; University of California San Francisco, San Francisco, CA

While microglia are key cells to maintain brain functions by preventing damage, it is becoming clear that aging changes microglial functions toward to having neuronal aggressive character. However, it remains unclear the details how aged microglia influences neurodegeneration.Dominant mutations in the human Progranulin (*GRN*) gene dramatically reduce Progranulin levels in the brain and are causally connected to frontotemporal dementia. To investigate how Progranulin deficiency promotes neurodegeneration, we have shown that Grndeficient ($Grn^{-/-}$) mice develop hyperactivation of microglia, which affects cytoplasmic TDP-43 aggregation and neuronal loss via excessive complement production. Another phenotype in $Grn^{-/-}$ mice is the abnormal lipidosis in aged brain, however, the mechanisms leading to these lipid phenotypes and how the lipid metabolic defect impact neurodegeneration in $Grn^{-/-}$ mouse brain are not revealed. Here, we combined sucrose density gradient-based subcellular fractionation of $Grn^{+/+}$ and $Grn^{-/-}$ aged mouse brains with proteomic and lipidomic analyses to show that Progranulin deficiency caused proteomic changes that affected the endo-lysosomal pathway and altered lipidomic profiles in $Grn^{-/-}$ brain early endosomes and lysosomes. Interestingly, confocal microscopic analyses

showed that drastic accumulation of lipids was occurred in *Grn*$^{-/-}$ microglia and neurons, not in astrocytes and oligodendrocytes. To determine the detail mechanisms how *Grn*$^{-/-}$ microglia show lipid metabolic defect, we performed lipidomic profiling in primary microglia and microglia conditional media from *Grn*$^{+/+}$ and *Grn*$^{-/-}$ mice and analyzed subcellular localization of lipids in *Grn*$^{+/+}$ and *Grn*$^{-/-}$ primary microglia. These data indicated that lipidomic alteration in *Grn*$^{-/-}$ microglia were caused by the failure to engage lipids to lysosome-mediated degradation, leading to increase in lipid storage and secretion. Using microglia-neuron co-culture system, we showed that the lipid-enriched *Grn*$^{-/-}$ microglia promote dendritic degeneration and cell death in *Grn*$^{-/-}$ neurons, which can be neutralized by monoclonal antibody E06, a functional blocker of oxidized phospholipids. These results propose novel insights how endo-lysosomal block in *Grn*$^{-/-}$ microglia promote disrupt microglia-neuron homeostasis, thereby promoting neurodegeneration by the accumulation and secretion of proinflammatory lipids.

Autolysosomal Exocytosis of Lipids Protect Neurons from Ferroptosis

I. Ralhan[1], J. Chang[1], M. J. Moulton[2], L. D. Goodman[2], N. Y. J. Lee[1], G. Plummer[1], H. Pasolli[3], D. Matthies[4], H. J. Bellen[2], M. S. Ioannou[1]; [1]University of Alberta, Edmonton, AB, CANADA, [2]Baylor College of Medicine, Houston, TX, [3]The Rockefeller University, New York, NY, [4]National Institutes of Health, Bethesda, MD.

During oxidative stress neurons release lipids that are internalized by glia and stored in lipid droplets. This process is essential to maintain the health and function of the nervous system. Defects in this coordinated process play an important role in several neurodegenerative diseases. Yet, the mechanisms of lipid release and its consequences on neuronal health are unclear. Here, we demonstrate that lipid-protein particle release by autolysosome exocytosis protects neurons from ferroptosis, a biochemically distinct form of cell death driven by lipid peroxidation. During oxidative stress in primary cell culture or fly retina, neuronal lipid release depends on the lysosomal exocytic machinery; VAMP7 and syntaxin 4. We show that these lipids are released through exocytosis of autolysosomes. We observe membrane-bound lipid-protein particles by transmission electron microscopy and demonstrate these particles are released from neurons using cryo-electron microscopy. Failure to release these lipid-protein particles causes lipid hydroperoxide accumulation and cell death by ferroptosis. Our results reveal how neurons use autolysosomal exocytosis to rid themselves of peroxidated lipids generated during oxidative stress. Given the number of brain pathologies that involve ferroptosis, defects in this pathway likely play a key role in the pathophysiology of neurodegenerative disease.

Aberrant neuronal connectivity between the ventral hippocampus and medial prefrontal cortex leads to social impairments in *Kansl1*-deficient mice

B. Jeon, T. Ford; Department of Biological Sciences, Kent State University, Kent, OH.

Koolen-de Vries syndrome (KdVS), also known as 17q21.31 microdeletion syndrome, is a neurodevelopmental disorder and displays social behavior deficits. While haploinsufficiency of the *KAT8 regulatory NSL complex complex subunit 1* (*KANSL1*) gene is associated with KdVS, the cellular basis of *KANSL1* haploinsufficiency regarding social impairments is unknown. Here, using *Kansl1* heterozygous knockout mice, we report that the brain circuit between the ventral hippocampus (vHi) and medial prefrontal cortex (mPFC) is disrupted in the *Kansl1* mutant mouse. Stereotaxic injections of

fluorescence-tagged AAVs and dyes revealed an increase in the vHi-mPFC connection in the *Kansl1* haploinsufficient mouse compared to the wild type control. Accordingly, the cellular activity marked by c-Fos expression is altered in the mPFC of the *Kansl1* mutant mouse. This change of the vHi-mPFC circuit appears to involve parvalbumin interneurons in the mPFC. We further show that the abnormal connection in the *Kansl1* mutants is functionally relevant to social deficits. *Kansl1* haploinsufficient mice display social exploration and recognition deficits. DREADD-mediated chemogenetic inhibition of the vHi-mPFC circuit improved the social phenotypes in the mutant mice. Our results highlight the critical status of the vHi-mPFC brain circuit as a potential pathogenic factor for KdVS.

B414/P2091

A Brain Permeable Bioluminescent Substrate for NanoLuc based Reporters

J. R. Walker[1], Y. Su[2], X. Wu[2], K. Casey[2], G. Hong[2], **T. A. Kirkland**[3], M. Z. Lin[2]; [1]Amgen CORPORATION, Thousand Oaks, CA, [2]Stanford University, Palo Alto, CA, [3]PROMEGA CORPORATION, Madison, WI

Here we report thediscovery of a new brain-permeant NanoLuciferase (NLuc) substrate which we arecalling cephalofurimazine (CFz). CFz is a fluorinated analog of furimazine, andwas discovered through extensive SAR studies looking for NLuc substrates thatshowed good penetration into the CNS and brain distribution. We show the signal from this substrate in thebrain of transgenic mice expressing NLuc fused to an orange fluorescent proteinCyOFP. This fusion was linked with two differentproteins, CamkIIa and Vglut2, that show known expression throughout the brain,and we demonstrate that the signal obtained is consistent with the known expressionpattern of those proteins in the mouse brain. We then demonstrate that the CFz/NLuc-CyOFP system is sufficient toimaging brain activity in freely moving mice using a head mounted camera. Finally, aided by the facility by which NLucbased biosensors can be constructed, we pair CFz with a calcium sensor based onNLuc and show calcium dependent bioluminescence in the brain in response tohind limb stimulation.

Exposure to the non-phthalate plasticizer, acetyl tributyl citrate (ATBC) results in cell cycle arrest in Neuro 2a cells

L. Carnell, K. A. Sease, A. K. Binder; Central Washington University, Ellensburg, WA

Phthalate plasticizers are noncovalently bound compounds used to make plastics malleable in a variety of household products such as plastic food wrap, personal care products, toys, and medical tubing. Phthalates have been shown to leach out of these plastic products and compromise organismal health by disrupting the nervous and reproductive systems. As a result of these detrimental effects, non-phthalates plasticizers have been developed and are being used as alternatives, but the effects of phthalate-free plasticizers on cellular health have not been extensively studied. Our goal was to examine the effects of one alternative plasticizer, acetyl tributyl citrate (ATBC), on neurons using the mouse neuroblastoma (Neuro2a) cell line as a model. Previous studies in our lab using Neuro2a cells demonstrated that ATBC at concentrations of 100µM or greater resulted in a significant decrease in the number of cells 72 hours after treatment. However, this decrease was not due to increased cell death as measured by propidium iodine staining. To further examine the mechanism for the decrease in cell number in ATBC-treated Neuro 2a cells, we utilized flow cytometry and quantitative reverse-transcriptase PCR (qRT-PCR) to measure cell cycle arrest and identify proteins involved in these pathways. We determined that 100 µM ATBC-treatment resulted in a decrease of cells in G2 by 14%

compared to vehicle-treated controls (P = .01109; N=2). Using qRT-PCR, we measured 24 hours after ATBC treatment a 1.9 fold increase (P = .01943; N=6) in expression of *p53*. Together these results suggest that ATBC is causing cell cycle arrest in dividing Neuro 2a cells. Further studies will examine whether these cells are undergoing senescence or continuing onto apoptosis. The data suggest that the phthalate-free plasticizer ATBC is also detrimental to cell proliferation and may not be a safer alternative for phthalates.

Synaptic Biology: Glucose Metabolism

B416/P2093

The role of mitochondrial Sirtuin 3 in the metabolic plasticity of synaptic transmission

A. Tiwari[1], A. Hashemiaghdam[1], M. Laramie[1], C. Bergom[2], G. Ashrafi[1]; [1]Cell Biology and Physiology, Washington University in St. Louis, St. Louis, MO, [2]Department of Radiation Oncology, Washington University in St. Louis, St. Louis, MO.

Neurons spend 70-80% of the brain's total ATP budget and much of this energy is directed to nerve terminals to support synaptic transmission. Neurons predominantly utilize glucose as their main energy source, however, they can also utilize alternative fuels like lactate when glucose becomes scarce during intense electrical activity or prolonged fasting. These alternative fuels are primarily oxidative and require mitochondrial oxidative phosphorylation (OXPHOS) to produce ATP. Metabolic plasticity in fuel usage is critical to maintain neuronal function in the face of glucose shortage, yet we know relatively little about when and how neurons utilize alternative fuels, or what the functional consequences might be. Here, we uncover a neuronal signaling pathway that is activated during glucose deprivation and enables nerve terminals to upregulate mitochondrial ATP synthesis and maintain synaptic transmission. To delineate neuronal metabolic response to fuel restriction, we first performed RNA sequencing analysis of cultured cortical neurons deprived of glucose. We uncovered the activation of the CREB pathway including induction of the transcription factor PGC1-a, a master regulator of mitochondrial function, and one of its known targets Sirtuin 3 (Sirt3). We similarly showed an induction of Sirt3 expression *in vivo* in the hippocampi of mice kept on intermittent fasting diet as compared to mice fed ad-libitum. Consistent with the upregulation of Sirt3 expression, we observed a reduction in the acetylation of mitochondrial proteins in glucose-deprived cultured neurons. The mitochondrial deacetylase Sirt3 has been shown to regulate ATP synthesis in non-neuronal cells through post-translational modification of OXPHOS enzymes. We examined how Sirt3 regulates ATP metabolism in neurons in absence of glucose. We focused on nerve terminals as they are the site of synaptic transmission and a locus of high ATP demand in neurons. Using the optical ATP sensor Syn-ATP, we determined that Sirt3 is required for maintenance of baseline ATP level in nerve terminals supplied with lactate. Through a combination of proteomic and optical methods, we revealed that Sirt3 regulates mitochondrial pyruvate uptake through deacetylation of the mitochondrial pyruvate carrier (MPC), and showed that an acetyl-mimetic form of the MPC subunit 1 was defective in pyruvate uptake. Furthermore, we demonstrated that Sirt3 is essential for metabolic support of synaptic vesicle retrieval after release in nerve terminals supplied with lactate. In summary, our study uncovers that the upregulation of Sirt3 during glucose deprivation ensures neuronal metabolic fitness and sustains neurotransmission by regulating mitochondrial pyruvate uptake.

Differential localization of specific isoforms of the glycolytic protein GPI-1 reveals subcellular organization of glycolysis in neurons

I. Gonzalez[1], A. Wolfe[1], R. Goodman[2], D. Colón-Ramos[1]; [1]Departments of Neuroscience and Cell Biology, Yale University, New Haven, CT, [2]Vollum Institute, Oregon Health & Science University, Portland, OR.

How glycolysis, a multi-step enzymatic pathway for glucose metabolism, is subcellularly organized is not well understood. Our lab has shown that glycolytic enzymes such as Phosphofructokinase (PFK-1.1) and Aldolase are capable of reversibly localizing to condensates near neuronal presynaptic sites upon transient energy stress (Jang et al., 2016; Jang et al., 2021). Here we demonstrate that glucose-6-phosphate isomerase (GPI-1), a glycolytic protein that catalyzes the second step of glycolysis, also shows presynaptic subcellular localization, and examine the implications of this localization for neuronal metabolism and synaptic function. The *gpi-1* gene encodes two isoforms (GPI-1A and GPI-1B) that differ in 35 amino acids in the N-terminus which is predicted to form a coiled-coil domain. We observe GPI-1A, which lacks the coiled-coil domain, displays diffuse localization throughout neurites, while the domain-containing GPI-1B isoform displays presynaptic enrichment. Fusion of the N-terminal domain of 35 amino acids to GFP is sufficient to drive presynaptic localization, while disruptions of predicted interaction residues in the coiled-coil domain eliminates presynaptic enrichment of GPI-1B. To examine the role of this localization in neuronal metabolism, we collaborated in adapting HYLight, a new sensor for the glycolytic metabolite FBP, for use *in vivo* in *C. elegans*. We determined that coiled-coil mutants with impaired GPI-1B localization display altered FBP accumulation, suggestive of abnormal rates of glycolysis as compared to wild type. *gpi-1* mutants also demonstrate impaired capacity for PFK-1.1 to form condensates near presynaptic sites during transient energy stress, revealing a role for GPI-1 in the formation of glycolytic condensates near synapses. Our *in vivo* studies uncover mechanisms of subcellular organization that depend on the cell-specific expression of specific isoforms of glycolytic proteins, and allow us to now examine how the tissue-specific subcellular organization of glycolytic proteins regulate metabolic and neuronal function *in vivo*.

B418/P2095

Neuronal activity-driven O-GlcNAcylation promotes mitochondrial plasticity

S. B. Yu[1], R. Sánchez[1], Z. Papich[1], T. Whisenant[2], **G. Pekkurnaz**[1]; [1]Neurobiology, UC San Diego, La Jolla, CA, [2]UC San Diego, La Jolla, CA.

Neuronal activity consists of a series of molecular events, from action potential firing to synaptic vesicle recycling, which require large expenditures of energy. Continuous fulfillment of this energy demand relies on fuel availability and mitochondrial ATP synthesis. However, the molecular mechanisms regulating the activity-driven stimulation of ATP production are largely unknown. Here, we describe a novel signaling pathway capable of regulating mitochondrial bioenergetics, mediated via the enzyme O-GlcNAc transferase (OGT) and O-GlcNAcylation. We used *in vivo* and *in vitro* approaches to demonstrate that neuronal activity upregulates O-GlcNAcylation in neuronal processes. We identified mitochondria as the loci of this modification. This mechanism is activated by an increase in glucose influx and consequent O-GlcNAcylation, which allows neuronal mitochondria to sense fuel availability and promotes mitochondrial bioenergetics to compensate for high energy expenditure. To determine which mitochondrial proteins are responsible for these adjustments, we mapped the mitochondrial O-GlcNAcome of neurons. A majority of identified proteins participate in oxidative phosphorylation and

ATP production. Finally, by measuring activity-dependent on demand ATP synthesis, we demonstrate that when mitochondrial O-GlcNAcylation is blocked, neurons fail to replenish ATP after neuronal stimulation. Our findings suggests that O-GlcNAc cycling provides fuel-dependent feedback control in neurons to optimize mitochondrial performance based on neuronal activity and energy demand. This mechanism thereby couples glucose metabolism to mitochondrial bioenergetics and plays a key role in sustaining neuronal energy homeostasis.

B419/P2096

The Role of Ketone Body Metabolism in Neuronal Function

M. I. Stunault, S. G. Clemens, M. Laramie, G. Ashrafi; Washington University in St. Louis, Saint Louis, MO.

Glucose is the main fuel resource for brain activity. However, when glucose availability is limited, neurons can switch to using ketone bodies (KB) in order to sustain neuronal activity. Three KB are synthetized in the liver by breaking down fatty acids: acetate, aceto-acetate and β-hydroxybutyrate. KB enter the blood circulation and peripheral organs, including the brain, where they are broken down by mitochondria to produce ATP. Ketogenic diets are effective treatment for several pathologies from heart failure to drug-resistant epilepsies. However in excess, KB can be harmful as for example in diabetic ketoacidosis. Therefore, a better understanding of the metabolic effects of KB on neuronal function is of great interest for the development of effective dietary interventions.Thus, the aim of this study is to determine the metabolic changes mediated by ketone body utilization in nerve terminals. We first investigated how supplementation of cultured cortical or hippocampal neurons with KB impacts their viability. In contrast to non-neuronal cell lines, KB improved neuronal viability in a dose-dependent manner, as compared to glucose-deprived conditions.

We have previously shown that neurons can utilize lactate and pyruvate to sustain synaptic activity, and the mitochondrial pyruvate carrier MPC1 was proposed to mediate neuronal KB utilization. Using an shRNA, we demonstrate here that MPC1 is not required for neuronal survival with KB, highlighting the distinction between ketone body and pyruvate metabolism.

To determine if neuronal metabolic plasticity in KB utilization is mediated by transcriptional reprogramming, we examined how the expression of key ketolytic genes were effected in the hippocampi and cortices of mice fed a ketogenic diet (KD). In particular, we aimed to determine whether neurons displayed a transcriptional signature that was consistent with elevated KB levels in the serum of KD-fed mice. To model neuronal KB utilization *in vitro*, we also examined the transcription changes induced by KB in cultured cortical neurons and compared these changes to KD-fed mice. We then investigated the metabolic effects of KB on neuronal function by determining whether mitochondrial oxidation of KB in neurons produces sufficient ATP for synaptic transmission. Using a live imaging technique, we quantified ATP levels in nerve terminals following electric stimulations in neurons supplied with either glucose, lactate and pyruvate, or ketone bodies. Together, our studies demonstrate the metabolic specialization of neurons in utilizing KB as an alternative fuel source. As the mammalian nervous system is composed of many cell types including glia, immune cells, and many neuronal subtypes, it is important to characterize the KB metabolism in a cell-type specific manner.

Establishing and Maintaining Organelle Structure

B421/P2097

Calcium dependence and kinetics of repair small membrane lesions in electropermeabilized cells

O. Pakhomova, S. Bhattacharya, U. Mangalanathan, M. Silkunas, G. Silkuniene, E. Gudvangen, A. Pakhomov; Frank Reidy Research Center for Bioelectrics, Old Dominion University, Norfolk, VA.

Electric stress, in particular with short high-power pulses, offers a unique opportunity to generate small and very small (1-10 nm) membrane lesions without the use of toxins or other chemicals. These lesions are highly permeable to ambient Ca^{2+}, which could expectedly initiate membrane repairs. At present, the involvement of active repair mechanisms and the role of Ca^{2+} in the restoration of electropermeabilized membranes have not been understood. We explored the impact of Ca^{2+} on the kinetics of membrane resealing in mammalian cells after injury with high-power electric pulses (EP). Membrane permeabilization and resealing were monitored by the uptake of YO-PRO-1 (YP) dye, which becomes brightly fluorescent upon entry into electropermeabilized cells and binding to nucleic acids. Bovine pulmonary arterial endothelial cells (BPAE) or human epithelial kidney cells (HEK-293) were grown in a monolayer on glass coverslips, which were positioned on a fluorescent microscope stage equipped with electrodes for EP delivery. Nano- or microsecond duration EP were delivered to selected cells on a coverslip. Ca^{2+} was removed or added after the EP by a fast-step perfusion system. The YP fluorescence intensity of the individual cells was recorded before and after EP application and quantified with MetaMorph software. The time constant τ for membrane recovery was calculated using exponential functions applied to fit YP uptake data. Kinetic analyses of YP dye entry into BPAE cells electroporated with nanosecond EP suggested the involvement of three repair processes: (1) fast, Ca^{2+}-independent repairs with τ of ~15 s; (2) slow, Ca^{2+}-dependent repairs with τ of ~60 s; and (3) still slower Ca^{2+}- independent repairs with τ of ~115 s. The time constants were not affected by the severity of membrane damage, indicating that the repairs were accomplished by recruiting the same repair machinery proportionally to the damage. Future work will attempt to link these processes to the specific cellular machinery.

B422/P2098

Signaling responses that mediate sarcolemmal membrane repair

N. Weisleder; Physiology and Cell Biology, Ohio State Universtiy, Columbus, OH.

Plasma membrane repair occurs in many different cell types as a necessary process to maintain the integrity of the lipid bilayer to provide the essential barrier function of membrane. The specific cellular mechanisms at work in membrane repair are known to involve multiple processes, including exocytosis of intracellular vesicles to the injury site to create a membrane repair patch, endocytosis of lined pores into vesicles to remove them from the membrane, and rearrangement of the cytoskeleton to facilitate membrane repair. Compromised membrane repair responses can lead to, or exacerbate, pathology in multiple human diseases, including muscular dystrophy, cardiovascular disease and neurodegenerative disorders. This is particularly true in the skeletal muscles where repeated contraction cycles and the resultant mechanical stress on the membrane causes disruptions in bilayer in the course of normal cell function. Influx of Ca2+ from the extracellular space through these disruptions and into the cytosol can damage multiple cellular components and result in cell death. Thus, this influx of Ca2+ in skeletal muscle triggers the exocytosis of intracellular vesicles to the injury site where they fuse to form a sarcolemma

repair patch that restores the barrier function of the membrane and allows cell survival. While these elements of this process are known there are several questions that remain about the molecular machinery that facilitates this process. Our work shows that conserved signaling cascades are essential for the induction of membrane repair in multiple cells types. Membrane repair assays on skeletal muscle and non-muscle cell lines demonstrated that this process is dependent on activation of the phosphatidylinositol-4,5-bisphosphate 3-kinase (PI3K) signaling axis through the downstream target Akt1. One mechanism found to increase membrane repair following PI3K/Akt1 activation is elevated exocytotic and endocytotic activity. Further studies indicate that the PI3K/Akt1 pathway is relevant to membrane repair in isolated mouse muscle bundles injured with multi-photon microscopy as PI3K or Akt1 inhibition prevents membrane resealing. Stimulation of this repair response through activation of PI3K/Akt1 signaling can increase membrane repair capacity in transfected muscles from dystrophic mice, indicating that increased PI3K/Akt1 may have potential as a therapeutic treatment for muscular dystrophy.

Sources of variation of nuclear shape dynamics ingrowing hiPSCs

J. Cass[1], .. Allen Institute for Cell Science[1], J. Theriot[2], S. Rafelski[1]; [1]Allen Institute for Cell Science, Seattle, WA, [2]Biology and Howard Hughes Medical Institute, Seattle, WA.

The Allen Institute for Cell Science aims to understand the principles by which human induced pluripotent stem cells (hiPSCs) establish and maintain robust dynamic localization of cellular structures, and how they transition between states during differentiation and disease. We focus first on the nucleus, asking how hiPSCs control robust growth and dynamic shape changes of this key cellular structure during colony growth. We took advantage of a mEGFP-tagged laminB1 line from the Allen Cell Collection of endogenous tagged hiPSC lines to capture nuclear dynamics during colony growth (allencell.org). We imaged live, growing hiPSC colonies in 3D over two days at five minute intervals and then used deep learning image transformation and segmentation methods to segment and track the individual nuclei in these colonies at high resolution. In a previous study we developed a framework to analyze the mean and variability of locations of cellular structures. Likewise, we now focus on investigating mean nuclear shape dynamics and their variability. We explore the mean trajectory of individual nuclei throughout nuclear shape space, and analyze the variations observed around this mean shape. Analysis of the timescale of these variations, relationship between individual and population variations, and links between growth rate and shape behaviors enable us to pursue the biological causes of observed nuclear shape dynamics. For example, we explore the role of the colony context in nuclear shape, characterizing the relationship between a nucleus' position within the colony, its mobility through that local environment and its path through shape space. We find that the growth rate of nuclei and their rate of shape change are correlated, indicating a link between how quickly nuclei grow and how rapidly they explore the available shape space. We also looked at how nuclear shape dynamics vary by initial colony size, and change in response to disruptions to key nuclear processes such as DNA synthesis and import. We found these perturbations to have different impacts on distinct aspects of shape. This general framework for analyzing growth and shape of cellular structures will be extended to each of the key intracellular structures in an integrative fashion.

B424/P2100

Integrated intracellular organization and its variations in human iPS cells

M. Viana[1], Allen Institute for Cell Science[1], J. Theriot[2], S. M. Rafelski[1]; [1]Allen Institute for Cell Science, Seattle, WA, [2]Department of Biology and Howard Hughes Medical Institute, University of Washington, Seattle, WA.

The Allen Institute for Cell Science aims to understand the principles by which human induced pluripotent stem cells (hiPSCs) establish and maintain cellular organization, and how they transition between states during differentiation and disease. As an initial step towards this goal, we generated the "hiPSC Single-Cell Image Dataset" with over 200,000 live cells in 3D spanning 25 major cellular structures. We used these images to develop a computational framework that embraces the vast cell-to-cell variability observed within a normal population and permits quantitative analyses of distinct, separable aspects of organization within and across different cell populations. The framework provides a systematic way of measuring the average locations both of individual structures and all pairs of structures (average location phenotype and average structure similarities), as well as the variability in these locations (stereotypy and concordance). We found cellular organization was very robust across the wide range of cell shapes in the normal interphase population. We also used our framework to perform a comparative study of cellular organization in two cell subpopulations that stood out morphologically in the dataset: colony edge cells and mitotic cells. We found that several structures showed a polarized location towards the colony edge but no change in the wiring (variability and relationships among structures). In contrast, our second subpopulation comparison focused on early mitotic cells confirmed that they undergo a dramatic intracellular reorganization, in which not only the average locations of structures, but also their wiring, changed substantially. A "meta-analysis" of our findings revealed a possible hierarchy of dependencies as cells reorganize. The conceptual aspect of our framework is generalizable, extensible and can be used to perform robust statistical analyses on cell shape and intracellular spatial locations and their variability across cell types and conditions. The experimental and algorithmic implementations of this analysis framework are modular. The choice of which to use is dependent on the specific biological question and this will dictate specific inputs required such as how many cells or cellular structures are needed, what kind of precision is possible, or what kinds of segmentation and data analysis algorithms should be used.

B425/P2101

Role of VRK1 in Nuclear Size Regulation in *Xenopus laevis*

H. Prabha, D. L. Levy; Molecular Biology, University of Wyoming, Laramie, WY.

Acquisition of the characteristic size of intracellular organelle is a fundamental question in cell biology. It is important to gain a better understanding of the mechanisms that control nuclear size in humans because nuclear size and shape are known to change in cancer. Vaccinia-Related Kinase (VRK1) is a serine-threonine protein kinase belonging to the casein kinase-1 family. Its expression is increased in actively dividing cells in testis, thymus, fetal liver and carcinomas with poor prognosis. VRK1 regulates entry into the cell cycle, chromatin condensation in G2/M, Golgi fragmentation, and Cajal body dynamics. VRK1 also plays important roles in the assembly and disassembly of the nuclear envelope, and a recent screen for nuclear morphology effectors identified VRK1 as a putative regulator of nuclear size. We are investigating the function of VRK1 in nuclear size regulation using *Xenopus laevis* egg extracts that support de novo nuclear assembly and growth. Immunofluorescence confirmed the presence of

VRK1 in egg extracts, revealing a punctate intranuclear staining pattern. In order to understand the role of VRK1 in regulating nuclear size we supplemented extract with a small molecule inhibitor of VRK1 either during or after nuclear assembly. We find that VRK1 inhibition results in a significant reduction in nuclear size concomitant with the appearance of nuclear membrane invaginations and nuclei remain import-competent and intact. This effect was more prominent when VRK1 was inhibited post-nuclear assembly. We also observed a redistribution of chromatin upon VRK1 inhibition. Future work will focus on identifying the VRK1 substrate relevant to the regulation of nuclear size.

B426/P2102

Role of Golgins in the cisternal stacking of Golgi apparatus

R. Dahara[1,2], **D. Bhattacharyya**[3,4]; [1]Cell and Tumor Biology, ACTREC, Tata Memorial Center, Navi Mumbai, INDIA, [2]Homi Bhabha National Institute,, Mumbai, INDIA, [3]Internal Medicine, University of Michigan, Ann Arbor, MI, [4]Homi Bhabha National Institute, Mumbai, INDIA.

Regulation of the exotic morphology of the Golgi apparatus is still an enigma. The core of the argument is the cisternal stacking problem, an elusive regulatory mechanism that holds the Golgi cisterna together. GRASP family of proteins was initially implicated in cisternal stacking; however, several groups recently demonstrably argued against such a role (Grond et al., 2020; Zhang and Seemann, 2021). The lack of functional GRASP proteins in model systems harboring stacked Golgi(Levi et al., 2010) also supports such a conclusion and rationalizes the existence of some other universal factors for cisternal stacking. A critical error is ignoring the Golgi apparatus's dynamic nature while framing the problem of cisternal stacking. In light of the cisternal maturation model, Golgi cisternal stacking needs to be a reversible mechanism— it needs to be initiated at the 'cis' side of the cisternal stack and be un-initiated at the 'trans' side. At the end of each such cycle, an unstacked TGN should be separated from the cisternal stack resulting in the form of 'TGN peeling.' 'TGN peeling' is direct experimental evidence of reversible cisternal stacking and has been microscopically validated (Jain et al., 2019; Mogelsvang et al., 2003). For the first time, we documented the role of the GRIP domain Golgin in the reversible cisternal stacking(Jain et al., 2019). Using budding yeast *Pichia pastoris*, we demonstrated how the Arl3-Arl1 GTPase cascade switch regulates GRIP domain Golgin *Pp*Imh1 to mediate reversible cisternal stacking between medial and trans cisterna. Since GRIP domain proteins are conserved in plants, animals, and fungi, it is plausible that this reversible cisternal stacking mechanism is evolutionarily conserved. In the present study, we have explored the role of other Golgins in regulating the cisternal stacking. Using double deletion analysis and chimera studies, we have analyzed the rate of TGN peeling effect and overall Golgi morphology in various conditions using live and electron microscopy. Our study indicates that PpImh1 and other Golgins function synergistically in mediating the reversible cisternal stacking. Our model and data reinforce our previous model and provide further details in Golgin mediated cisternal stacking of the Golgi apparatus.

B427/P2103

Multivesicular body (MVB) maturation involves immobilization on a subset of microtubules by septin GTPases

B. P. Robinson, N. R. Bass, E. T. Spiliotis; Department of Biology, Drexel University, Philadelphia, PA.

Multivesicular bodies (MVBs) are endocytic organelles which sort ubiquitinated proteins into intraluminal vesicles (ILVs) and target them for lysosomal degradation or extracellular release in

exosomes. The intracellular positioning of MVBs is critical for these cargo outcomes, but it is poorly understood how MVBs mature and traffic along the microtubule (MT) cytoskeleton. Previous work has shown that septin GTPases are essential for MVB maturation and ILV formation, but the underlying function(s) and mechanism(s) are unknown. Here, we have discovered that in MDCK epithelia, ~70% of MVBs, which contain the tetraspanin marker protein CD63, the ESCRT-I protein TSG-101 and the intraluminal vesicle lipid lysobisphosphatidic acid (LBPA), associate with a subset of microtubules which are coated with septin GTPases. In contrast to MVBs, a smaller percentage (~35%) of EEA1-containing early endosomes localize to septin-coated microtubules. Quantitative analysis of CD63-positive MVBs showed that immature EEA1-positive/LBPA-negative MVBs were more preferentially bound to septin (SEPT7)-coated microtubules than mature EEA1-negative/LBPA-positive MVBs. Quantitative analysis of CD63-positive MVBs showed that immature EEA1-positive/LBPA-negative MVBs were more preferentially bound to septin (SEPT7)-coated microtubules than mature EEA1-negative/LBPA-positive MVBs. Time-lapse microscopy showed that CD63-containing MVBs were more immotile and continuously bound to septin-coated microtubules, while EEA1-containing early endosomes were overall more mobile and less associated with septin-bound microtubules. To test whether septins slow down MVB motility on microtubules, we reconstituted in vitro the motility of CD63-GFP-positive MVBs, which were isolated from MDCK cells. Strikingly, MVBs were largely immotile on microtubules that were decorated with recombinant SEPT2/6/7/9 complexes, while they moved processively in the absence of septins. Taken together, these data indicate that MVB biogenesis requires septin-mediated immobilization of maturing MVBs on a subset of microtubules, which may allow for protein sorting, acidification, and cargo exchange with endosomes prior to trafficking and fusion with the lysosome or the plasma membrane.

Transmembrane mucins regulate the morphology of the endoplasmic reticulum through negative curvature generation.

M. C. Goudge[1], J. C. H. Kuo[2], M. J. Paszek[2]; [1]Nancy E. and Peter C. Meinig School of Biomedical Engineering, Cornell University, Ithaca, NY, [2]Robert Frederick Smith School of Chemical and Biomolecular Engineering, Cornell University, Ithaca, NY.

The endoplasmic reticulum (ER) is a large, highly dynamic membrane-bound organelle that is essential for many basic cellular functions. Necessary for its proper function are the diverse set of morphologies that the ER membrane exhibits. While an increasingly large body of work has centered around proteins responsible for curvature generation through insertion into the cytoplasmic face of the ER membrane, relatively little is known about protein curvature generators acting on the lumenal face of the ER membrane. Here, we show that transmembrane mucins, a family of membrane anchored biopolymers, generate membrane curvature through entropic crowding forces on the lumenal face of the ER membrane. Using a genetically-encoded Muc1 expression system in combination with live-cell imaging, we find that a surprisingly large fraction of cellular mucin is localized to the ER. We show that with increasing concentrations of intracellular mucin, the prominence of sheets increases in the ER concomitant to a loss in tubules. This morphological transition occurs rapidly and reversibly, with sheets forming and disappearing on the order of hours upon mucin synthesis and translational inhibition, respectively. By applying expansion microscopy, we characterized these mucin-induced sheets at high resolution. Notably, these sheets are organized as cisternae lying perpendicular to the radial direction of the cell. Finally, we characterized mitochondrial morphology and spatial organization in response to the

mucin-induced ER restructuring. Mitochondria in Muc1-expressing cells were found to be less tubulated, smaller, and less homogenously distributed throughout the cell than in their non-Muc1 expressing counterparts. Together, these results suggest a novel role for the large transmembrane mucins to regulate the morphology of the ER and its interactions with other organelles.

Vimentin intermediate filaments scaffold Endoplasmic Reticulum (ER) tubule matrices and pattern global ER mass distribution via Nesprin3/Plectin

A. S. Moore, J. Lippincott-Schwartz; Howard Hughes Medical Institute, Ashburn, VA.

The endoplasmic reticulum (ER) is a continuous membrane-bound organelle found in all eukaryotes. In cultured cells, the ER adopts an elaborate net-like organization characterized by densely stacked sheets in the perinuclear region, sparsely interconnected tubules in the cell periphery, and a complex mixture of both sheets and tubule matrices therebetween. These local ER geometries are maintained by membrane shaping proteins, which tune nanoscale ER curvature to support either planar or highly curved ER organizations. Whilst the factors controlling local ER membrane morphology have been extensively investigated, the mechanisms by which these geometries are spatially compartmentalized within different regions of the cytoplasm are not well understood. Here, using advanced light and electron microscopy techniques, we explore the cytoskeletal control of ER mass distribution. We find that the vimentin intermediate filaments (VIFs) make extensive contacts with the ER and, in concert with microtubules, control the global distribution of ER mass throughout the cytoplasm. In multiple cell types, we observe VIF densities termed “knots” assemble on and stabilize highly concentrated matrices of peripheral ER tubules. Tubules within vimentin-scaffolded ER matrices are immobilized and constricted in diameter, with reduced luminal content and a higher surface area-to-volume ratio than surrounding ER. Vimentin assembly on the ER is coordinated by the LINC complex protein Nesprin3, which recruits cytoplasmic intermediate filaments to the surface of the ER via the giant cytolinker protein plectin. Vimentin-scaffolded ER matrices entrap other cytoplasmic organelles including mitochondria and lysosomes, facilitating extensive and prolonged organelle-organelle contact. Depletion of vimentin eliminates ER matrices and results in an increased abundance of planar ER in the cell periphery. Together, these data provide the first evidence that the vimentin cytoskeleton plays important roles in the stabilization and positioning of tubular ER.

The sorting factor VPS13A is pivotal for quality control of mitochondria and endoplasmic reticulum

G. Rodriguez[1], E. Tank[1], R. Fuller[2], A. Tidball[1], J. Parent[1], S. Barmada[1]; [1]Neurology, University of Michigan, Ann Arbor, MI, [2]Biological Chemistry, University of Michigan, Ann Arbor, MI.

Chorea acanthocytosis (ChAc) is an autosomal-recessive neurodegenerative disorder caused by mutations in the gene encoding vacuolar protein sorting factor 13A (VPS13A). The yeast orthologue, VPS13, aids in the transport of lipids between organelles, and the N-terminal region shows strong sequence homology to the evolutionarily conserved autophagy-related genes (*Atg*) protein family. Although these studies suggest a function for VPS13 proteins in lipid transfer and autophagy, the physiological function and regulation of VPS13A in mammalians cells remains unknown.Here I utilized HEK293T cells in which the native VPS13A has been labeled with mNeonGreen, to identify VPS13A interactors by mass spectroscopy and unbiased proteomics. I also used VPS13A-KO HEK293T cells to

determine how functional loss of VPS13A affects critical pathways relevant to ChAc. These studies, as well as published work on yeast VPS13, led me to investigate specialized branches of autophagy that may be regulated by VPS13A. Loss of VPS13A affects the level of receptors involved in mitochondria-specific autophagy (mitophagy) and endoplasmic reticulum-limited autophagy (ER-phagy). These findings highlight a central function for VPS13A in ER-phagy and mitophagy, a hypothesis I am now exploring through dynamic studies of ER-phagy and mitophagy in HEK293T cells.Future studies will examine the contribution of VPS13A to protein clearance and cellular survival, in human neurons differentiated from induced pluripotent stem cells donated by individuals with ChAc. Collectively, these investigations will help define a function for VPS13A in neurons, outline disease mechanisms, and highlight pathways that may be targeted to prevent neuron loss in this disorder.

In situ architecture of the lipid transport protein VPS13C at membrane contacts

S. Cai[1,2,3,4], Y. Wu[1,2,3,4], A. Guillén-Samander[1,2,3,4], W. Hancock-Cerutti[1,2,3,4], J. Liu[5], P. DeCamilli[1,2,3,4]; [1]Departments of Neuroscience and Cell biology, Yale University School of Medicine, New Haven, CT, [2]Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT, [3]Program in Cellular Neuroscience, Neurodegeneration and Repair, Yale University School of Medicine, New Haven, CT, [4]Aligning Science Across Parkinson's (ASAP) Collaborative Research Network, Chevy Chase, MD, [5]Department of Microbial Pathogenesis, Yale University School of Medicine, New Haven, CT.

VPS13 is a eukaryotic lipid transport protein localized at membrane contact sites. Previous studies had suggested that it may transfer lipids between adjacent bilayers by a bridge-like mechanism. Direct evidence for this hypothesis from a full-length structure and from electron microscopy (EM) studies in situ was still missing, however. Recently, by using cryo-focused ion beam (cryo-FIB) milling and cryo-electron tomography (cryo-ET), we revealed the presence of rod-like densities bridging two adjacent membranes at human VPS13C-mediated membrane contacts in HeLa cells (see Abstract #392 2021 ASCB meeting). We have now applied two approaches to verify that these rod-like densities represent VPS13C. First, we examined a VPS13C truncated mutant, which is predicted to be ~5nm shorter compared with full-length VPS13C by AlphaFold. We found that both the length of rod-like density and the intermembrane space were ~5 nm shorter (Cai, Wu, Guillen-Samander, Hancock-Cerutti, Liu, & De Camilli, pmid: 35858323). Second, subtomogram averaging of rod-like densities in cells expressing full-length VPS13C revealed a twisting rod-like structure, which is overall consistent with the AlphaFold predicted structure showing a twisted β-sheet running along the entire length of the rod. One intriguing finding from subtomogram averaging analysis is that the density is less continuous with the ER membrane than with the endo/lysosome membrane (pmid: 35858323). Ongoing work further investigates transport mechanism of VPS13C by examining its conformational heterogeneity in situ. Taken together, our study provides in situ evidence for a bridge model of VPS13 in lipid transport. (This work was supported in part by a postdoctoral fellowship from the Parkinson Foundation to SC)

Establishing a role for ATG2-mediated Lipid Transport at the Lipid Droplet

J. L. Korfhage, N. Wan, K. M. Reinisch, T. J. Melia; Cell Biology, Yale University, New Haven, CT.

ATG2 is a member of the VPS13-family of rod-shaped proteins thought to facilitate bulk lipid transport between membranes. ATG2 has primarily been studied in the context of autophagy wherein it is thought

to serve as the primary route of lipid flow into the growing phagophore. ATG2 can bind approximately 20 lipids, and its ability to transport lipids between liposomes has been well established *in vitro*. Although its role has primarily been defined in the context of autophagy, ATG2 localizes overwhelmingly to lipid droplets (LDs), and double knockout of ATG2A and B (ATG2 DKO) leads to marked growth and accumulation of LDs as well as defects in fatty acid transport from LDs to mitochondria. Importantly, both of these phenotypes are independent of autophagy. Furthermore, ATG2 intrinsically supports two functions: tethering of two membranes in support of contact site maintenance as well as biochemical facilitation of lipid transport. Thus, how ATG2 supports LD homeostasis and specifically whether its lipid transport function is necessary has not been tested.
To test whether lipid transport is necessary for any phenotype of an VPS13-family protein, lipid transport *per se* must be blocked without disrupting the protein's capacity to bridge membranes. Here we **1)** develop a lipid transport dead ATG2 mutant (TD-ATG2A) which folds properly and localizes to LDs. TD-ATG2A maintains the overall tertiary structure of WT ATG2A while the N-terminal region of the hydrophobic groove is occluded by the mutation of 10 hydrophobic residues to hydrophilic residues. **2)** Using *in vitro* lipid transport assays based on FRET dequenching, we show that TD-ATG2A is incapable of facilitating liposome to liposome lipid exchange. **3)** Expression of WT ATG2A but not TD-ATG2A in an ATG2 DKO background rescues LD accumulation observed in ATG2 DKO cells, thereby establishing ATG2 lipid transport activity as necessary for the maintenance of LD homeostasis in cells.

B433/P2109

ATG9 vesicles are incorporated into nascent autophagosome membranes

T. J. Olivas[1], S. Yu[1], Y. Wu[1,2,3], L. Luan[1], P. Choi[1], S. Nag[1], P. De Camilli[1,2,3], K. Gupta[1,4], T. J. Melia[1]; [1]Cell Biology, Yale University, New Haven, CT, [2]Neuroscience, Yale University, New Haven, CT, [3]Howard Hughes Medical Institute, New Haven, CT, [4]Nanobiology Institute, Yale University, West Haven, CT.

The autophagosome is a double-membrane organelle that traps cytoplasmic cargo and traffics it to the lysosome for degradation. How the autophagosome forms is uncertain, but a prevailing model suggests lipids are moved from the ER through the lipid transporter ATG2 to ATG9 vesicles, which then expand to comprise the growing autophagosomal membrane. However, incorporation of ATG9 into the expanding phagophore is not readily observed; detection of this putative autophagosome-resident protein is made challenging both because the majority of ATG9 vesicles in the cell are not involved in the biogenesis at any given time and because the dilution of one or a few vesicle membranes by potentially millions of transported lipids would result in a very low density of ATG9 on the mature autophagosome. Here we develop approaches to address each of these limitations. We show that in genetic knockouts of ATG2, ATG9 vesicles accumulate at sites of aborted autophagosome formation. Focused-ion beam scanning electron microscopy reveals that without ATG2, these putative autophagosome seed vesicles do not expand, but instead accumulate within a large vesicle cluster surrounded by ER that we have termed the pre-ATG2 compartment. By fluorescence microscopy, we also detect downstream modifiers of the autophagosome membrane in this compartment, including the lipid-anchored form of the LC3 proteins, which suggests that a biochemically competent seed membrane is present. To establish whether ATG9A is found on the same membrane as LC3B, we use styrene maleic acid (SMA) copolymer nanodiscs to isolate nanoscale spans of autophagosome membrane away from all other potential contaminants. Through rigorous combinations of isolation and purification, we reveal that ATG9A and LC3B are co-resident within the same 10 nm diameter membrane segment and likely engage in a protein-protein

complex on both autophagosome precursor membranes from the pre-ATG2 compartment and WT autophagosomes. Thus, we assert that the ATG9 vesicle is the seed membrane for the autophagosome.

The NTPase activity of the Double FYVE Domain Containing Protein 1 (DFCP1) regulates lipid droplet metabolism.

V. A. Ismail, T. Naismith, D. J. Kast; Washington University in St. Louis, Saint Louis, MO.

Lipid droplets (LDs) are dynamic lipid storage depots that play a central role in cellular metabolism by providing lipids for the repair and biogenesis of membranous organelles, and serving as a source of energy during times of nutrient stress. However, the molecular mechanisms that regulate the growth and degradation of LDs are poorly understood. It has emerged that proteins that makes contact between LDs and the ER play a critical role in regulating LD metabolism. Recently, the autophagy related protein, Double FYVE Domain Containing Protein 1 (DFCP1) was shown to reside at the interface of the ER and LDs, however little is known about DFCP1's roles in autophagy and LD metabolism. Using a combination of cell biology and biochemical approaches, we show that DFCP1 is a novel NTPase that regulates FFA metabolism by modulating the catabolism of LDs. Specifically, we show via Seahorse assays and TLC that DFCP1 inhibits fatty acid-dependent cellular metabolism and that DFCP1 KD increases overall processing of triacylglycerides. By expressing strategic truncations in cells and then purifiying LDs, we show that DFCP1 accumulation on LDs is independent of PI3P-binding, but requires a combination of the ER-binding domain and a unique NTPase domain. Using size-exclusion chromatography and antibody-based NTPase assays, we show that this novel NTPase domain has the ability to dimerize and can hydrolyze ATP and GTP. Furthermore, mutations in the DFCP1 that impact nucleotide hydrolysis or dimerization result in changes in the accumulation of DFCP1 on LDs, LD density and size, and targeting of LDs by autophagosomes. Importantly, the magnitude of these changes depends on the nutritional status of the cell. Collectively, our findings indicate that DFCP1 is a nucleotide-dependent metabolic switch that modulates the cellular storage of free fatty acids.

Yeast Lunapark inhibits atlastin-mediated ER fusion by interfering with formation of *trans*-atlastin complexes.

E. Jang[,1], Y. Jun[,1]; GIST, Gwangju, Korea, Republic of

The overall structure of the endoplasmic reticulum (ER) is composed of sheets and networks. The ER network is a dynamic structure, constantly undergoing fusion and fission. In *Saccharomyces cerevisiae*, ER membrane fusion is mediated by the dynamin like GTPase Sey1p. The ER network is maintained by the membrane proteins; reticulon/Rtn1p, DP1/Yop1p and Lnp1p, a member of the conserved Lunapark family, stabilizes three-way junctions. Although there are evidences which suggest that Lnp1p acts as antagonist of Sey1p to balance polygonal network formation, the underlying mechanism remains unclear. Here, we designed an in vitro assay to quantify trans-, cis- Sey1p complex formation using isolated yeast microsomes. Using this assay, we identified increase of *trans*-Sey1p complex formation in the absence of Lnp1p. Moreover, the N-terminus deleted (NTΔ) Lnp1p lost its inhibitory function in Sey1p mediated membrane fusion. Similar to Lunapark in higher eukaryotes, Lnp1p is also attaches to the membrane using N-terminus, but without myristoylation site. Through the N-terminus of Lnp1p attached to the membrane, NTD (GTPase-Helix bundle) of Sey1p attaches to the membrane. Membrane-

attached Sey1p by N-terminus of Lnp1p is limited in formation of trans- Sey1p complex for ER membrane fusion. Collectively, our data suggest that Lnp1p acts as an antagonist of Sey1p before ER membrane fusion by inhibiting the formation of trans-sey1p complex through its N-terminus prior to initiation stages of ER membrane fusion.

B436/P2112

Membrane fusion by *Drosophila* atlastin does not require GTP hydrolysis

D. Crosby, T. H. Lee; Carnegie Mellon University, Pittsburgh, PA

Atlastin (ATL) GTPases undergo trans dimerization and a power stroke-like crossover conformational rearrangement to drive endoplasmic reticulum membrane fusion. Fusion depends on GTP, but the role of nucleotide hydrolysis has remained controversial. For instance, nonhydrolyzable GTP analogs block fusion altogether, suggesting a requirement for GTP hydrolysis in ATL dimerization and crossover, but this leaves unanswered the question of how the ATL dimer is disassembled after fusion. We recently used the truncated cytoplasmic domain of wild-type *Drosophila* ATL (*D*ATL) and a novel hydrolysis-deficient D127N variant in single turnover assays to reveal that dimerization and crossover consistently precede GTP hydrolysis, with hydrolysis coinciding more closely with dimer disassembly. Moreover, while nonhydrolyzable analogs can bind the *D*ATL G domain, they fail to fully recapitulate the GTP-bound state. This predicted that nucleotide hydrolysis would be dispensable for fusion. Here we report that the D127N variant of full-length *D*ATL drives both outer and inner leaflet membrane fusion with little to no detectable hydrolysis of GTP. However, the trans dimer fails to disassemble and subsequent rounds of fusion fail to occur. Our findings confirm that ATL mediated fusion is driven in the GTP-bound state, with nucleotide hydrolysis serving to reset the fusion machinery for recycling.

B437/P2113

Single-particle cryo-EM analysis of the purinosome

S. J. Calise, J. Molfino, M. S. Dickinson, J. Quispe, J. M. Kollman; University of Washington, Seattle, WA

The purinosome is a membraneless organelle assembled from the six enzymes of the *de novo* purine nucleotide biosynthesis pathway, which dynamically reorganize in the cytosol to increase metabolic flux when cellular purine demand is high. Recent studies have used cell-based assays to demonstrate liquid-like properties of the purinosome, despite the lack of intrinsically disordered or low-complexity domains in pathway enzymes. We aim to reconstitute the purinosome structure and biochemical activity of the pathway *in vitro* to define the molecular mechanisms of assembly and potential allosteric regulation among purinosome enzymes. Here, we employed single-particle cryogenic electron microscopy (cryo-EM) to determine structures of purified human purinosome components in solution. We determined a 4.1 Å resolution cryo-EM structure of the bifunctional phosphoribosylaminoimidazole carboxylase/succinocarboxamide synthetase (PAICS) apoenzyme in its octamer state, which catalyzes the sixth and seventh steps in purine synthesis and is thought to be a hub for purinosome assembly. Although PAICS interacts with all other pathway enzymes in cells, it did not make binary or ternary interactions with different combinations of trifunctional purine biosynthetic protein adenosine-3 (GART), phosphoribosylformylglycinamidine synthase (PFAS), adenylosuccinate lyase (ADSL), or aminoimidazole carboxamide ribonucleotide transformylase/inosine monophosphate cyclohydrolase (ATIC) in our *in vitro* assays, suggesting assembly requires more complex multimeric mixtures or a missing cellular cofactor yet to be identified. Crystal structures exist for most pathway enzymes, but no

previous structures of human PFAS had been determined, likely owing to its insolubility when expressed in *E. coli*. To get around solubility issues, we optimized purification of PFAS from human Expi293F cells. Twin-Strep-tagged PFAS was initially purified by affinity capture, prior to removal of the tag with tobacco etch virus protease and subsequent purification by size-exclusion chromatography. We then determined high-resolution cryo-EM structures of PFAS in its apoenzyme state (3.2 Å), in complex with substrate analogues (4.4 Å, preliminary), and in complex with products (4.2 Å, preliminary), establishing a structural basis for human PFAS function. Additional cryo-EM structures of remaining pathway enzymes will be critical for future *in vitro* reconstitution of the purinosome.

Reconstitution of membrane fusion by human atlastin-3 reveals differential regulation of ATL paralogs

S. Bryce, D. Crosby, T. Yang, M. Stolzer, D. Durand, T. H. Lee; Biological Science, Carnegie Mellon University, Pittsburgh, PA.

Atlastin (ATL) GTPases maintain endoplasmic reticulum (ER) network structure through GTP-dependent membrane fusion. Among the three differentially expressed ATL paralogs (1-3) in humans, ATL1 and ATL2 catalyze membrane fusion in vitro, are sufficient to rescue ER defects in ATL1/2/3 knockout (KO) cells and are autoinhibited by their respective C-termini. Although ATL3 shares sequence and structural conservation with ATL1/2, whether it has a similar function has been questioned for several reasons. First, its fusion activity has not been reconstituted; second, there are conflicting reports as to whether ATL3 is sufficient to maintain ER network structure; and third it has lower GTPase activity. Consequently, it has been hypothesized that ATL3 does not primarily act as a fusogen.
Here we demonstrate that ATL3 catalyzes efficient GTP-dependent membrane fusion in vitro. Though the ATL3 G domain dimer affinity is lower than ATL1/2, this is offset by its higher abundance in cells, and ATL3 is sufficient to rescue ER defects in ATL1/2/3 KO cells. Surprisingly, human ATL3 lacks detectable C-terminal autoinhibition prompting us to investigate the evolution of ATL autoinhibition. Phylogenetic analysis, as well as the functional diversity of autoinhibitory C-termini in ATL1/2 splice isoforms suggests that C-terminal autoinhibition is a recent evolutionary innovation that may help fine tune ER structure under diverse conditions.

B439/P2115

Structures of Vac8-containing protein complexes reveal the underlying mechanism by which Vac8 coordinates multiple cellular processes

N. KO[1,2], H. Kim[3,2], J. PARK[1,2], H. Kim[3,2]; [1]GIST, GWANGJU, Korea, Republic of, [2]Cell Logistics Research Center, GIST, Gwangju, Korea, Republic of, [3]UNIST, ULSAN, Korea, Republic of

Vac8, a yeast vacuolar protein with armadillo repeats, mediates various cellular processes by changing its binding partners; however, the mechanism by which Vac8 orchestrates these processes remains poorly understood. Vac8 interacts with Nvj1 to form the nuclear-vacuole junction (NVJ) and with Atg13 to mediate cytoplasm-to-vacuole targeting (Cvt), a selective autophagy-like pathway that delivers cytoplasmic aminopeptidase I directly to the vacuole. In addition, Vac8 associates with Myo2, a yeast class V myosin, through its interaction with Vac17 for vacuolar inheritance from the mother cell to the emerging daughter cell during cell divisions. Here, we determined the X-ray crystal structure of the Vac8-Vac17 complex and found that its interaction interfaces are bipartite, unlike those of the Vac8-Nvj1 and Vac8-Atg13 complexes. When the key amino acids present in the interface between Vac8 and

Vac17 were mutated, vacuole inheritance was severely impaired in vivo. Furthermore, binding of Vac17 to Vac8 prevented dimerization of Vac8, which is required for its interactions with Nvj1 and Atg13, by clamping the H1 helix to the ARM1 domain of Vac8 and thereby preventing exposure of the binding interface for Vac8 dimerization. Consistently, the binding affinity of Vac17-bound Vac8 for Nvj1 or Atg13 was markedly lower than that of free Vac8. Likewise, free Vac17 had no affinity for the Vac8- Nvj1 and Vac8-Atg13 complexes. These results explain how vacuole inheritance and other Vac8-mediated processes, such as NVJ formation and Cvt, occur independently of one another.

GM130 scaffolds the Golgi ribbon by associating with RNA

Y. Zhang, J. Seemann; UT Southwestern Medical Center, Dallas, TX

The Golgi apparatus is essential for processing and sorting of membrane proteins. This secretory function of the Golgi is highly conserved and is performed by stacks of flattened cisternae. Vertebrate cells contain about 100 stacks that are interconnected into a single continues ribbon that resides next to the centrosomes. This distinct polarized localization of the Golgi ribbon facilitates directional protein sorting and is indispensable for cell polarization. Golgi ribbon fragmentation is commonly observed in a broad range of diseases, including neurodegenerative diseases and muscular dystrophies. Under physiological conditions, the ribbon structure is altered in response to cellular stress and during mitosis. However, the molecular mechanism that dynamically remodel the ribbon structure remain unclear. Previous data suggested that the ribbon is organized by the Golgi membrane proteins GRASP55 and/or GRASP65. However, our data showed the two proteins only indirectly maintain the ribbon integrity together with GM130 and Golgin-45. In efforts to define their co-factors, we identified a complex of RNA with GRASP65 and GM130 and confirmed that it is GM130 that directly binds RNA and further recruits RNA binding proteins. Acute degradation of RNA or GM130 disrupted the lateral linking of Golgi ribbon and caused Golgi fragmentation. We further found that GM130 together with RNA undergoes liquid-liquid phase separation to form RNA-dependent condensates in cells. We conclude that the GM130-RNA association is essential to dynamically organize the Golgi ribbon and support the integrity of the Golgi structure.

Role Of *Atlastin* In Organising Axonal ER And CNS Lipid Droplets In *Drosophila*

E. Gonzaga, A. Riaz, L. Zhao, E. Zlámalová, T. Doherty, F. Gallo, K. Müller, C. O'Kane; University of Cambridge, Cambridge, United Kingdom

Hereditary Spastic Paraplegias (HSPs) are a rare group of inherited diseases characterised by progressive weakness and spasticity of the lower limbs. HSP patients endure physical impairments, bladder dysfunction, neuropathic pain and, in complicated cases, seizures. Over 73 causative Spastic Paraplegia genes (SPGs) are attributed to this clinically and genetically diverse disease. SPG3A, caused by *atlastin1* (*ATL1*) mutations, is the second most common autosomal dominant SPG, and affect a protein that appears instrumental in fusing endoplasmic (ER) tubules to form 3-way junctions and a continuous network. To find links between this function and axonal maintenance, we use *Drosophila* to understand the role of its single Atlastin protein in modelling axonal ER.
Homozygous *atl* mutant *Drosophila* larvae exhibit severe locomotion defects. Using fluorescence confocal microscopy, we see that *Drosophila atl* loss-of-function mutant larvae have increased levels of

ER in motor axons compared to controls, and serial EM shows an increased number of ER tubules. Consistent with the molecular role of *atlastin* in ER tubule fusion, fluorescence recovery after photobleaching (FRAP) experiments show reduced continuity of ER in mutant axons compared to controls. The elevated levels of ER and reduced continuity can both be rescued by a wildtype *atlastin* construct. Additionally, BODIPY staining shows that lipid droplet numbers are elevated in *atl* mutant larval nerves compared to controls. Our findings suggest that ATL1/SPG3A mutations may contribute to distal axonopathy via impaired ER continuity, and support the importance of neuronal ER in HSP pathology.

The Mammalian Rhomboid-Like Derlins Regulate Endoplasmic Reticulum Morphology

N. A. Scott, S. E. Neal; University of California, San Diego, La Jolla, CA

The endoplasmic reticulum (ER) forms a continuous intracellular membrane system, consisting of the nuclear envelope, flat sheets, and an elaborate network of tubules throughout the cytoplasm. The ER plays a role in several essential cellular processes such as the synthesis of transmembrane and secreted proteins, post-translational modification of proteins, lipid synthesis, and Ca^{2+} homeostasis. Moreover, the ER is susceptible to protein misfolding. To survive the constant threat of protein misfolding, cells are equipped with ER protein quality control systems that detect and degrade these aberrant molecules. Previously, we and others have demonstrated that rhomboid-like derlins are major mediators of ER protein quality control where they are involved in the retrotranslocation of ubiquitinated misfolded substrates from the ER for cytosolic degradation by the proteasome. To survey for potential substrates of derlins, we employed liquid chromatography-tandem mass spectrometry (LC-MS/MS)-based proteomics in derlin knockout (KO) HEK293 cells. To our surprise, ATL-3 was significantly enriched in the derlin KOs, indicating that ATL-3 is a potential substrate of derlins. ATL-3 belongs to a family of proteins known as atlastins (ATL), which is comprised of three mammalian isoforms: ATL-1, ATL-2, and ATL-3. ATLs are membrane anchored GTPases in which their major function is to shape the ER via fusion of ER membrane tubules. Although the generation of different ER morphologies is well known, how the ER shape is regulated is not well characterized. In this study, we biochemically validated that derlins regulate the level of ATL proteins. Furthermore, we demonstrate that derlins KO affects the shape and distribution of the ER. Taken together, our studies suggest a novel role for derlins in modulating ER shape and morphology. Because mutations in ATLs are associated with hereditary spastic paraplegia, our findings will aid in the understanding of how rhomboid-like derlins contribute to this pressing malady.

Topological constraints in ER-vacuolar network enables damping during ultra fast cellular contractions

R. Chang, M. Prakash; Department of Bioengineering, Stanford University, Stanford, CA.

Cellular systems are known to exhibit some of the fastest movements in the biological world - but little is known as to how single cells can dissipate this energy rapidly and adapt to such large accelerations without sub-cellular damage. To study intracellular adaptations under extreme forces - we investigate Spirostomum ambiguum - a giant cell (1-4mm in length) well known to exhibit ultrafast contractions (50% of body length) within 5 msec with a peak acceleration of 15g. Utilizing transmitted electron

microscopy (TEM) and confocal imaging, we discover a novel association of rough endoplasmic reticulum (RER) and vacuoles throughout the cell - forming a contiguous fenestrated cubic membrane architecture that topologically entangles these two organelles. A nearly uniform inter-organelle spacing of 60nm is observed between RER and vacuoles, closely packing the entire cell. Using an overdamped molecular dynamics simulation, with parameters matching all relevant mechanical properties of vacuoles and RER, we demonstrated that the topological constraints created by RER can enhance the ability of vacuoles to resist boundary forces and preserve spatial relationships between organelles. Because this dynamics arises primarily from entanglement of two networks incurring jamming transition at a subcritical volume fraction - we term this phenomena "topological damping". Our findings suggest a new mechanical role of RER-vacuolar meshwork as a metamaterial capable of dissipating energy in an ultra-fast contraction event.

Scs2 modulates mitochondria-ER contact sites through Num1

J. C. Casler, H. L. Anderson, L. L. Lackner; Northwestern University, Evanston, IL.

Membrane contact sites (MCSs) are sites of close membrane apposition that tether organelles to organize their intracellular distribution and facilitate the exchange of biological materials. In yeast, the mitochondria-ER cortex anchor (MECA) is a tripartite MCS between the plasma membrane (PM), the ER, and mitochondria. The core component of MECA, Num1, is required for the cortical distribution of the mitochondrial network and also functions in nuclear inheritance by serving as an anchor for dynein. Previous work has shown that Num1 interacts with the PM and mitochondria via two distinct lipid binding domains; however, the molecular mechanism by which Num1 interacts with the ER is unknown. Here we demonstrate that Num1 contains a two phenylalanines in an acidic tract (FFAT) motif in its C-terminus that interacts with the integral ER membrane protein Scs2. Deletion of the FFAT motif disrupts Num1-ER localization but is dispensable for mitochondrial tethering and dynein anchoring. Interestingly, ectopically localizing Num1 is sufficient to modulate the extent of organelle contacts with the ER in a manner that depends on the Num1 FFAT motif. This work defines the molecular mechanism by which a tripartite MCS is formed and demonstrates how cells can modulate these interactions to alter the extent of organelle contacts. We hypothesize that dynamic regulation of these Num1-organelle interactions allows MECA to serve as a central organizational hub that facilitates the exchange of lipids or metabolites between organelles in response to cellular needs.

In Situ Cryo-CLEM of a Tethering Complex at the ER-Mito Contact Sites

R. Paraan[1], K. Nakamura[2], S. Aoyama[2], T. Nagao[2], Y. Hirabayashi[2], F. Polleux[3], B. Carragher[1], C. Potter[1]; [1]NYSBC-SEMC, New York, NY, [2]Department of Chemistry and Biotechnology, University of Tokyo, Tokyo, JAPAN, [3]Zuckerman Institute, Columbia Univeristy, New York, NY.

The eukaryotic organelles such as the endoplasmic reticulum (ER), the nuclear envelope, mitochondria, and the endosomes can come to a close vicinity of each other and engage in dynamic ultrastructures known as contact sites. These contact sites are regulated by various tethering complexes most of which are not fully known specially in mammalian cells. The ER-mitochondria contact sites carry out diverse physiological functions such as calcium ion and lipid transport, hence their possible involvement in the early pathophysiology of neurodegenerative diseases such as Alzheimer's. Despite their important role

in cell health and disease, the molecular landscape of these contact sites are poorly understood. In this study we have identified an ER-resident protein PDZD8 and its mitochondrial binding partner and we have shown that they form tethering complexes at ER-mito contact sites of mammalian cells. First, a list of candidates for the mitochondrial binding partners of PDZD8 was obtained using the TurboID method. The interaction between PDZD8 and one of the candidates was confirmed by Co-ImmunoPrecipitation. We showed by fluorescence microscopy that the two proteins co-localize at the contact sites of mammalian cells and that the overexpression of the mitochondrial protein up-regulated PDZD8. We used cryo-correlative light and electron microscopy to capture this molecular interaction in close-to-native conditions. Using focused ion-beam milling, 35 lamellae or thin sections were prepared for cryo-electron tomography from HeLa cells overexpressing the mitochondrial partner tagged with a fluorophore. The overexpression increased the abundance of the contact sites most of which were occupied by the overexpressed protein as confirmed by correlative fluorescence imaging of the lamellae. A few thousand tethering complexes were identified in the tomograms in total with some heterogeneity in terms of the length of the tethers. We are using sub-tomogram averaging to generate a map of the different domains of these complexes. Coupled with the cryo-EM single particle analysis of a truncated complex, we aim to characterize the tethers in their native environment.

Regulation of lipid droplet biogenesis and maintenance at endoplasmic reticulum-mitochondria contact sites

V. F. Monteiro-Cardoso[1], V. Guyard[1], M. Omrane[2], C. Boulogne[3], N. El Khallouki[1], R. Le Bars[3], O. Faklaris[4], N. Vitale[5], A. R. Thiam[2], **F. Giordano**[1]; [1]Institute for Integrative Biology of the Cell (I2BC), CEA, CNRS, Inserm U1280, Université Paris-Saclay, Gif-sur-Yvette, FRANCE, [2]Laboratoire de Physique de l'École Normale Supérieure, ENS, Université PSL, CNRS, Sorbonne Université, Université de Paris, Paris, FRANCE, [3]Institute for Integrative Biology of the Cell (I2BC), CEA, CNRS, Université Paris-Saclay, Gif-sur-Yvette, FRANCE, [4]MRI, BioCampus Montpellier, CRBM, Univ. Montpellier, CNRS, Montpellier, FRANCE, [5]Centre National de la Recherche Scientifique, Université de Strasbourg, Institut des Neurosciences Cellulaires et Intégratives, Strasbourg, FRANCE.

Lipid droplets (LDs) are intracellular organelles that play a central role in lipid metabolism and regulate cellular energy balance. In their hydrophobic core, surrounded by a phospholipid monolayer, LDs store energy in the form of neutral lipids and prevent their toxic accumulation in the cell. LDs originates from the endoplasmic reticulum (ER) membranes and alterations in their biogenesis are associated with many metabolic diseases such as diabetes and heart disease or viral infections. The ER-protein seipin, localizing at ER-LD junctions, controls LDs nucleation and growth. However, the molecular mechanisms that spatially and temporally regulate LD biogenesis in the cell remain largely unknown. By using a combination of biochemical and cell biology approaches, including live cell imaging, proximity ligation assays and electron microscopy, we have found that the ER subdomains closely associated to mitochondria, also called Mitochondria-Associated ER Membrane (MAMs), are hotspots for LD biogenesis. We have started to reveal the morphological and molecular features of these subdomains, identifying key proteins localized at the ER-mitochondria interface that are involved in the regulation of LD formation. Among those, we have shown that the lipid transfer proteins ORP5 and ORP8 relocate to MAM subdomains where LD originate at earlier steps of LD biogenesis. We have also shown that ORP5/8 regulate seipin recruitment to MAM-LD contacts, and their loss of function impairs LD biogenesis. Importantly, the integrity of ER-mitochondria contact sites is crucial for ORP5/8 function in regulating

seipin-mediated LD biogenesis. Our study uncovers a new role for ORP5/8 in orchestrating LD biogenesis and maturation at MAMs and brings novel insights into the metabolic crosstalk between mitochondria, ER, and LDs at membrane contact sites.

Investigating the Role of ER-Mitochondria Junctions on Store-Operated Ca^{2+} Entry

Y. Lin[1], F. Tsai[1,2]; [1]Department of Pharmacology, College of Medicine, National Taiwan University, Taipei, TAIWAN, [2]Department of Internal Medicine, National Taiwan University Hospital, Taipei, TAIWAN.

Store-operated Ca^{2+} entry (SOCE) is the major Ca^{2+} influx that regulates essential cellular functions. SOCE is mediated by the ER-Ca^{2+} sensor STIM1 and plasma membrane protein ORAI1. Numerous studies revealed that mitochondria are also regulators of SOCE. However, the exact mechanism is still unclear. The percentage of mitochondria that contact with ER is around 5-20%. Many substances can be transferred at the contact sites between ER and mitochondria, including Ca^{2+}. This ER-mitochondria connection and the ability of ER to spatially and temporally coordinate with plasma membrane may allow mitochondria to regulate SOCE activity. To elucidate the role of mitochondria-associated membranes in SOCE regulation, we disrupted ER-mitochondrial junctions (EMJs) by knocking down MFN2 and PDZD8, which are known ER-mitochondrial tethering proteins. Our preliminary data revealed that EMJs were required for SOCE activation and maintenance. We noticed that mitochondria were re-distributed to STIM1-ORAI1 regions upon SOCE activation, which supported our hypothesis. To elucidate how EMJs affect SOCE, we further examined STIM1 dynamics in EMJs-depleted cells. STIM1 oligomerization was suppressed in MFN2- and PDZD8-knockdowns cells. Moreover, STIM1 puncta were unstable in these EMJs-depleted cells. We also noticed a similar increase of puncta decomposition in cells expressing mutant STIM1 that could not bind to EB1. Furthermore, knocking down RHOT1 and TRAK1, which coordinately transport mitochondria along microtubules, also suppressed SOCE, supporting an important role of microtubules in EMJ-regulated SOCE. We are now working on the mechanisms of how ER-mitochondria and microtubules are coordinated, providing the cells with stable SOCE for important cellular functions.

B448/P2124

MIGA2 is a lipid transporter and its lipid transfer ability is essential for its role in mitochondrial and lipid droplet biology

Z. Hong, J. Adlakha, N. Wan, E. Guinn, F. Giska, K. Gupta, T. J. Melia, K. Reinisch; Yale University, New Haven, CT.

Lipid transport proteins at membrane contact sites, where organelles are closely apposed, are critical in redistributing lipids from the endoplasmic reticulum (ER), where they are made, to other cellular membranes. Such protein mediated transfer is especially important for maintaining organelles disconnected from secretory pathways, like mitochondria. Here we identify mitoguardin-2, a mitochondrial protein at contacts with the ER and/or lipid droplets (LDs), as a lipid transporter. An X-ray structure shows that the C-terminal domain of mitoguardin-2 has a hydrophobic cavity that binds lipids. Mass spectrometry analysis reveals that both glycerophospholipids and free fatty acids co-purify with mitoguardin-2 from cells, and that each mitoguardin-2 can accommodate up to two lipids. Mitoguardin-2 transfers glycerophospholipids between liposomes as well as between lipid droplets and liposomes in vitro, and this transport ability is required for roles both in mitochondrial and LD biology. While it is not

established that protein-mediated transfer at contacts plays a role in LD metabolism, our findings raise the possibility that mitoguardin-2 functions in transporting fatty acids and glycerophospholipids at mitochondria-LD contacts.

PLIN5 interacts with FATP4 at membrane contact sites to promote lipid droplet-to-mitochondria fatty acid transport

G. E. Miner, C. M. So, W. Edwards, S. Cohen; University of North Carolina Chapel Hill, Chapel Hill, NC.

Cells adjust their metabolism by remodeling membrane contact sites that channel metabolites to different fates. Lipid droplet (LD)-mitochondria contacts change in response to fasting, cold exposure, and exercise. However, their function and mechanism of formation have remained controversial. We focused on perilipin 5 (PLIN5), an LD protein that tethers mitochondria, to probe the function and regulation of LD-mitochondria contacts. We demonstrate that efficient LD-to-mitochondria fatty acid (FA) trafficking and ß-oxidation during starvation of myoblasts requires both phosphorylation of PLIN5 and an intact PLIN5 mitochondrial tethering domain. We further identified the acyl-CoA synthetase, FATP4 (ACSVL4) as a novel mitochondrial interactor of PLIN5. The C-terminal domains of PLIN5 and FATP4 constitute a minimal protein interaction capable of inducing organelle contacts. Our work suggests that starvation leads to phosphorylation of PLIN5, lipolysis, and subsequent channeling of FAs from LDs to FATP4 on mitochondria for conversion to fatty-acyl-CoAs and subsequent oxidation.

B450/P2126

A generalizable tool platform for visualizing lipid droplet-organelle contact sites

X. Li[1], L. Climer[1], C. Lindow[1], A. G. Tebo[2], **C. Chang**[1]; [1]St. Jude Children's Research Hospital, Memphis, TN, [2]HHMI - Janelia Research Campus, Ashburn, VA.

Lipid droplets are dynamic fatty acid storage depots essential for cellular lipid and energy homeostasis. Lipid droplets dynamically stockpile surpluses of fatty acids from the endoplasmic reticulum (ER), and transport them to mitochondria, peroxisomes, and endo-lysosomal system, where fatty acids are utilized in lipid synthesis and ATP production to meet metabolic demands. Targeted transport of fatty acids relies on lipid droplet-organelle contact sites, dynamic apposing nanodomains between organelles that allow directed and efficient material flux. Defects in the formation of lipid-organelle contact sites are associated with developmental, metabolic, and neurological disorders. However, many facets of contact site biology remain unclear, primarily because detection of these dynamic, minute loci in living cells is technically challenging. To overcome this difficulty, we engineered a tool platform based on Flurogen-Activated Bimolecular Complementation at CONtact sites, FABCCON, using the reversible splitFAST system to visualize and control the formation of organelle contacts sites. We engineered the C-terminal fragment of splitFAST onto the cytosolic surface of lipid droplets by fusing it with tandem repeats of Spastin's hairpin motif known to insert into lipid droplets. The N terminal half of splitFAST was targeted to other organelles of interest by using corresponding localization sequences. After optimizing the affinity of FABCCON and cognate fluorogen, we successfully visualized lipid droplet-ER, -mitochondria, -peroxisomes, and -lysosomes contact sites in living cells, shortly after fluorogen addition. Complementation of splitFAST at contact sites is completely reversible as the signal disappeared shortly following fluorogen washout indicating minimal perturbation to the contact sites. Our data also showed that FABCCON can provide higher spatial-temporal precision of contact site detection compared to

conventional organelle colocalization analysis. In addition, FABCCON can quantitively enhance contact site formation with higher concentration of fluorogen, providing the possibility to rescue the deficiency of contact sites caused by genetic alteration. Notably, FABCCON is applicable to contact sites between any organelles provided with specific targeting information. We have applied the FABCCON platform to detect mitochondria-peroxisome and -lysosome contact sites where active fatty acid trafficking occurs. Altogether, FABCCON is a generalizable platform for quantitative detection and enhancing of organelle contact sites with increased spatial-temporal precision.

Employing inducible mitochondrial tethers to characterize membrane contact site function

C. Harper, L. Lackner; Northwestern University, Evanston, IL.

Organelles perform distinct, essential functions in the cell, and while once thought to operate independently, it is increasingly clear that organelle membrane contact sites (MCSs) are critical for organelle function and overall cellular homeostasis. The contact site between mitochondria, the ER, and the plasma membrane in *S. cerevisiae*, known as the mitochondria-ER-cortex-anchor (MECA), is important for mitochondrial distribution, nuclear inheritance, mitochondrial function, and homeostasis of other contact sites. We hypothesize that MECA also establishes mitochondrial membrane tension required for proper mitochondrial division and health. Characteristic of MCSs, MECA formation is driven by a tether protein, called Num1. To investigate the role of Num1 in facilitating contact site functions, we engineered inducible organelle tethers using native MCS proteins and well-characterized organelle-interaction domains coupled with dimerization systems, such as rapamycin-induced dimerization. By controlling the formation and dissociation of the engineered tethers, we can assess the kinetics of contact site formation and functions. We find that although many synthetic tethers between mitochondria and the plasma membrane replicate wild type mitochondrial distribution, only those that include specific domains of Num1 rescue all contact site functions. Thus, Num1 establishes a specific environment at MECA, perhaps to facilitate molecular transport, that is critical for the myriad of functions of this contact site. Deciphering the role Num1 plays in each function of MECA will inform our understanding of the processes facilitated and coordinated by MCSs and how organelles interact for optimal cellular function.

Peroxisomes maintain mitochondrial redox homeostasis through a novel contact site

L. DiGiovanni[1,2], M. Boutry[1], P. Khroud[1,2], P. Kim[1,2]; [1]The Hospital for Sick Children, Toronto, ON, Canada, [2]University of Toronto, Toronto, ON, Canada

Robust reduction of mitochondrial derived reactive oxygen species (ROS) is essential to maintain mitochondrial and cellular health. Peroxisomes, a metabolic organelle with high redox capacity, are suspected to contribute to the redox homeostasis of mitochondria. Loss of peroxisome biogenesis or peroxisomal antioxidant function results in elevated mitochondrial oxidative stress, suggesting that peroxisomes may function as a sink to quench mitochondrial derived ROS. However, the mechanism of this role, and specifically how exchange of ROS between two organelles could be spatially and temporally achieved, is not understood. Here, we show for the first-time direct evidence of peroxisomes functioning to reduce mitochondrial derived ROS through contact of peroxisomes with mitochondria. We define a novel contact site mediated by peroxisomal membrane protein Acyl-CoA Binding Domain

Containing 5 (ACBD5), that facilitates direct contact between peroxisomes and mitochondria. Contact deficient cells had measurable mitochondrial dysfunction through multiple metrics. Mitochondria from ACBD5 deficient cells had an elevated sensitivity to oxidative stress, as measured using mitochondrially targeted redox probe roGFP, and could be rescued using an artificial peroxisome-mitochondria tether. We further showed that the peroxisome redox environment was sensitive to increases in mitochondrial ROS production, dependent on ACBD5 mediated peroxisome-mitochondria contact, providing evidence for the exchange of ROS between mitochondria and peroxisomes at sites of contact. Peroxisome-mitochondria contact increased in response to elevated mitochondrial oxidative stress, suggesting peroxisome contact is an adaptive cellular response to mitochondrial stress. This study demonstrates the novel and critical role peroxisome contact plays in mitochondrial antioxidant defense.

B453/P2129

Lipid transfer activity of ORP3 at ER-plasma membrane contacts maintains exocytic sites by stabilizing membrane association of LL5β

C. J. Bott, J. Y. Lim, J. E. Casanova; Cell Biology, University of Virginia, Charlottesville, VA.

ER-Membrane Contact Sites (ER-MCS) are hubs for a large number of lipid transfer proteins, which facilitate non-vesicular transport of lipids between adjacent membrane domains, and are thus major determinants of local membrane composition and functional identity. We have previously shown that the lipid transfer protein ORP3, in a complex with the Arf-GEF IQsec1, extracts plasma membrane PI4P in exchange for ER phosphatidylcholine at MCS immediately adjacent to focal adhesions. Using mass spectroscopy, we found that ORP3 and IQSEC1 co-immunoprecipitated multiple members of the Cortical Microtubule Stabilizing Complex (CMSC), including KANK2, liprin, LL5β, CLASP2, and ELKS, which was confirmed via western blot. ELKS facilitates the targeting of post-Golgi RAB6+ exocytic carriers to specific plasma membrane sites that, like ORP3-containing MCSs, are clustered adjacent to focal adhesions. ELKS is anchored at the plasma membrane through its interaction with the PIP3-binding protein LL5β, and previous studies have shown that the CMSC, anchored by LL5β, marks 'exocytic hotspots'. The interaction between ORP3 and the CMSC suggested that ORP3 could affect CMSC localization or function. In support of this hypothesis, we found that lentiviral knockdown of ORP3 disrupted the targeting of microtubule tips to the plasma membrane. While ORP3 depletion did not obviously change the steady-state localization of ELKS or LL5β via TIRF microscopy, it did reduce the interaction of ELKS with LL5β, and with Rab6, by co-immunoprecipitation. We posit that ORP3, via its lipid exchange activity, modulates the stability of the LL5β/ELKS/RAB6 complex at the plasma membrane. We have previously shown that the ORP3/IQSec1 complex is recruited to ER/PM contact sites in response to STIM/ORAI-mediated calcium influx. To determine how ORP3 affects LL5β/ELKS/RAB6 complex dynamics, we performed time-lapse imaging via TIRF microscopy. Thapsigargin, which induces Store Operated Calcium Entry (SOCE), triggers rapid recruitment of ORP3 to ER/PM contacts and triggers its lipid exchange activity. We found that the amount of GFP-LL5β in plasma membrane puncta remained relatively constant in response to calcium influx. In contrast, ~30% of LL5β dissociated from the PM after 20 minutes of thapsigargin treatment in ORP3-depleted cells. This loss could be rescued with WT-ORP3, but not by an ORP3 mutant that is deficient in lipid transfer. Taken together, these data suggest that ORP3-mediated lipid transfer stabilizes the CMSC at the plasma membrane during Ca2+ influx. Future directions include monitoring the dynamics of other CMSC components, its interaction with Rab6+ vesicles, and quantifying the effects of ORP3 dysfunction on secretion.

B454/P2130

PDZD8 and its mitochondrial binding partner tether the ER and mitochondria

K. Nakamura[1], **S. Aoyama-Ishiwatari**[1], T. Nagao[1], R. Paraan[2], Y. Sakurai[1], Y. Du[1], S. Suga[1], M. Tsuboi[1], M. Nakakido[1], K. Tsumoto[1,1,1], Y. Kishi[1], C. Kwak[3], H.-W. Rhee[3,3], H. Kosako[4], B. M. Humbel[5,6], B. Carragher[2], C. Potter[2], F. Polleux[7,7,7], Y. Hirabayashi[1,1]; [1]The University of Tokyo, Tokyo, Japan, [2]New York Structural Biology Center, New York, NY, [3]Seoul National University, Seoul, Korea, Republic of, [4]Tokushima University, Tokushima, Japan, [5]University of Lausanne, Lausanne, Switzerland, [6]Okinawa Institute of Science and Technology, Onna-son, Okinawa, Japan, [7]Columbia University, New York, NY

Mitochondria and endoplasmic reticulum (ER) form membrane contact sites (MERCSs), where the organelle membranes are closely apposed within the range of 10 to 30 nm but not fused. MERCs play critical roles in cellular functions such as lipid biogenesis and regulation of Ca^{2+} dynamics. We have identified Pdzd8, an ER-resident protein, as an important ER-mitochondria tethering protein (Hirabayashi et al. Science 2017) but its binding partner on the outer mitochondrial membrane (OMM) was still unknown. Using a combination of CRISPR-Cas9 knockin cell lines and (1) unbiased mass spectrometry screens following immunoprecipitation of endogenous PDZD8 and (2) proximity labeling by PDZD8-TurboID, we identified proteins in complex with PDZD8 and localizing in the proximity of PDZD8, respectively. Analyses using recombinant proteins showed that one of the mitochondrial proteins identified in our proteomic screens interacts directly with PDZD8 and immunofluorescence analysis combined with high resolution microscopy reveal that Pdzd8 and this OMM protein are juxtaposed at MERCS. Electron microscopy analysis revealed that this protein is required for tethering the ER and mitochondrial membranes. Knocking out both proteins reveal no additive effects compared to individual knockout cells demonstrating that these two proteins form not only a structural complex but function in the same complex. Finally, we are implementing Cryo-EM tomography to visualize this new tethering complex in cells. These findings suggest that the PDZD8 protein complex is essential for the formation of the MERCS ultrastructure and investigation of this protein complex will uncover the physiological functions of this new tethering complex at MERCs in various cell types including neurons.

B455/P2131

Motion of single molecular tethers reveals dynamic subdomains at ER-mitochondria contact sites

C. J. Obara[1], J. Nixon-Abell[2], A. S. Moore[1], C. Blackstone[3], J. Lippincott-Schwartz[1]; [1]HHMI, Ashburn, VA, [2]University of Cambridge, Cambridge, United Kingdom, [3]Massachusetts General Hospital and Harvard Medical School, Charlestown/Boston, MA

To coordinate cellular physiology, eukaryotic cells rely on the inter-organelle transfer of molecules at specialized organelle-organelle contact sites. Endoplasmic reticulum-mitochondria contact sites (ERMCSs) are particularly vital communication hubs, playing key roles in the exchange of signaling molecules, lipids, and metabolites. ERMCSs are maintained by interactions between complementary tethering molecules on the surface of each organelle. However, due to the extreme sensitivity of these membrane interfaces to tether disruption, a clear understanding of their fine structure and regulation is still lacking. Here, we combine 3D electron microscopy with high-speed molecular tracking of a model organelle tether, VAPB, to map the structure and diffusion landscape of ERMCSs. From EM reconstructions, we identified subdomains within the contact site where ER membranes dramatically deform to match local mitochondrial curvature. In parallel live experiments, we observed that the VAPB tethers that mediate this interface were not statically enriched, but rather highly dynamic, entering and

leaving the site in seconds. These subdomains enlarged during nutrient stress, indicating ERMCSs can readily remodel under different physiological conditions. A disease-associated mutation in VAPB altered the normal fluidity of contact sites, likely perturbing effective communication across the contact site and preventing remodeling. These results establish high speed single molecule imaging as a new tool for mapping the structure of contact site interfaces and suggest that the diffusion landscape of VAPB is a crucial component of ER-mitochondria contact site homeostasis.

B456/P2132

Elucidating the identity and function of mitochondrial membrane contact site tethers in budding yeast gametogenesis

C. Ruediger[1], E. Sawyer[2], G. King[1], D. Jorgens[3], E. Ünal[1]; [1]University of California, Berkeley, Berkeley, CA, [2]University of Colorado, Boulder, Boulder, CO, [3]Electron Microscope Lab, University of California, Berkeley, Berkeley, CA

Mitochondria are essential organelles containing their own genome. As such, mitochondrial segregation is a crucial aspect of gametogenesis necessary to produce viable gametes. However, how mitochondria are inherited into gametes remain unknown. Budding yeast gametogenesis provides a powerful model to uncover and dissect mechanisms of mitochondrial inheritance. During budding yeast gametogenesis, the mitochondrial network detaches from the cell periphery upon regulated degradation of a mitochondrial-plasma membrane tethering complex (MECA) and forms extensive membrane contacts with the nuclear envelope in meiosis II as chromosomes are segregated into newly forming gametes. Subsequently, portions of the network are pinched off and re-establish mitochondrial-plasma membrane associations within the nascent gametes. I examined the role of previously known and recently discovered mitochondrial tethers, including ERMES, *LAM6*, and *CNM1*, during gametogenesis. These analyses revealed the individual contributions of these tethers to be largely dispensable for both mito-nuclear contacts and mitochondrial inheritance, suggesting the existence of redundancy between known pathways and/or novel regulators. Finally, I found that ectopic tethering of mitochondria to the cell periphery with an engineered tether increased the production of respiratory-incompetent gametes, suggesting remodeling of mitochondrial contact sites is critical to ensure gamete health.

B457/P2133

Regulation of mitochondria and endoplasmic reticulum dynamics via O-GlcNAcylation

R. G. Sanchez, 1[1], W. Paul, 1[2], G. Pekkurnaz, 1[1]; [1]UCSD/SDSC, NIST, La Jolla, CA, [2]Pomona College, Pomona, CA

Normal 0 false false false EN-US X-NONE X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Table Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0in 5.4pt 0in 5.4pt; mso-para-margin-top:0in; mso-para-margin-right:0in; mso-para-margin-bottom:8.0pt; mso-para-margin-left:0in; line-height:107%; mso-pagination:widow-orphan; font-size:11.0pt; font-family:"Arial",sans-serif;} The endoplasmic reticulum (ER) is a vast network of tubules and sheets that span from the nucleus to the plasma membrane. The ER plays a major role in protein secretion, Ca^{2+} homeostasis and lipid synthesis, the latter two functioning synergistically with mitochondria. It is known that the mitochondria and the ER can form mitochondrial-ER contact sites (MERCS) that facilitate lipid, and Ca^{2+} homeostasis. However, the mechanism behind the formation and dynamics of MERCS is not well understood. Here we propose

that the post-translational modification O-GlcNAcylation, a major nutrient sensor that couples metabolism with cellular function and signaling, is altering mitochondrial and ER dynamics to favor MERCS. We show that increased O-GlcNAcylation decreases mitochondrial and ER motility in COS7 cells. Both the mitochondria and ER demonstrate a perinuclear clustering when O-GlcNAc is increased. In addition, ER analysis reveals decreased tubular length and width primarily affecting the perinuclear region of the cell. Using Split-green fluorescent Protein based Contact site. Sensor (SPLICS) associated with the ER and mitochondrial outer membranes we identified MERCS motility and localization differences influenced by O-GlcNAc. We propose that co-regulation of ER and mitochondria via MERCS is essential for cellular morphological alterations in response to cellular stress.

Organelle Membrane Contacts Toolbox: Dimerization-dependent Fluorescent Probes to Visualize Lipid Droplet-Organelle Contact Sites

J. V. Ragusa, G. E. Miner, S. Y. Smith, W. Showalter, C. M. So, S. Cohen; University of North Carolina At Chapel Hill, Chapel Hill, NC

Eukaryotic cells contain membrane-bound organelles that compartmentalize various molecules and biochemical processes. Although many studies have identified unique attributes of each organelle, there is increasing interest in visualizing and evaluating the functional consequences of organelle interactions. Lipid droplets are dynamic organelles that store lipids which can be readily mobilized for membrane synthesis, signal transduction, or energy. Unlike other organelles, lipid droplets are characterized by a single phospholipid monolayer that renders them incompatible with vesicular trafficking. Thus, lipid droplets must form physical contacts, called membrane contact sites, with other organelles for the exchange of molecules. Membrane contact sites are defined as sites where two organelles are within 10-70 nm. They are traditionally visualized by electron microscopy to achieve high resolution, but it is costly, low throughput, and not amenable to live cell imaging. Epifluorescence and confocal microscopy reconcile these limitations but cannot distinguish organelle proximity from true membrane contacts due to the diffraction limit of 200 nm. Therefore, we generated a toolbox of genetically encoded dimerization-dependent fluorescent probes to accurately visualize membrane contact sites within live cells. Using minimal targeting sequences, we developed probes for lipid droplets, mitochondria, endoplasmic reticulum, peroxisomes, lysosomes, and the plasma membrane. Organelles are labeled with quenched monomers of a fluorescent heterodimer that fluoresce brightly upon dimerization when two organelles are within 10-70 nm. We show that the probes accurately localize to targeted organelles and fluoresce only at membrane contact sites. Titration of plasmid concentration is crucial for using these probes without driving membrane contact site formation. Because these probes dimerize reversibly, we also demonstrate the ability of these probes to visualize the dynamics of membrane contact sites over time. This toolbox will be a valuable resource for cell biologists studying organelle-organelle contacts.

Mitochondria in Pathology

Endosomal removal and disposal of dysfunctional, immunostimulatory mitochondrial DNA

L. E. Newman[1], N. Tadepalle[1], S. Weiser Novak[1], C. R. Schiavon[1], G. R. Rojas[1], J. A. Chevez[2], I. Lemersal[3], M. Medina[4], S. Rocha[1], C. G. Towers[1], D. A. Grotjahn[4], U. Manor[1], G. S. Shadel[1]; [1]Salk Institute for Biological Studies, La Jolla, CA, [2]University of California, San Diego, La Jolla, CA, [3]La Jolla Institute for Immunology, La Jolla, CA, [4]The Scripps Research Institute, La Jolla, CA

Maternally inherited mitochondrial DNA (mtDNA) encodes essential subunits of the mitochondrial oxidative phosphorylation system, but is also a major damage-associated molecular pattern (DAMP) that engages innate immune sensors when released into the cytoplasm, outside of cells or into circulation. Release of mtDNA during infection contributes to antiviral resistance in response to a growing number of viruses, but unfortunately also causes pathogenic inflammation in many disease contexts. Cells experiencing mtDNA stress due to depletion of the mtDNA-packaging protein, Transcription Factor A, Mitochondrial (TFAM), or Herpes Simplex Virus 1 (HSV-1) infection exhibit elongated mitochondria, mtDNA depletion, enlargement of nucleoids (mtDNA-protein complexes), and activation of cGAS/STING innate immune signaling via mtDNA released into the cytoplasm. However, the relationships between enlarged nucleoids, altered mitochondrial dynamics, and mtDNA-mediated activation of the cGAS-STING pathway remain unclear. Here, we show that entire enlarged nucleoids are released from mitochondria, remain bound to TFAM, and colocalize with the cytosolic innate immune sensor cGAS. These nucleoids arise at sites of mtDNA replication due to a block in mitochondrial fission at a stage when endoplasmic reticulum (ER) actin polymerization would normally commence, which we propose is a checkpoint to ensure that mtDNA has completed replication and is competent for segregation into daughter mitochondria through fission. After release, enlarged nucleoids colocalize with the late endosomal marker RAB7, suggesting that enlarged nucleoids traffic through endosomes. Blocking the activation of RAB5, which mediates the early steps in the endosomal pathway, prevents escape of enlarged nucleoids from mitochondria, indicating that endosomes extract faulty nucleoids. Endosomal rupture then allows for mtDNA escape into the cytosol and cGAS activation. Thus, we propose that defects in mtDNA replication and/or segregation enact a late mitochondrial fission checkpoint that, if persistent, leads to selective removal of dysfunctional nucleoids by a mitochondrial-endosomal pathway. Immunostimulatory mtDNA is ultimately degraded by late endosomes to prevent excessive innate immune signaling, but overload of this pathway causes mtDNA escape from endosomes and cGAS/STING signaling. This mtDNA quality control pathway might represent a therapeutic target within the context of mtDNA-driven antiviral defenses, as well as chronic inflammatory diseases where mtDNA has been implicated.

B460/P2136

Metatranscriptomic analysis uncovers prevalent mitovirus sequences compatible with mitochondrial translation

A. Begeman[1], A. Babaian[2], S. C. Lewis[1]; [1]University of California, Berkeley, Berkeley, CA, [2]Independent researcher, Vancouver, BC, CANADA.

Despite RNA viruses being ubiquitous components of the biosphere, relatively little is known about their general biodiversity or how they may adapt replication strategies to exploit the biology of their host. A

hallmark of (+)ssRNA viruses is the ability to remodel host endomembranes for their own replication; however, the interplay between viruses and host organelles that already harbor native gene expression systems, such as mitochondria, remains poorly characterized. Here we search thousands of publicly available RNA sequencing runs for novel viral species and report the discovery of 763 new virus sequences belonging to the family Mitoviridae, a family of (+)ssRNA viruses that have previously been suggested to interact with the mitochondria. The identified sequences fill in existing gaps in known mitovirus diversity, and allow us to further identify previously uncharacterized mitovirus clades, and potentially a new virus class all together. Using this new expansion of diversity, we were able to annotate new mitovirus specific protein motifs, and identify hallmarks of mitochondrial translation such as mitochondrial specific codons and adapted mitochondrial codon usage. Together, this data expands the known diversity of mitochondrial viruses, and provides strong evidence for their evolutionary adaptation to co-opt mitochondrial biology for their survival.

Damaged mitochondria recruit the effector NEMO to activate NF-κB

O. Harding, E. L. F. Holzbaur; Department of Physiology, University of Pennsylvania, Philadelphia, PA.

Mitochondrial damage presents an immediate danger to cellular homeostasis. Dysfunctional mitochondra fail to produce the energy required to maintain cellular function and can release reactive oxygen species or initiate other damaged-induced signaling pathways that promote inflammatory responses. Mitophagy is a quality control pathway by which damaged mitochondria are isolated and cleared via the activation of the ubiquitin ligase Parkin and subsequently, mitophagy receptors. Mutations that impair mitophagy or environmental perturbations to the clearance pathway are associated with neurodegenerative diseases including Parkinson's disease and ALS. Here we demonstrate a novel link from mitochondrial dysfunction to the activation of NF-κB, the principal transcription factor that regulates immune activation. Following mitochondrial damage, the NF-κB essential regulator NEMO/IKKɣ is recruited to mitochondria in a Parkin- and p62/SQSTM1-dependent manner. Although NEMO and the well-studied mitophagy receptor Optineurin (OPTN) are structurally similar, NEMO and OPTN maintain separate domains on the outer mitochondrial membrane. Instead, NEMO colocalizes extensively with p62, suggesting that NEMO and p62 together form phase-condensates that can activate the NF-κB inflammation pathway via the kinase IKKβ. Indeed, active phospho-IKKβ colocalizes with NEMO on damaged mitochondria, and cells with mitochondrial damage exhibit upregulation of inflammatory cytokines. These findings demonstrate that damaged mitochondria serve as an intracellular platform for innate immune signaling by promoting the formation of activated IKK complexes in a Parkin-dependent manner. Finally, mitochondria that recruit NEMO are less likely to be engulfed by clearance autophagosomes. Thus, we propose that mitophagy and NF-κB signaling are competing pathways regulating the response to cellular stress.

Enhanced Mitochondrial Biogenesis Promotes Cell Survival in Human Stem Cell Derived Retinal Ganglion Cells of the Central Nervous System

M. Surma, K. Anbarasu, K. Huang, J. S. Meyer, **A. Das**; Indiana University, Indianapolis, IN.

Mitochondrial dysfunction has been the primary suspect for central nervous system (CNS) disorders such as glaucoma, parkinson's disease (PD) and amyotrophic lateral sclerosis (ALS). Mitochondrial

quality control (MQC) is a complex process which includes degradation of damaged mitochondria (mitophagy), biogenesis of healthy mitochondria and fission/fusion dynamics. It is still unclear the mechanism of improving mitochondrial homeostasis that will confer neuroprotection to the CNS neurons. Among CNS neurons, retinal ganglion cells (RGCs) are the most sensitive towards mitochondrial dysfunction. As such, inherited optic neuropathies such as Leber hereditary optic neuropathy (LHON) and dominant optic atrophy (DOA) are diagnosed by the presence of mutations in the mitochondrial electron transport subunits or fusion gene OPA1 respectively. Among glaucoma patients with normal eye pressure, ~17% patients showed Optineurin (OPTN-E50K) mutation, OPTN is a critical player for mitophagy. E50K forms insoluble aggregates with its regulator Tank-binding kinase1 (TBK1) which also found mutated among several glaucoma and ALS patients. Thus, RGCs provide a unique CNS neuron type for the investigation of improving MQC mechanisms for developing neuroprotection strategy.Here, we used patient derived induced pluripotent stem cells (iPSCs) and CRISPR edited human embryonic stem cells (H7-ESC, WiCell) with E50K mutation for developing RGC protection mechanism. We used a robust well-characterized human stem cell differentiated RGCs (hRGCs) for this work. Our data shows hRGCs promote mitobiogenesis under acute mitochondrial stress by CCCP as a compensatory mechanism for survival. TBK1 negatively regulates mito-biogenesis by suppressing AMPK mediated PGC1α activation. Remarkably, we found TBK1 inhibition by a potent drug BX795 led to E50K aggregate dissolution, activation of the mitobiogenesis pathway and reduced mitochondrial swelling in E50K hRGCs by biochemical, confocal and electron microscopy experiments. Furthermore, we observed BX795 increased respiratory capacity and cell survival for both the wild-type and E50K hRGCs as an indication for neuroprotection. Our study for the first time identified mechanisms of improving mitochondrial homeostasis that conferred glaucoma neuroprotection which may be applicable for other CNS disorders where mitochondrial homeostasis is compromised.

B463/P2139

Neuronal specific *CASK* deletion in mice is lethal and produces aberrant cortical mitochondrial and neuronal activities

H. S. Bhonsle[1], K. Mukherjee[1], H. Goodkin[2], S. Srivastava[1,3]; [1]Fralin Biomedical Research Institute at Virginia Tech Carilion, Roanoke, 24016, VA, [2]Department of Neurology, University of Virginia School of Medicine, Charlottesville, 22908, VA, [3]Department of Internal Medicine, Virginia Tech Carilion School of Medicine, Roanoke 24016, VA.

CASK is an X-linked gene in mammals, encoding for calcium/calmodulin-dependent serine protein kinase that is ubiquitously expressed in all tissues. Constitutive *CASK* deletion in mice causes neonatal lethality, and CASK deletion in human males is incompatible with life suggesting its essential role for survival. Pathogenic mutations in *CASK* exhibit a diverse clinical spectrum including intellectual disability, autism spectrum disorder, microcephaly with pontine and cerebellar hypoplasia, epileptic encephalopathy (EE), and growth retardation. Notably, *CASK* heterozygous mutations in females causes MICPCH, whereas *CASK* hemizygous mutations in males are linked to EE. To better understand the function of CASK and underlying etiopathogenic mechanisms, we generated a neuronal-specific *CASK* knockout ($CASK^{NKO}$) mouse by using the Cre-LoxP system. Interestingly, we found that the $CASK^{NKO}$ mice exhibit severe growth retardation and infantile-onset recurrent tonic spasms and myoclonus beginning postnatal day 8 (P8) which progressively worsens with age, and die before adulthood (i.e. P25). The overall brain size of $CASK^{NKO}$ mice is ~35-40% small along with a disproportionately small cerebellum and an isometrically small cortex compared to the age-and-sex-matched $CASK^{wildtype}$ littermate control mice. Electron

microscopy analysis revealed reduced number of mitochondria in the cortex of *CASK*^{NKO} mice compared to the control mice. A significant decrease in brain mitochondrial respiration was also observed in the *CASK*^{NKO} mice compared to the control mice. Strikingly, an unbiased RNA sequencing analysis revealed significant changes in the levels ~228 mitochondrial transcripts encoded by both nuclear and mitochondrial genomes in the brain of *CASK*^{NKO} mice compared to the control mice indicating a severe impairment in mitochondrial gene expression. Finally, we determined alterations in neuronal morphology, pathology, and activity by performing the immunohistochemical staining of cortical brain sections using confocal microscopy analysis. Although we observed no changes in brain lamination and synaptic density, surprisingly, we found that cortical layer-specific markers (i.e. CUX1 and TBR1) were mis-expressed in the *CASK*^{NKO} mice, cortex width was also reduced associated with an increase in neuronal density, and c-fos staining was decreased compared to the control mice. Additionally, astrocyte-specific GFAP immunostaining was markedly increased in the cortex of *CASK*^{NKO} mice compared to the control mice suggesting increased reactive astrogliosis and proliferation. Altogether, our findings suggest that neuronal CASK is essential for postnatal brain development and plays critical roles in regulating both mitochondrial and neuronal functions.

Endolysosome iron dyshomeostasis is mechanistically linked to endocytosed HERV-K envelope protein-induced mitochondrial depolarization and neurotoxicity

P. W. Halcrow[1], N. Kumar[1], D. Quansah[1], J. Steiner[2], A. Nath[2], J. D. Geiger[1]; [1]Biomedical Sciences, University of North Dakota School of Medicine and Health Sciences, Grand Forks, ND, [2]Section for Infections of the Nervous System, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD.

Human endogenous retroviruses (HERVs) are associated with the pathogenesis of amyotrophic lateral sclerosis (ALS); a disease characterized by motor neuron degeneration and cell death. The HERV-K subtype HML-2 envelope protein (HERV-K Env) is activated in brain of people living with ALS and through CD98HC-linked interactions causes motor neuron degeneration, mitochondrial dysfunction, and cell death. HERV-K Env-induced increases in oxidative stress are implicated in the pathogenesis of ALS, and ferrous iron (Fe^{2+}) generates reactive oxygen species (ROS). Endolysosome stores of Fe^{2+} are central to iron trafficking and endolysosome de-acidification releases Fe^{2+} into the cytoplasm. Because HERV-K Env is an arginine-rich protein that is likely endocytosed and arginine is a pH-elevating amino acid, it was important to determine HERV-K Env effects on endolysosome pH and whether HERV-K Env-induced neurotoxicity is downstream of Fe^{2+} released from endolysosomes. Here, we showed using SH-SY5Y neuroblastoma cells that HERV-K Env (1) is endocytosed via CD98 receptors, (2) concentration-dependently de-acidified endolysosomes, (3) decreased endolysosome Fe^{2+} levels, (4) increased cytosolic and mitochondrial Fe2+ and ROS levels, (5) depolarized mitochondrial membrane potential, and (6) induced cell death; effects blocked by an antibody against the CD98 receptor and deferoxamine an endolysosome-iron chelator. Thus, HERV-K Env-induced increases in cytosolic and mitochondrial Fe^{2+} and ROS as well as cell death appear to be mechanistically caused by HERV-K Env endocytosis, endolysosome de-acidification, and endolysosome Fe^{2+} efflux into the cytoplasm.

Mitochondrial Morphology and MICOS Complex Changes Across Aging in Cardiac Muscle of C56Bl/6 Male Mice

A. G. Marshall[1], Z. Vue[1], E. Garza-Lopez[2], K. Neikirk[1], L. Vang[1], H. K. Beasley[1], S. Murray[3], A. Hinton, Jr.[1]; [1]Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN, [2]Internal Medicine, University of Iowa, Iowa City, IA, [3]Department of Cell Biology, The University of Pittsburgh School of Medicine, Pittsburgh, PA.

Introduction Cardiovascular diseases (CVD) remain a major cause of death globally and new therapies are sorely needed. The heart is an energetically demanding tissue, with mitochondria estimated to comprise 1/3 of adult cardiomyocytes, representing an interesting target for novel therapeutics. Key factors regulating mitochondrial morphology, such as the mitochondrial contact site and cristae organizing system (MICOS), have not been well explored in cardiac tissues. **Materials and Methods** We used transmission electron microscopy (TEM) and serial block facing-scanning electron microscopy (SBF-SEM) to quantitatively analyze the 3D networks in cardiac muscle samples of mice through advanced aging. **Results** Across aging, we observed breakdown of mitochondria: decreased area, increased number, fragmentation, and loss of cristae morphology. Knockdown of key MICOS proteins in fibroblasts mimicked what was observed in aged cardiac tissue. **Conclusion.** We have identified the MICOS complex as potential targets for intervention in cardiac health.

B466/P2142

3D Reconstruction of Mouse Gastrocnemius Muscle Show Decrease in the MICOS Complex and Altered Mitochondrial Morphology Across Age

K. Neikirk[1], Z. Vue[1], L. Vang[1], E. Garza-Lopez[2], A. Hinton, Jr.[1]; [1]Vanderbilt University, Nashville, TN, [2]University of Iowa, Iowa City, IA.

Mitochondria are active organelles, undergoing harmonized cycles of fission and fusion, driven by 'mitochondrial dynamics,' to retain their morphology, distribution, and size. Mitochondrial dynamics has emerged as a critical process in maintaining cellular homeostasis. Interestingly, it has been long respected that a decrease in mitochondrial function escorts aging in specific tissues. For example, skeletal muscle gradually loses mass, strength, endurance, and oxidative capacity during aging. This decrease might, in turn, contribute to the observed age-dependent decline in organ function by mutations or alterations in mitochondrial fusion and fission proteins associated with several diseases. However, new players in regulating mitochondrial shape and cristae shape have been recently studied, such as the mitochondrial contact site and cristae organizing system (MICOS) complex. The MICOS complex is a multi-protein interaction hub that helps define cristate and mitochondria architecture. However, the MICOS complex has not been implicated in regulating organelle structure changes during aging. Thus, we hypothesized that loss of the MICOS complex during aging may increase mitochondrial fragmentation, decrease nanotunnels, and alter cristae morphology. To do this, we examined the three-dimensional morphology of mitochondria networks in young (3-month) and aged (2-year) murine gastrocnemius muscle via serial block face-scanning electron microscopy and the Amira program for segmentation, analysis, and quantification. We found differences in mitochondrial network configuration, nanotunneling, size, shape, number, contact sites, and MICOS gene expression in skeletal muscle during aging. We also found an association between OPA-1 and the MICOS complex in the gastrocnemius with mitochondrial aging. Furthermore, the loss of the MICOS complex was linked with

decreased oxidative capacity and altered mitochondrial metabolism. Potentially, this suggests a novel relationship between the MICOS complex and aging in skeletal muscle.

3D Reconstruction of Aged Kidney Shows Unique and Diverse Mitochondrial Phenotypes in the Tubular Epithelium

T. Barongan[1], Z. Vue[2], L. Vang[2], K. Neikirk[1], J. McBride[3], A. O. Hinton, Jr.[2]; [1]University of Hawaii At Hilo, Hilo, HI, [2]Vanderbilt University Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN, [3]Vanderbilt Institute of Nanoscale Science and Engineering, Vanderbilt University, Nashville, TN.

The kidney is a vital organ that demands an astonishing amount of energy, in terms of mitochondrial count and oxygen consumption, to maintain its functions, such as metabolism, hormone secretion, nutrients reabsorption, and filtration of blood. In recent years, cristae (mitochondrial inner membrane folds) have been shown to be important for mitochondrial function and has been associated with human diseases due to aberrant cristae morphologies, such as renal sclerosis and acute glomerulonephritis. We hypothesized that 3D reconstruction would show mitochondrial dysfunction marked by fragmentation across aging in kidney. To confirm this hypothesis, we used serial block face-scanning electron microscopy to observe mitochondrial 3D reconstruction of the kidney tubule epithelium in 3-month (young adults) and 2-year (elderly) mice. In all samples, we observed round mitochondria next to the nucleus, whereas further away from the nucleus, the mitochondria display unique structures, such as large, fragmented, elongated, compact, nanotunnels and toroid. Overall, we observed more fragmentation in the 2-year compared to the 3-month mice, marked by a decrease in area and volume. From these studies, we conclude that fragmentation occurs in aged kidney samples, which may contribute to decreased performance.

B468/P2144

Changes in Mitochondrial Cristae Morphology that Occur with Aging in Brown Adipose Tissue

A. Crabtree[1], Z. Vue[1], D. Stephens[1], A. Marshall[1], H. K. Beasley[1], S. Damo[2,1], A. Hinton, Jr.[1]; [1]Vanderbilt University, Nashville, TN, [2]Fisk University, Nashville, TN

Mitochondria are required for energy production and give brown adipose tissue (BAT) its characteristic color due to their high iron content. The physiological function and bioenergetic capacity of mitochondria are connected to the structure, folding, and organization of its inner-membrane cristae. During the aging process, mitochondrial dysfunction is observed, and the regulatory balance of mitochondrial dynamics is often disrupted, leading to increased mitochondrial fragmentation in aging cells. Dysregulation of mitochondrial dynamics is thought to play a role in age-related disorders and higher susceptibility of cells to various stress conditions during progressive aging. Therefore, we hypothesize that the morphological changes observed in aging BAT mitochondria and cristae can imply alterations to energy dynamics. To test this hypothesis, we developed a quantitative three-dimensional approach to map cristae network organization in mouse BAT at electron microscopy resolution. Using this methodology, we investigated the three-dimensional morphology of mitochondrial cristae in young (3-month) and aged (2-year) murine BAT tissue via serial block face-scanning electron microscopy and the Amira program for segmentation, analysis, and quantification. Upon analysis, we found that there were changes in mitochondrial volume, cristae volume, tubular ratios, maximum length/ minimum

length ratios, and cristae surface/ mitochondrial volume ratios during aging. Additionally, we observed changes in mitochondria morphology and lipid droplet appearance, structural integrity, decreased cristae surface area, and mitochondrial interactions with lipids in 2-year aged BAT murine samples compared to 3-month murine samples. Overall, these data define the nature of the mitochondrial structure in BAT, quantify young and old mitochondrial morphology, lipid droplet, and cristae morphology differences, and suggest that changes in structure may lead to alterations in functionality and bioactivity.

B469/P2145

Cardiomyocytes treated with particulate matter and palmitate increase apoptosis through mitochondrial fission

Y.-L. CHEN; College of Medicine, National Taiwan University, Taipei, Taiwan

There is growing evidence that exposure to fine particulate matter (PM) air pollution increases the risk of cardiovascular disease morbidity and mortality. According to previous studies, PM in the air enters the respiratory tract, contacts the alveoli, and enters the blood circulation, leading to the progression of cardiovascular disease. Who is most vulnerable is uncertain. Individuals with cardiometabolic disease, including hyperlipidemia and obesity, may be at greater risk. PM pollution may also lead to cardiometabolic disturbances, increasing the risk of cardiovascular disease. The effect of PM on cardiac function and mitochondrial damage under a high-lipid treatment is currently unknown. We used rat cardiomyocytes (H9c2) as an in vitro cell model using palmitic acid (PA) and PM to simulate hyperlipidemia and an air pollution environment. These results demonstrated that the apoptosis-related factor PUMA, a regulator of apoptosis upregulated by p53, was increased in cardiomyocytes treated with PA or PM alone, whereas PUMA expression was significantly increased in cells co-treated with PA and PM. Apoptosis was aggravated in cardiomyocytes treated with PA and PM, as measured by TUNEL assay and Annexin V/PI. Western blot results showed that under the combined treatment of PA+PM, CASPASE3 were significantly increased, and BCL2 (B-cell lymphoid 2) was significantly decreased. Simultaneous exposure to PA and PM increases mitochondrial reactive oxygen species (ROS) production by MitoSOX Red staining. Furthermore, using Mitotracker staining, PA+PM treatment significantly shortened mitochondrial length, indicating mitochondrial fission. The expression of mitochondrial fission-related proteins p-DRP1 (phosphodynamics-related protein 1) and FIS1 (mitochondrial fission 1 protein) was significantly increased compared to the PA or PM-treated groups alone. According to these results, combined exposure of PA and PM worsens mitochondrial function and leads to cardiomyocyte apoptosis. In conclusion, co-exposure of PA and PM increased oxidative stress and mitochondrial fission, and further exacerbated cardiomyocyte apoptosis

B470/P2146

COVID-19 treatment drug Remdesivir increases mtDNA copy number, but only causes mild changes to mitochondrial function.

N. DeFoor[1], J. L. Browning[1], E. K. G. Basso[1], V. Stevenson[2], S. Li[3], T. Ge[3], A. M. Pickrell[1]; [1]Virginia Tech, Blacksburg, VA, [2]Virginia-Maryland College of Veterinary Medicine, Blacksburg, VA, [3]Medical University of South Carolina, Charleston, SC

SARS-CoV-2 causes the severe respiratory disease COVID-19 which has led to illness in an estimated 615 million people worldwide. Remdesivir (RDV) was the first fast-tracked FDA approved treatment drug for

COVID-19. RDV acts as an antiviral ribonucleoside (adenosine) analogue that becomes active once it has been metabolized in the liver. It then diffuses into the host cell and terminates viral RNA transcription due to its ability to evade proofreading exoribonucleases. Previous studies have shown that certain nucleoside analogues unintentionally inhibit mitochondrial RNA or DNA polymerases or cause mutational changes to mitochondrial DNA (mtDNA) itself. For instance, the human immunodeficiency virus (HIV) treatment drug Zidovudine (AZT) works as a thymidine analogue to halt viral DNA transcription during reverse transcription. However, patients treated with AZT years later displayed myopathies, which was later discovered to be due to off-target mitochondrial damage from long-term usage. Similarly, Fialuridine (FIAU) was tested for the treatment against hepatitis B virus (HBV), but did not pass Phase II clinical trials due to unforeseen mitochondrial damage. These past findings on the mitochondrial toxicity of ribonucleoside analogues motivated the study to investigate what effects RDV may have on mitochondrial function. Using in vitro and in vivo models treated with RDV, we characterized changes to mtDNA copy number and mitochondrial protein expression. We found that a 2.5uM treatment of RDV increases mtDNA copy number in Mv1Lu (mink lung) cells over 72 hours with concomitant increases in mtDNA-encoded proteins. However, these changes do not appear to affect enzymatic activity. When testing young adult CD-1 mice given a 10 day course of RDV, liver tissue also displayed increased mtDNA levels 30 days post-treatment. However, mitochondrial protein expression and liver pathology appeared mostly unaffected. When examining skeletal muscle, lung, and cardiac tissue, mtDNA and mtDNA-encoded proteins appeared mostly unaffected. Pathology performed on lung tissue displayed normal cellular morphology and no gross changes upon examination. Future studies will determine how RDV increases mtDNA copy number during acute treatment periods and if aged animals display a heightened sensitivity to RDV treatment paradigms.

B471/P2147

IL-1β-induced Inflammation Impairs Immunometabolic Response in Corneal Epithelial Cells

J. Sanches[1], N. Mussi[1], H. Baniasadi[1], D. M. Robertson[2]; [1]UT Southwestern Medical Center, Dallas, TX, [2]UT Southwestern Medical Center, White, TX

Purpose: As a mucosal surface, the corneal epithelium plays an important role in mediating innate immune responses across the front surface of the eye. Pathogens, changes in tear film osmolarity, and tissue damage can all trigger inflammation, leading to tissue damage. In the present study, we used the pro-inflammatory cytokine, IL-1β, to investigate the effects of inflammation on mitochondrial and metabolic homeostasis in corneal epithelial cells.**Methods:** Telomerase-immortalized human corneal epithelial cells were cultured in serum-free keratinocyte basal media. To establish an inflammatory environment, cells were treated with 50 ng/mL or 100 ng/mL of IL-1β for 72 hours. Metabolism was measured in real time using a Seahorse metabolic flux analyzer. Total cell number per well was used for normalization. Protein expression for metabolic, mitochondrial, and mitophagy-related proteins was assessed using western blot. Confocal microscopy was used to evaluate intracellular reactive oxygen species (ROS) production. Cytokines were measured by ELISA and liquid chromatography mass spectrometry analysis was used for targeted metabolomics.**Results:** IL-1β-induced inflammation promoted a fuel switch indicating metabolic adaptation between 50 ng/mL and 100 ng/mL. This was associated with an increase in spare and maximum respiratory capacity (p=0.043 and p=0.001, respectively). The higher concentration of IL-1β increased the ECAR response (p=0.03) and non-mitochondrial oxygen consumption (p=0.002). Long-term treatment with IL-1β-induced inflammation downregulated mitochondrial and mitophagy proteins in a mTOR independent manner.IL-1β-induced

inflammation increased IL-8 and IL-6 levels, as well as intracellular ROS production. Targeted metabolomics analyzed 69 metabolites ($p<0.05$). Glucose-6-phosphate and fructose-6-phosphate were more prominent in the control group. Oxidative enzymes such as NADH and NADPH were prominent in IL-1β treated cells, as well as coenzyme A, fumarate, nicotinamide, and phosphoenolpyruvate. IL-1β also enhanced levels of several amino acids, including as glutamate, alanine, and tryptophan. **Conclusion:** These data confirm that inflammation triggers metabolic and mitochondrial changes in corneal epithelial cells. The increase in spare respiratory capacity enables the cell to better respond to stress and promote cell survival.

B472/P2148

Relocation of the mitochondrial protein HADHA to the cell surface under starvation and hypoxic stress conditions.

F. Veloso-Bahamondes[1], C. Retamal[1], A. González[1,2,3], **C. Oyanadel**[1]; [1]Universidad San Sebastián, Santiago, Chile, [2]P. Universidad Católica de Chile, Santiago, Chile, [3]Centro Científico y Tecnológico de Excelencia Ciencia & Vida, Santiago, Chile

Most of mitochondrial proteins are synthesized in the cytosol as precursors bearing an N-terminal targeting signal. Beta-oxidation mitochondrial-trifunctional-protein (MTP) is a mitochondrial matrix protein but its alpha-subunit, hydroxyacyl-CoA deshydrogenase (HADHA), has also been found at the cell surface, corresponding to the otherwise called Gastrin Binding Protein (GBP). GBP binds gastrin and mediates autocrine mitogenic effects in normal gastric and colon carcinoma cells. The mechanism addressing HADHA/GBP from the cytosol to either the mitochondria or the cell surface remains unknown. Interestingly, cytosolic HADHA has recently been described to interact with LC3, a protein crucial in autophagy processes. Autophagy increases during starvation, removes cytosolic components and also mediates unconventional secretion of cytosolic cargoes, which is an alternative trafficking route of integral membrane proteins to the plasma membrane. In this work we study whether HADHA presequence has sorting information to target the protein to the cell surface in a regulated manner, especially under stress conditions usually found in tumoral microenvironments, such as starving and hypoxic conditions. We used GFP coupled to HADHA presequence as reporter and performed surface biotinylation assays to assess the cell surface distribution and confocal imaging to visualize mitochondria dynamics. We show that HADHA/GBP contains sorting information to target both mitochondria and plasma membrane. Interestingly, starvation and chemical hypoxia with cobalt chloride both increased GBP/HADHA at the cell surface of tumoral cells, along with the described mitochondrial fragmentation and LC3-II expression reflecting autophagy under this treatment. As mitochondrial fragmentation and autophagy imply metabolic changes, these results suggest that tumor cells under stress conditions can increase the targeting of HADHA/GBP to cell surface as the result of metabolic adaptative process. The functional consequences of such protein relocation remains unknown. Mitochondrial calcium overload in alzheimer's disease

P. Jadiya[1], D. Tomar[1], J. Elrod[2]; [1]Wake Forest School of Medicine - Winston-Salem, NC, Winston-Salem, NC, [2]Temple University, Philadelphia, PA

Background. We recently reported that compromised mitochondrial calcium ($_mCa^{2+}$) efflux (mitochondrial Na^+/Ca^{2+} exchanger or NCLX-dependent) causes $_mCa^{2+}$ overload in Alzheimer's Disease (AD). Genetic deletion of neuronal NCLX (the primary route for $_mCa^{2+}$ efflux) in the 3xTg-AD mouse model accelerated memory deficits and AD progression. Furthermore, increased neuronal $_mCa^{2+}$ efflux using NCLX overexpression in the 3xTg-AD mouse model reduced AD-phenotype. Our previous study suggests that $_mCa^{2+}$overload is a primary contributor to AD pathology by promoting metabolic dysfunction and neuronal cell death. However, whether $_mCa^{2+}$ overload alone is sufficient to cause neuronal pathology independent of amyloidosis or tau pathology remains unidentified. **Methods.** To test this, we generated a neuronal-restricted knockout of NCLX, its loss predisposes to $_mCa^{2+}$ overload, in wild-type mice (Nclx-nKO), and evaluated age-associated changes in cognitive functions and neuropathology. **Results.** We observed that neuronal-specific loss of $_mCa^{2+}$ efflux in wild-type mice increased amyloid deposition with an age-dependent decline in spatial memory, suggesting that $_mCa^{2+}$ overload is sufficient to promote an AD-like phenotype.

Chemical Genetics Screen to Identify Functional Effects of a Quinazoline Derivative, EVP4593, in Budding Yeast

L. Hiestand[1], Y. S. Shen[1], W. Sloan[2], D. Lashley[2], O. Kerscher[3]; [1]Biology, The College of William and Mary, Williamsburg, VA, [2]Chemistry, The College of William and Mary, Williamsburg, VA, [3]Biology, William & Mary, Williamsburg, VA.

Mitochondria are essential eukaryotic organelles. Dysfunction of mitochondria can lead to mitochondrial myopathies and may contribute to neurodegenerative diseases, cancer, and diabetes. EVP4593 is a 6-aminoquinazoline derivative that has been shown to inhibit complex I of the mitochondrial electron transport chain, causing the release of reactive oxygen species (ROS). EVP4593 inhibits respiration of isolated mitochondria in the nanomolar range (IC50 = 14-25 nM). In contrast, we established that wildtype budding yeast cells can survive up to ~100µM EVP4593 when grown on a non-fermentable carbon source. To better understand the cellular pathways and processes affected by EVP4593, we conducted a genome-wide chemical genetics screen of the yeast knockout collection. The objective was to identify yeast gene deletion strains that exhibit growth defects when subjected to a sublethal concentration of EVP4593 [15µM]. We screened ~5100 yeast mutants and identified 20 yeast genes that are required for resistance to 15µM EVP4593 in glycerol-containing media. In summary, the genes identified in our screen are functionally involved in 1) regulating mitochondrial metabolism, 2) vacuolar targeting, 3) DNA replication, and 4) stress tolerance. Additionally, we investigated cellular phenotypes associated with the exposure to EVP4593, such as changes in mitochondrial structure and the accumulation of oxygen radicals. In conclusion, our study leverages the powerful yeast models system to identify the genetic pathways involved in EVP4593 sensitivity and the mechanisms the cell uses to protect its mitochondria from damage.

Exercise benefits the human body in many ways. Irisin is secreted by muscle, increased with exercise, and conveys many physiological benefits, including thermogenesis in adipose tissues, bone remodeling, and improved cognition and resistance to neurodegeneration. Irisin acts via αV integrins; however, a mechanistic understanding of how small polypeptides like irisin can signal through integrins is poorly understood. Using mass spectrometry and cryo-EM, we demonstrate that the extracellular heat-shock protein 90α (eHsp90α) is secreted by muscle with exercise and acts, without involving its chaperone activity, as a required cofactor that “opens” the integrin αVβ5 structure to allow for high affinity irisin binding and signaling through an eHsp90α/αV/β5 complex. The extracellular Hsp90α-mediated integrin activation is independent of any of the known intracellular activation mechanisms. By including hydrogen/deuterium exchange data, we generate and experimentally validate a 2.98 Å RMSD irisin/αVβ5 complex docking model. Irisin binds very tightly to an alternative interface on αVβ5 distinct from that involved in its interaction with known ligands. These data together elucidate a non-canonical mechanism by which a small polypeptide hormone like irisin can function through integrins.

Compartment-Specific Activation of Proton-Sensor GPR65 is Uncoupled from Receptor Trafficking

L. M. Morales-Rodriguez, M. Puthenveedu; Pharmacology, University of Michigan, Ann Arbor, MI.

Proton-sensing G protein-coupled receptors (GPCRs) allow cells to sense and respond to changes in physiological pH. This family of GPCRs are unique in that, upon internalization and trafficking to acidic intracellular compartments, they are exposed to environments that are more likely to activate the receptor. However, little is known about whether and how proton-sensing receptors signal from intracellular compartments, and how proton-sensing GPCR signaling is regulated. Here we use proton-sensing receptor GPR65 as a prototype to study how receptor location at intracellular compartments influences proton-sensing receptor signaling. We use live imaging of GPR65-expressing cells to show that GPR65 internalizes from the plasma membrane and localizes to early and late endosomes at both neutral and acidic pH. Further, GPR65 internalization is required for a full cAMP response after exposure to acidic extracellular pH. Together, our findings show that GPR65 dynamically traffics to and signals

from multiple cellular compartments. Importantly, our results suggest that, unlike for most known GPCRs, activation of GPR65 is uncoupled from receptor trafficking.

The Disulfide Bonds in the C-terminal Domains of the Insulin Receptor Regulate Insulin-mediated Receptor Endocytosis

S. H. Park, E. Choi; Department of Pathology and Cell Biology, Vagelos College of Physicians and Surgeons, Columbia University, New York, NY.

Insulin receptor (IR) endocytosis plays a key role in insulin homeostasis. IR, a subfamily of receptor tyrosine kinases, is a dimer consisting of two protomers connected by disulfide bonds. The IR has an inverted V-shape in the absence of insulin. Upon insulin binding, IR undergoes a large conformational change and forms a T-shape which allows the intracellular tyrosine kinase domains of each protomer to get closer. The insulin activated IR triggers activation of its downstream pathways and initiates insulin internalization through the IR endocytosis. Disulfide bonds of the cysteine triplet at the C-terminus of the a-subunit of IR (a-CT), connect two IR protomers. As insulin binding to IR induces a large distance relocation of the a-CT, certain structural flexibility of the a-CT is required for the active IR conformation and IR signaling. Here, we examined how altering the disulfide bonds to break the link affects the IR endocytosis. We generated stable cell lines of HepG2 stably expressing IR-GFP wild-type (WT) and a mutant expressing IR with a shorter linker by deleting five amino acids from the linker (IR-del5). The levels of ectopically expressed IR-GFP WT and mutants were higher than that of the endogenous IR. Then we observed IR internalization across the time point after insulin treatments. Cells were fixed and the amount IR on the plasma membrane was analyzed through immunofluorescence assay. As expected, 100 nM of insulin treatment induces IR-GFP WT internalization. However, HepG2 cells expressing IR-del5 failed to carry out insulin-mediated endocytosis in comparison to IR-WT, likely due to the lack of structural flexibility. This result further suggests that the structural flexibility of disulfide linked a-CTs is a key factor for the conformational transformation and activation of downstream pathways.

B479/P2154

Gs-independent Activation of AC9 by the CAP1-Rap1 Complex in Mammalian Cells

X. Zhang[1], **D. Altschuler**[1], A. Pizzoni[1], C. Qi[2], V. Korkhov[2]; [1]University of Pittsburgh, Pittsburgh, PA, [2]Institute of Molecular Biology and Biophysics, Paul Scherrer Institute, Zurich, SWITZERLAND.

Gs-coupled GPCRs (GsPCRs) are involved in many biological functions due to their role on cAMP production. While cAMP was classically considered to originate solely from the plasma membrane, recent results demonstrated that GsPCRs can sustain cAMP signaling from an internalization-dependent endocytic compartment. However, the molecular mechanisms involved in sustained signaling are still unknown. Cyclase-Associated Protein 1 (CAP1), highly conserved in evolution, was originally isolated in yeasts as a bifunctional protein required for Ras-mediated cyclase activation and F-actin dynamics regulation. However, its adenylyl cyclase (AC)-associated function was thought to be lost in mammals. We have reported that mammalian CAP1, via its C-terminal domain interacts with Rap1 in a geranylgeranyl-specific manner. Moreover, CAP1 in complex with Rap1 binds and activates mammalian cyclase *in vitro* and modulates cAMP dynamics in mammalian cells. We will discuss new data showing that only AC9, a Golgi/TGN localized AC isoform, manifested CAP1-Rap1 sensitivity. Utilizing purified reagents, we showed that while CAP1's N-terminal coiled-coil domain (CC) interacts with AC9's C1a loop,

Rap1, like GαS-GTP, binds AC9's C2 catalytic loop and activates AC9 in a GTP and effector domain-dependent manner. Moreover, Rap1-GTP competes with GαS-GTP for AC9 binding and, like GαS, Rap1-GTP communicates allosterically to the forskolin binding site. Furthermore, CAP1-Rap1 action on AC9 can be recapitulated in GαS-deficient cells. Our experimental results are consistent with a model in which CAP1-Rap1 wraps around the C1-C2 domains of AC9; the CC domain of CAP1 binds AC9-C1 and Rap1-GTP interacts with AC9-C2, leading to a GαS-independent AC activation. Thus, like CAP/srv2-Ras2 in yeast, CAP1-Rap1 plays a role in cAMP dynamics in mammalian cells via AC9 activation. Since Rap1 is a bona fide downstream effector of cAMP, we propose that AC9-CAP1-Rap1 represents a new positive feedback loop working as a regulatory unit and a signal amplifier responsible for the intracellular GsPCR's sustained signaling.

Investigating the relation between G protein regulation and spermathecal contraction

M. Raisa Amin, E. J. Cram; Biology, Northeastern University, Boston, MA.

Cell contractility is vital for the maintenance and regulation of several biological systems, including the circulatory, respiratory, and digestive systems, etc. To study cell contraction, we use the C. elegans spermatheca, a contractile tube composed of smooth muscle-like cells, that stores sperm and is the site of oocyte fertilization. Regulated spermathecal contraction is needed to push the embryo into the uterus. Spermathecal cell contraction is regulated by actin and myosin, and is activated, in part, by the phospholipase, PLC-1. Previous studies have shown that the heterotrimeric G-protein alpha subunit, GSA-1/Gαs, and protein kinase KIN-1/PKA-C are involved in ovulation and Ca2+ release. Hence, we conducted a candidate RNAi screen on genes implicated in smooth muscle disorders; to identify candidates with defects in oocyte transit through the spermatheca. We identified several candidates that increased oocyte trapping in the spermatheca, including ftt-2. Interestingly, some of these genes may be involved in G protein regulation. Our preliminary results suggest that the study of spermathecal contractility may reveal conserved role of genes in human smooth muscle disorders.

B481/P2156

Control of skin stem cell homeostasis by G-alpha-s signaling

K. Lund, R. Iglesias-Bartolome; Laboratory of Cellular and Molecular Biology, National Cancer Institute, NIH, Bethesda, MD.

G-alpha-s (Gs) is a heterotrimeric G protein activated downstream of G-protein-coupled receptors (GPCRs) and is involved in numerous physiological and pathological processes. Gs signals by increasing cyclic AMP (cAMP) levels, activating the kinase PKA and the exchange factor EPAC. Previous work in our lab has shown that the knockout of Gs in mouse skin keratinocytes leads to rapid stem cell expansion by the inactivation of PKA. However, Gs-activating and cAMP-inducing agents are commonly used to increase keratinocyte proliferation in cell culture, and Gs activation can lead to hair follicle stem cell proliferation in the skin. This project aims to understand how specific pathway components contribute to this dual role of Gs signaling in keratinocytes and, ultimately, identify targets to modulate skin stem cell activity.

We first sought to identify the pathways that Gs uses to increase keratinocyte proliferation in isolated keratinocytes. As previously reported, the GPCR-Gs signaling activator epinephrine increased keratinocyte proliferation in 2D and 3D organotypic cultures. On the other hand, downregulation of Gs

by small interference RNA (siRNA) resulted in reduced keratinocyte proliferation. This reduction in proliferation could be partially rescued by the cAMP-inducing agent forskolin, indicating that Gs and cAMP are necessary for keratinocyte proliferation in vitro.
To investigate if PKA mediates the role of Gs, we activated this pathway by expressing a constitutive-active mutant form of PKA. As a complementary experiment, we used a PKA inhibitor peptide (PKI) to evaluate the effects of reduced PKA activity. Remarkably, no difference in proliferation or 3D organotypic culture thickness was observed in either overactive or inhibited PKA conditions.
Since PKA mediates the effect of Gs inactivation in vivo, these results indicate that Gs can function through different mechanisms to regulate keratinocyte proliferation. We are currently in the process of characterizing the pathway downstream of Gs that leads to keratinocyte proliferation. Interestingly, we found that EPAC knockdown does not affect keratinocyte proliferation, revealing that a non-canonical cAMP-regulated event might mediate the effect of Gs.

B482/P2157

Hyperactivation of Insulin-like growth factor signaling in Adipose-derived stem cells promotes early onset of metabolic syndrome in prenatally arsenic exposed mice

K. Koshta[1,2], A. Chauhan[1,2], V. Srivastava[1,2]; [1]Developmental Toxicology Division, CSIR- Indian Institute of Toxicology Research, Lucknow, INDIA, [2]Academy of Scientific & Innovative Research, Ghaziabad, INDIA.

Metabolic Syndrome (MetS) is the cluster of multiple pathological conditions including glucose intolerance, obesity, increased serum triglycerides, reduced HDL-C and hypertension which increases the risk for cardiovascular diseases, type 2 diabetes and various cancerous outcomes. Adipose dysfunction is one of the mechanisms for progression of MetS, particularly upon exposure to endocrine disrupting chemicals such as arsenic. In our animal experiments, gestational exposure to arsenic (0.04mg/kg) lead to early onset of metabolic syndrome in offspring which was associated with adipose dysfunction. The role of arsenic in gestational programming of adipose-derived stem cells (AdSCs) and its contribution to MetS needs to be assessed. We isolated the AdSCs from epididymal white adipose tissue (EWAT) of male offspring to determine the effects of gestational arsenic conditioning on their proliferation and differentiation potential. The functional assays such as insulin stimulated glucose uptake (ISGU) and adipokines secretion were evaluated after differentiation and underlying cellular mechanisms were identified. We observed accelerated proliferation and differentiation potential in arsenic exposed AdSCs. The expression of adipogenic markers such as Perilipin, C/EBPα, PPARγ and Stearoyl-CoA Desaturase 1 (SCD1) were significantly increased. Excess lipid accumulation, verified through lipophilic Nile red staining, resulted in adipocyte hypertrophy. Several pro-inflammatory adipokines were elevated in arsenic exposed AdSCs including Leptin and TNF-α along with Resistin which mediates insulin resistance. Reduced ISGU suggested impaired insulin response in arsenic exposed AdSCs. Insulin-like growth factor 1 (IGF1) was found to be highly expressed in arsenic exposed AdSCs. It was accompanied by hyperactivation of its receptor-IGF1R through phosphorylation and enhanced lipid accumulation. The levels of downstream phospho-Akt & ERK1/2 were elevated leading to accelerated proliferation and differentiation. Our findings suggest that prenatal arsenic exposure results in enhanced adipogenic potential of AdSCs leading to adipocyte hypertrophy to accommodate excess lipid. Hyperactivation of IGF1-MAPK signaling cascade is found to be primarily responsible for this accelerated adipogenesis. Adipocytes trigger insulin resistance as a defensive conduct to prevent further lipid deposition which could be further contributing to ectopic lipid deposition in non-adipose tissues such as kidney, liver, pancreas and muscle fibers leading to early onset of metabolic syndrome.

FGFR mediates TGFβR signaling to switch fibroblast differentiation between adipocytes and myofibroblasts

T. Hong[1], T. Lu[1], E. Yen[1], F. Tsai[1,2]; [1]Department of Pharmacology, National Taiwan University College of Medicine, Taipei, TAIWAN, [2]Department of Internal Medicine, National Taiwan University Hospital, Taipei, TAIWAN.

Thyroid eye disease (TED) is a severe orbitopathy that frequently occurs in patients with Grave's disease. TED patients suffer from accumulation of adipose and fibrous tissue within the orbital cavity, indicating aberrant activities of growth hormone signaling. Fibroblast growth factors (FGF) are a growth hormone that plays a crucial role in regulating fibroblast proliferation and differentiation into adipocytes. Our recent work revealed that serum levels of FGF1 and FGF2 were elevated in patients with TED, and that FGF1 transformed orbital fibroblasts into pre-adipocytes while FGFR inhibitors transformed them into myofibroblasts. Since FGFR signaling regulates TGFβR signaling through microRNAs let-7 and miR-20a, we examined if FGF effects on orbital fibroblasts were also through TGFβR modulation. Using immunoblots, we confirmed that TGFβ increased the expression of α-SMA, the marker of myofibroblast activation and that FGF and FGFR inhibitors reduced and increased α-SMA, respectively, compatible with our previous results of FGF effects on orbital fibroblasts. Interestingly, TGFβ inhibition blocked α-SMA, supporting the pivotal role of TGFβR on FGFR-mediated α-SMA. Surprisingly, immunoblots showed that FGFR inhibitors enhanced TGFβ effects on α-SMA, but knockdown of FGFR inhibitors enhanced TGFβ effects on α-SMA, implying the complex nature of FGFR signaling on TGFβR modulation. We are currently elucidating their underlying mechanisms, with the ultimate goal to develop valid FGFR- TGFβ-based therapy for TED.

B484/P2159

The Role and Regulation of mTORC2 in Lung Cancer Cell Migration

A. N. Werner, A. I. Kumar, P. G. Charest; University of Arizona, Tucson, AZ.

The mechanistic Target of Rapamycin Complex 2 (mTORC2) is a signaling complex playing a key role in promoting cell migration and has been implicated in the migration of cancer cells. Cancer cell migration is a key step in the metastasis of cancer, which is responsible for 90% of cancer-related deaths. However, the regulation and role of mTORC2 signaling in cancer cell migration is incompletely understood. Recent evidence suggest that the Ras oncogene promotes mTORC2 activation in cancer. Here, we investigated the role of Ras and other signaling pathways in regulating mTORC2 activation and function in the migration of Non-Small Cell Lung Cancer (NSCLC) cells, using A549 cells as a model. We observed that activation of the chemokine receptor, CXCR4, and growth factor receptor, EGFR, activate mTORC2, both individually and in a cooperative manner, in a way that suggests receptor crosstalk. We also find that activation of CXCR4 and EGFR lead to cell migration that is mediated by mTORC2. Interestingly, we observed that increased mTORC2 activation by CXCR4 and EGFR does not increase cell migration. In addition, we find that Ras is not involved in mTORC2-mediated cell migration in A549 cells. These cells express an oncogenic constitutively activating mutation in the K-Ras isoform, which we also found to not play a role in mTORC2-mediated cell migration in A549 cells. Instead, our results suggest a signaling pathway that utilizes PI3K in mTORC2 activation by both CXCR4 and EGFR. Current work investigates the subcellular location of mTORC2 activation by EGFR and CXCR4, as well as other potential

players in the involved signaling pathways. A better understanding of the signaling pathways mediating lung cancer cell migration could lead to the identification of potential targets to prevent the metastatic spread of lung tumors.

B485/P2160

D-Galactose induces Toll-like Receptor-2 gene expression and Mitochondrial dysfunction in Neonate Skin Fibroblast Cultures

G. Dhaunsi, M. Al-Essa; Kuwait University, Kuwait, KUWAIT.

Objective: Galactosemia is an autosomal recessive disorder with a wide range of clinical abnormalities ranging from liver cirrhosis, cataracts, neurological defects and an increased risk of infections, and its underlying pathogenic mechanisms are still being investigated. Mitochondrial energy production is essential for cell survival and Toll-like receptor-2 (TLR-2) expression is linked with apoptotic cell death, however their role in pathogenesis of Classical Galactosemia has remained unexplored. This ex vivo study was carried out to examine mitochondrial β-oxidation of fatty acids and gene expression of Toll-like receptor-2 under conditions of hyper-galactosemia and/ high glucose. *Methods*: Fibroblasts were grown from post-circumcision foreskin of 3-8 days old healthy neonates and cultured to confluency in RPMI growth medium. Confluent cell cultures were treated with varying concentrations (0-20mM) of galactose (Gal) and/or high glucose (25 mM. HG) for 24 -72 hrs. Following treatment of cell cultures with experimental agents, cells were harvested and homogenized in 50mM Tris-HCl buffer, pH 7.4 for assay of palmitoyl-CoA oxidase and cytochrome c oxidase enzyme activities. Gene expression of Carnitine palmitoyl-CoA transferase (CPT-I) and TLR-2 was examined using RT-PCR and Western blot analysis. *Results:* Treatment of cell cultures with high glucose (HG) and 10 -20 mM D-Galactose (D-Gal) for 72 hrs. significantly ($p < 0.05$) decreased the palmitoyl CoA oxidase activity when compared with that in cells cultured under normal glycemic conditions (control). Both HG and D-Gal markedly decreased the gene expression of CPT-1 after 24 hrs. of treatment, however the reduction in levels of CPT-1 was statistically significant ($p < 0.01$) in cells co-treated with HG and D-Gal when compared with control cells or those treated with HG or D-Gal alone. D-Gal significantly decreased ($p < 0.01$) the Cytochrome c oxidase activity whereas HG did not have any marked effect of its own but further enhanced the D-Gal-induced reduction in cytochrome c oxidation. RT-PCR and Western blot analyses revealed significantly increased ($p <0.01$) gene expression of TLR-2 in cells treated with 10 -20 mM D-Gal which was found to be markedly enhanced by co-treatment with HG. *Conclusion*: This study demonstrates that D-Gal treatment impairs activities of key tow mitochondrial enzymes, CPT-1 and Palmitoyl CoA oxidase, that are involved in β-oxidation of fatty acids and induces gene expression of TLR-2. Co-treatment with HG enhanced the D-Gal-induced mitochondrial dysfunction and TLR-2 gene expression suggesting that high glucose potentially worsens pathogenic events of Galactosemia.

B486/P2161

Mechanism of the Class A GPCR Pathway Underlying Osteogenic Differentiation of Mesenchymal Stromal Cells and Hard Tissue Regeneration

S. Park, E. Choi, J. Jung, J. Kim; School of Dentistry, Seoul National University, Seoul, KOREA, REPUBLIC OF.

Mesenchymal stromal cells (MSCs) have high proliferation potential with multi-lineage differentiation capacity and is a key cellular component for regeneration of hard tissue such as teeth and bone.

Previous studies have attempted to apply MSCs to induce hard tissue regeneration, but the trial remains a challenge. G protein-coupled receptor (GPCR), a membrane protein that play an important role in various pathological and physiological controls, is regarded as the main targets in the pharmaceutical market. However, the development of a drug targeting GPCRs has not been established for regeneration of damaged hard tissues. Here we present a targeting strategy of class A GPCRs for hard tissue regeneration by promoting the differentiation of endogenous MSCs into osteoblastic and odontogenic progenitor cells. Through *in vitro* screening designed to target class A GPCRs, we discovered six target receptors (LPAR1, F2R, F2RL1, F2RL2, S1PR1, ADORA2A) and candidate drugs with potent effect on biomineralization. When the discovered candidates were treated to cultured human MSCs, alizarin red and osteogenic marker gene responses were induced. Through bulk RNA sequencing, transcriptional changes related to phosphatidylinositol 3-kinase (PI3K)-protein kinase B (AKT) signaling pathways were identified in common. In particular, the expression of p53 protein, a downstream signaling component of the PI3K-AKT pathway, was increased upon treatment with core candidate drugs. In the regenerative process, p53 acts as a key transcription activator for genes that modulate osteogenic differentiation. Moreover, the therapeutic potential of class A GPCR-targeting drugs was demonstrated in tooth pulpotomy and calvaria defect models. In this study, we discovered a key candidate group of class A GPCRs and targeted inhibitors associated with regeneration of hard tissue. Collectively, the findings of this study provide a theoretical background for a new regenerative strategy of damaged hard tissues.

Phase Separation of Epidermal Growth Factor Receptor (EGFR) Directs Spatiotemporal Adaptor Protein Organization

M. Ullo, L. Case; Biology, Massachusetts Institute of Technology, Cambridge, MA.

Receptors at the plasma membrane receive and transmit environmental cues to guide a cell's behavior. The Epidermal Growth Factor Receptor (EGFR) family of receptors are critical in regulating cellular growth and survival by coordinating localization of cytosolic adaptor and signaling molecules to direct activation of MAPK and PI3K pathways. Unfortunately, EGFR and its family members are commonly hyperactivated in several cancers including non-small-cell lung cancer and breast carcinoma. This leads to uncontrolled receptor clustering and dysregulated protein recruitment to hyper-activate cell proliferation and survival—necessary processes for tumorigenesis. However, the spatiotemporal recruitment and organization of downstream adaptor molecules to these EGFR signaling clusters during both physiological and oncogenic signaling remains poorly understood. Recently, it has been demonstrated that many transmembrane receptors, including EGFR, can undergo phase separation to form micron-sized biomolecular condensates on the plasma membrane. These condensates concentrate adaptor proteins and signaling molecules and can alter signaling dynamics. Whether phase separation influences signaling downstream of EGFR-family receptor condensate formation remains unclear. Therefore, we hypothesize unique combinations of EGFRs and adaptor proteins GAB1 and GRB2 yield distinct variation in phase separated condensate kinetics and characteristics. To systematically determine how specific adaptor proteins influence EGFR condensate kinetics and characteristics, we use *in vitro* biochemical reconstitution and TIRF microscopy. We purified and fluorescently labelled recombinant proteins. We attached the intracellular domain of EGFR to a supported lipid bilayer and image with TIRF microscopy and induced clustering and phase separation by adding cytosolic adaptor proteins. We predict that adding different concentrations of GRB2 and GAB1 can induce EGRF clustering and phase separation. Experiments are ongoing to quantify the kinetics of condensate formation, the

material properties of condensates, and the composition of condensates. From these experiments, we will determine if EGFR phase separation, and potentially downstream signaling, can be modulated by the recruitment of different adaptor proteins.

Structural insights into extracellular TAM receptor tyrosine kinase organization

C. Starbird, K. Ferguson; Yale University, New Haven, CT, CT.

TAM receptors are a clinically important and mechanistically under-studied receptor tyrosine kinase (RTK) subfamily. These receptors have a vital role in maintaining cellular homeostasis through the clearance of apoptotic cells and control of inflammatory and immune responses. Linked to their important regulatory roles, dysregulation of TAM receptors is implicated in numerous disease states including cardiovascular disease, hereditary blindness, infertility, autoimmune disorders, chronic inflammation and cancer. In addition, TAM receptor mediated signaling pathways can be hijacked by viruses to gain entry into host cells. While there is growing interest in TAM receptors as therapeutic targets, their multiple roles in homeostatic processes create challenges for developing therapeutic strategies. Understanding TAM receptor activation mechanisms is important for further investigation of the potential development of targeted therapies. While these receptors are commonly believed to be activated through classical receptor-induced dimerization, there are no current studies that confirm this activation mechanism applies for TAM receptors and preliminary work suggests alternative mechanisms may be possible. My work utilizes a combination of structural, biophysical and biochemical approaches to investigate TAM oligomerization and cross-talk with other receptors, and here I will present early structural analysis of TAM receptors and intriguing similarities to cell-cell adhesion molecules and receptors that are involved in higher order oligomerization or clustering. Furthermore, my presentation will introduce some of the future goals of my new lab, which officially opens in February of 2023.

B489/P2164

Expression of non-receptor tyrosine kinase RNAs in the mature sea star egg.

D. A. Alcázar[1], A. Whetzel[2], D. J. Carroll[2,3]; [1]College of Graduate Studies, Midwestern University, Glendale, AZ, [2]Department of Biochemistry and Molecular Genetics, Midwestern University, Glendale, AZ, [3]Arizona College of Osteopathic Medicine, Midwestern University, Glendale, AZ.

In Patiria miniata, the increase of calcium at fertilization activates the egg resulting in the permanent block to polyspermy and the re-initiation of the cell cycle. In some animals, Src-family kinases (SFK3, SFK1) play a role in this signal transduction pathway by activating PLCγ via tyrosine phosphorylation. Since non-receptor tyrosine kinases (NRTK) play a major role in multiple signal transduction pathways that are regulated by tyrosine phosphorylation events, the objective of this project is to identify other NRTK mRNAs that are expressed in the sea star egg by examining orthologs of known NRTKs in the P. miniata mature egg transcriptome (NCBI BioProject PRJNA398668). Common NRTK families include Src, Csk, Syk, Tec, Jak, Fak, Abl, Fes, Frk, and Ack. The human orthologues for each NRTK were used as target sequences to identify sea star RNAs encoding putative NRTK proteins utilizing the National Center for Biotechnology Information (NCBI) tblastn software. The putative proteins were predicted using ORFinder followed by blastp against the NCBI non-redundant protein database. Sea star orthologues were identified in 9 out of 10 NRTK families queried, with varying degrees of similarity. The percent identity between putative sea star protein and human orthologue can be as high as 68.52% as seen in

Alb1 and Abl2, which are known to play a key role in cellular growth and survival. There were multiple NRTK open-reading frames discovered to share 100% identity with the putative sea star proteins searched, such as Src and Abl1/2. Other NRTK open-reading frames were seen to maintain a high percentage of identity as well. No orthologue was identified for the vertebrate Frk protein. Expression of each sea star RNAs will be confirmed using RT-PCR on newly isolated sea star egg mRNA. Future experiments will be focused on determining if any of these NRTK proteins play a role at fertilization, including confirming the expression of these NRTK proteins in the mature sea star egg via western blotting.

Signaling from the PM/cytoplasm to the Nucleus

Activating the cAMP pathway promotes NF-κB and TNF-α expression in LPS-treated Schwann Cells

C. Henry, P. Kimmel, M. Wilcox, A. Asirvatham; Misericordia University, Dallas, PA.

Schwann cells have been found to play a critical role in neuron repair following peripheral nerve injury. During nerve injury, the myelin sheath becomes damaged, stimulating Schwann cells to secrete cytokines and initiate an inflammatory response. This recruits immune cells to the site of injury so that the myelin debris can be cleared. Neuronal growth is then facilitated by heregulin and an unknown growth factor that stimulates the cAMP pathway. Although it is clear Schwann cells play a role in nerve repair, there is still yet to be known regarding the exact mechanisms by which they do so. One potential mechanism is via the nuclear factor kappa B (NF-κB) pathway. Lipopolysaccharide (LPS), a cell wall immunostimulatory component of Gram-negative bacteria, can be used to activate the NF-κB pathway and stimulate the production of inflammatory mediators, like tumor necrosis factor alpha (TNF-α). Preliminary studies on Schwann cells treated with different concentrations of LPS at various time points revealed that lower doses promoted cell growth compared to higher concentrations. To further explore the effects of LPS on cell proliferation, the role of NF-κB and TNF-α secretion were examined. It was hypothesized that cells treated with LPS and growth factors will express less NF-κB and TNF-α than cells treated with LPS only. Cells from the immortalized S16 cell line were treated with or without 1 µg/mL of LPS for 3 hours without growth factors (control media, N_2), 12.5 ng/mL heregulin (H), 2 µM forskolin (F), or H+F. Using immunoblotting, NF-κB expression, as measured by densitometry analysis and expressed as a percent control, was higher in LPS-treated cells than in unstimulated cells. Surprisingly, NF-κB expression was higher in LPS-treated cells with H, F, or H+F (1500%, 1243%, and 1557%, respectively) than without growth factors (526%). The increase in NF-κB expression for the LPS-treated cells was accompanied by an increase in TNF-α expression. As expected, TNF-α expression was highest in LPS-treated cells without growth factors (444%) and lowest in untreated cells with F or H+F (34% and 70%, respectively). In summary, it appears as though 1 ug/mL of LPS and growth factors may act synergistically to upregulate NF-κB while downregulating TNF-α expression. These findings suggest that, during nerve injury, there may be some crosstalk between the cAMP and NF-κB pathways in Schwann cells. Therefore, a better understanding of these pathways may reveal a therapeutic target for the treatment of nerve injury and inflammation.

B491/P2166

Creatine treatment upregulates AKAP149 and creatine kinase expression in S16 Schwann cells.

P. Kimmel, C. Henry, M. Wilcox, A. Asirvatham; Misericordia University, Dallas, PA.

Creatine is an important component of the high-energy phosphate transfer, and is primarily involved in cellular metabolism to regulate levels of ATP. This high-energy phosphate transfer from creatine is facilitated by creatine kinase in the mitochondria. The functions of creatine supplementation are well studied in the muscular and skeletal system; however, the role of creatine in stimulating Schwann cell growth is relatively unknown. Schwann cell growth in vitro is facilitated by heregulin, a neuronal growth factor, and forskolin, a pharmacological agent that activates the cyclic AMP/protein kinase A (PKA) pathway. Anchoring of the cAMP dependent PKA in the mitochondria is accomplished by AKAP149, a scaffolding protein that coordinates multiple signaling proteins. Preliminary studies have shown that incubation of Schwann cells with creatine at a concentration of 2µM, or 20µM stimulated significant proliferation. To explore the expression of AKAP149 and creatine kinase in Schwann cells, it was hypothesized that these proteins would be up-regulated when cells are treated with increasing concentrations of creatine. Furthermore, the expression of AKAP149 and creatine kinase will be increased when the cAMP pathway is stimulated. Immortalized S16 Schwann cells were treated with no growth factors (control media N2), heregulin (12.5ng/mL), forskolin (2µM), heregulin plus forskolin (H+F) and various doses of creatine at 2 or 20 µM, for 1, 3, or 6 hours. Densitometry data generated from Western blots revealed that 2µM creatine treatment for 6 hours combined with forskolin increased both AKAP 149 (214.3%) and CRK (716.9%) expression in comparison to control and other treatments. Furthermore, cells treated with forskolin and 20µM creatine exhibited a synergistic expression of CRK (5448.7%) in contrast to control (143.2%) and mitogen-stimulated cells (H: 89.7%, H+F: 15.4%). Surprisingly, cells stimulated with 20µM creatine under control conditions revealed an increase in AKAP149 expression (278.29%) in comparison to unstimulated cells (H: 30.67%, H+F: 71.77%). These results suggest that creatine treatment augments AKAP149 and CRK expression in the process of Schwann cell growth. Furthermore, AKAP149 as a scaffolding protein may play a role in coordinating creatine kinase with other signaling proteins to regulate cellular concentrations of ATP.

B492/P2167

Creatine attenuates the effect of LPS treatment in S16 Schwann cells

M. Wilcox, C. Henry, P. Kimmel, A. Asirvatham; Misericordia University, Dallas, PA.

Schwann cells are found in the peripheral nervous system and form the myelin sheath that wraps around axons to protect the nerves. Schwann cell growth is regulated by heregulin, a neuronal growth factor, and an unknown mitogen that activates the cAMP pathway. When neurons are injured, inflammation ensues and Schwann cells change their phenotype to begin dividing, which allows remyelination of the neuron. However, the pathways regulating remyelination are not well known. In vitro, the exposure of Schwann cells to lipopolysaccharide (LPS), a bacterial endotoxin, simulates an inflammatory environment. Preliminary observations have shown that creatine, a compound involved in storage of cellular energy, stimulates Schwann cell proliferation, whereas LPS at high doses inhibits cell growth. Based on these observations, it was hypothesized that the addition of creatine to Schwann cells treated with LPS will have higher rates of growth in comparison to cells incubated without creatine. Schwann cells were incubated at a density of 35,000 cells/well in a 96 well plate and treated with control media (N2), heregulin (H), forskolin (F), a pharmacological activator of cAMP, or H+F. The

mitogen-stimulated cells were then incubated with creatine at a concentration of either 2µM or 20µM and LPS at a dose of 500ng, 1µg, or 10µg for 6 hours. Using the MTT viability assay, cell proliferation was calculated by measuring the optical density and then expressed as percent control. The addition of 20µM creatine to the mitogen-stimulated cells elicited an increased cell growth for H (222.8187±44.3188%), and H+F (243.2414±27.4556%) but not F (232.3024±26.7549%) when compared to cells incubated without creatine (H: 116.5053±11.5595%, H+F: 143.8382±25.9536%, F: 252.7071±101.4468%,). Meanwhile, Schwann cells treated with 10µg LPS and growth factors revealed a decrease in proliferation (H: 108.7881±4.9824%, F: 125.3875±3.3548%, H+F: 115.3533±11.9785%). However, addition of 20µM creatine to LPS-treated cells revealed an increase in proliferation for H (256.5137±47.6774%), F (151.7791±20.4877%) and H+F (213.8792±39.8517%). Based on these observations, it was concluded that a dose of 20µM creatine stimulated cell proliferation, treatment with LPS caused a dose-dependent decrease in cell growth, and Schwann cell recovery caused by the addition of creatine after LPS treatment was dependent on the concentration of creatine. Overall, creatine appears to help Schwann cell viability by providing sufficient energy for cells to recover after LPS treatment.

Protein Interactions Identification of Myocardin-Related Transcription Factors A and B Mechanosensitive Transcriptional Cofactors in Prolonged Cultured Hepatocytes

A. Jiménez-Escobar, G. Vázquez-Victorio; Micro and Nanotechnology Laboratory, Facultad de Ciencias, Universidad Nacional Autónoma de México, Mexico City, MEXICO.

The liver is a fundamental organ for the human homeostasis due to the continuous performance of some vital processes mainly made by hepatocytes. They have a unique polarity generated by intracellular lumen (canaliculi) and sinusoidal extracellular matrix (ECM) interactions. Intercellular forces and ECM properties change in some pathologies such as fibrosis where the stiffness and collagen I deposits increase substantially. Stiffness and loss of polarity are associated with the loss of the hepatocytes phenotype in vitro together with alterations in their metabolic functions, as a consequence. Myocardin-related transcription factors a and b (MRTF-A/B) are transcriptional cofactors involved in cytoskeleton dynamics because of the downstream activity of their target genes. They are also controlled by the cytoskeleton as well. Specifically, they are negatively regulated by the actin polymerization as a result of their RPEL domain interaction with G-actin. Also, these cofactors have other protein domains that allow them to interact with other proteins like ERK and FHL2, which affect MRTF-A/B activity positively and negatively, respectively.

It has been shown that MRTF-A/B are physiologically active in the liver and that they are also involved in liver fibrosis, mostly due to their role in hepatic stellate cells activation. However, it is unknown their role in hepatocytes as well as its regulation by their different interactions. Therefore, to elucidate this problem, the aim of this work is to detect protein interactions of MRTF/A-B of primary fresh hepatocytes and on long-term culture.

We have found a noticeable MRTF-A/B upregulation on stiff and long term cultured hepatocytes. There is a nuclear accumulation of MRTF-A/B in primary hepatocytes in a time dependent manner, however MRTF-B was slightly more cytoplasmic retained even at 72 h of culture. Similarly, stiffness also caused the increase in the MRTF-A/B nuclear accumulation, and it was more accentuated for MRTF-A even. It probably reflects differences in their regulation, as a consequence of modifications in their protein interactions. To clarify this, immunoprecipitations of MRTF-A/B were performed in order to characterize

known interactions, like SRF and actin, in order to detect novel interactions with MS/MS. The results obtained in this project highlights the activity of MRTF-A/B in hepatocytes and points up the relevance of searching the regulatory mechanisms of MRTF-A/B in hepatocytes.

ER stress promotes REDD1-dependent NF-kB activation and increased inflammatory cytokine expression in the heart

M. K. Gonzalez Aguiar, S. A. Stevens, S. Sunilkumar, A. L. Toro, M. D. Dennis; Penn State College of Medicine, Hershey, PA.

Heart failure is the leading cause of mortality and morbidity in patients with diabetes and obesity. Endoplasmic reticulum (ER) stress and inflammation are hallmarks of myocardial impairment, and interplay between these stress response pathways contributes to disease progression. Here, we investigated a role for the stress response protein regulated in development and DNA damage response 1 (REDD1, also known as DDIT4/RTP801) as a molecular link between ER stress and pro-inflammatory signaling in cardiomyocytes. In the hearts of obese mice fed a pro-diabetogenic diet (42% kcal fat, 34% sucrose by weight), REDD1 mRNA and protein expression was increased as compared to littermates fed a control chow. In coordination with the increase in REDD1 expression in heart of obese mice, markers of ER stress and expression of the pro-inflammatory cytokine IL-1β were upregulated. When human AC16 cardiomyocytes were exposed to thapsagargin to promote ER stress, expression of REDD1 and IL-1β were increased. ER stress was also sufficient to enhance activity of the transcription factor NF-κB in wild-type HEK293 cell cultures, whereas REDD1 deletion prevented the effect. REDD1 deletion also reduced IL-1β expression and macrophage infiltration in the hearts of obese $REDD1^{-/-}$ mice fed a pro-diabetogenic diet, as compared to $REDD1^{+/+}$mice. Overall, the results support a model wherein ER stress contributes to the development of chronic inflammatory response in cardiomyocytes by promoting REDD1-dependent NF-κB activation.

GLI phase separation for Sonic Hedgehog pathway regulation

S. Row[1], D. Stewart[1], P. A. Umberger[2], S. Ogden[1]; [1]Cell and Molecular Biology, St Jude Children's Research Hospital, Memphis, TN, [2]CMB and Integrated Biomedical Sciences Program, University of Tennessee Health Science Center, Memphis, TN.

The GLI family of transcription factors (GLI1, 2, and 3) are effectors of the Hedgehog (HH) signaling pathway, which directs tissue morphogenesis and homeostasis through induction of precise transcriptional programs. Dysregulation of HH signaling can lead to developmental disorders and cancers including basal cell carcinoma, medulloblastoma, and rhabdomyosarcoma. In the absence of the HH ligand, the transcriptional effectors GLI2/3 are targeted for proteolytic cleavage into truncated repressor forms. Binding of HH to the receptor Patched (PTCH) activates the pathway by inducing PTCH internalization and degradation, thus allowing the signal transducer Smoothened (SMO) to signal to stabilize GLI2/3 in their full-length active forms. Active GLI2/3 translocate to the nucleus and initiate transcription of target genes including *Ptch* and *Gli1*, which drive negative and positive feedback loops, respectively. The E3 ubiquitin ligase substrate adaptor protein Speckle Type BTB/POZ Protein (SPOP) targets GLI2/3 in the nucleus for ubiquitination and subsequent degradation, effectively limiting the transcriptional response. Although the fundamental steps of how HH signal transduction regulates GLI2

in the cytoplasm are established, the details regarding organization and regulation of GLI2 activity in the nucleus have yet to be resolved. GLI proteins have a conserved and structured central zinc finger (ZF) motif flanked by amino- and carboxyl- terminal unstructured domains. The presence of intrinsically disordered regions (IDRs) is sufficient to drive phase transition of proteins in cells. We previously reported that GLI3 enters into SPOP-containing nuclear biomolecular assemblies with Liquid-liquid phase separation (LLPS) characteristics. Herein, we examine LLPS behavior of GLI2 and show that it demonstrates distinct assembly behaviors in the absence and presence of SPOP.

New View on Information Processing with pH Dynamics Regulating Transcription Factor-DNA Binding Selectivity

K. Kisor, D. L. Barber; University of California, San Francisco, San Francisco, CA

Intracellular pH (pHi) dynamics regulates myriad cell behaviors, including proliferation, migration, cytoskeleton and adhesion remodeling, stem cell differentiation, and transformation, which makes it integral in information processing. We previously identified pH sensitive proteins mediating many of these cell behaviors with pH regulated kinase activity, protein-protein and protein-phospholipid binding. Whether pH regulates protein-nucleotide binding for established effects of pHi dynamics on gene expression, however, remains unknown. We identified at least 65 transcription factors in diverse families that have a conserved histidine, which in available structures forms hydrogen bonds with DNA nucleotides. With the ability of histidine to titrate in the cellular pH range, electrostatic principles of protein-nucleotide hydrogen bonds, and nuclear and cytoplasmic pH being similar, we predicted that transcription factors with histidine-nucleotide hydrogen bonds could have pH regulated DNA binding selectivity. All FOX family transcription factors contain a conserved histidine in their DNA-binding domain (DBD) that in available structures forms hydrogen bonds with nucleotides**.** We confirmed pH regulates DNA binding of FOXM1 and FOXC2 DBDs using fluorescence anisotropy and a canonical FkhP DNA motif for binding to a thymine, with higher affinity at pH 7 compared with 7.5. This finding is consistent with thymine being a hydrogen bond acceptor and binding a protonated histidine. We confirmed the significance of histidine with a mutant FOXC2-His122K, with lysine mimicking a protonated residue with pKa > 12, that had high affinity but pH independent binding and a mutant FOXC2-H122N recurring in cancers that had low affinity pH independent binding. We also confirmed pHi regulates FOXC2 activity in cells. Using MDA-MB-436 cancer cells with a high pHi of 7.7 and a luciferase assay we found increased transcriptional activity for an FkhP motif when pHi was lowered to 7.4 with EIPA, an inhibitor of the proton-extruding NHE1. Our data identify pH dynamics as a previously unrecognized regulator of DNA-binding selectivity for FOXM1 and FOXC2. This regulatory mode has broad significance because histidine-DNA nucleotide binding is also reported for most transcription factors in the SOX family, all members of the MITF/Myc family, and selective members of STAT and ETS families.

B497/P2172

Mechanistic study for mTORC1-dependent regulation of the lysosomal and autophagic transcription factor TFEB

Z. Cui[1], G. Napolitano[2], M. E. G. de Araujo[3], L. A. Huber[3], A. Ballabio[2,4], J. H. Hurley[1]; [1]University of California, Berkeley, Berkeley, CA, [2]Telethon Institute of Genetics and Medicine (TIGEM), Naples, Italy, [3]Medical University of Innsbruck, Innsbruck, Austria, [4]Baylor College of Medicine, Houston, TX

The transcription factor TFEB is a master regulator of lysosomal biogenesis and autophagy. The phosphorylation of TFEB by the mechanistic target of rapamycin complex 1 (mTORC1) is unique in its mTORC1 substrate recruitment mechanism, which is strictly dependent on the amino-acid-mediated activation of the RagC GAP FLCN. TFEB lacks the TOR signaling (TOS) motif responsible for the recruitment of other mTORC1 substrates. We used cryo-electron microscopy (cryo-EM) to determine the structure of TFEB as presented to mTORC1 for phosphorylation. Two full Rag-Ragulator complexes present each molecule of TFEB to the mTOR active site. One Rag-Ragulator complex is bound to Raptor in the canonical mode seen previously in the absence of TFEB. A second Rag-Ragulator complex (non-canonical) docks onto the first via a RagC GDP-dependent contact with the second Ragulator complex. The non-canonical Rag dimer binds the first helix of TFEB in a RagCGDP-dependent aspartate clamp in the cleft between the Rag G domains. Mutation of the clamp drives TFEB constitutively into the nucleus whilst having no effect on mTORC1 localization. The remainder of the 108-amino acid TFEB docking domain winds around Raptor and then back to RagA. This structure presents the phosphorylatable Ser residues of TFEB to the mTORC1 active site in a suitable geometry for their phosphorylation. The double use of RagC GDP contacts in both Rag dimers explains the strong dependence of TFEB phosphorylation on FLCN and the RagC GDP state.

The ubiquitin ligase HUWE1 potentiates WNT/β-catenin signaling through a mechanism mediated by APC, AXIN1 and GSK3A/B that is independent from the control of CTNNB1 stability

J. K. McKenna, Y. Wu, P. Sonkusre, **A. M. Lebensohn**; National Cancer Institute, National Institutes of Health, Bethesda, MD

The WNT pathway is a cell signaling system involved in patterning and morphogenesis during embryonic development, and in maintenance and regeneration of adult tissues in all animals. Defects in WNT signaling lead to many severe developmental abnormalities and adult-onset diseases, including many types of cancer. The WNT/β-catenin pathway is a branch of WNT signaling mediated by the transcriptional co-activator β-catenin (CTNNB1). During WNT/β-catenin signaling, the regulated accumulation and nuclear translocation of CTNNB1 drives the expression of WNT target genes, which execute diverse cellular programs. In the absence of WNT ligands, phosphorylation of CTNNB1 by the so-called 'destruction complex' (DC), a multi-protein assembly composed of several scaffolds and kinases, targets it for ubiquitination and proteasomal degradation. Binding of WNT ligands to their co-receptors disrupts the activity of the DC, preventing further CTNNB1 degradation. CTNNB1 accumulates in the cytoplasm and is translocated into the nucleus, where it drives transcription of WNT target genes. Through comparative genetic screens in haploid human cells, we previously identified HUWE1 as a potent positive regulator of the WNT/β-catenin pathway. HUWE1 is a ubiquitin ligase that regulates dozens of cellular processes. Surprisingly, the contribution of HUWE1 to WNT/β-catenin signaling was only evident when the pathway was hyperactivated by loss of the DC kinase casein kinase 1α (CSNK1A1), but not by loss of the DC scaffold adenomatous polyposis coli (APC). These results were striking because CSNK1A1 and APC have a shared function in the DC controlling CTNNB1 protein stability, and therefore loss of either CSNK1A1 or APC would be expected to have the same effect on signaling. However, the differential contribution of HUWE1 to WNT/β-catenin signaling in cells lacking CSNK1A1 or APC suggested additional, unique functions for CSNK1A1 or APC. Genetic interaction analyses and a novel 'suppressor of suppressor' genetic screen revealed the reason for these paradoxical results: a subset of

DC components, including AXIN1, APC and glycogen synthase kinase 3α or β (GSK3A/B), but excluding CSNK1A1 and AXIN2, are required for HUWE1 to potentiate WNT/β-catenin signaling. Furthermore, HUWE1 promotes WNT/β-catenin signaling through at least two distinct mechanisms, one that increases CTNNB1 protein abundance, and another that is independent from the control of CTNNB1 stability. These results reveal a new role for AXIN1, APC and GSK3A/B in mediating WNT/β-catenin signaling through HUWE1, distinct from their established activity controlling CTNNB1 stability as part of the DC. The implications of these findings for the many cellular processes regulated by WNT/β-catenin signaling remain to be elucidated.

Soluble Cyclase-mediated Nuclear cAMP Synthesis is Sufficient for Cell Proliferation

A. Pizzoni, X. Zhang, N. Naim, D. Altschuler; University of Pittsburgh, Pittsburgh, PA

G-protein coupled receptors (GPCRs) are the largest family of mammalian receptors accounting for one-third of the targets of current market drugs. Gs-coupled GPCRs that signal through cAMP, representing half of these GPCR-targeted drugs, are involved in many physiological and pathophysiological conditions. While cAMP was classically considered to originate solely from the plasma membrane (PM), this view was recently challenged by results demonstrating that GsPCRs can sustain cAMP signaling from an internalization-dependent intracellular compartment. Importantly, this second cAMP wave was strictly associated with nuclear PKA translocation, cAMP diffusion into the nucleus, and activation of nuclear transcriptional events responsible for triggering specific biological responses. We will discuss new data showing that GsPCRs trigger an internalization-dependent accumulation of nuclear cAMP unexpectedly mediated solely by local soluble adenylyl cyclase (sAC) activation, rather than cAMP diffusion from the cytosol. Both pharmacological and genetic sAC inhibition, which did not affect the cytosolic cAMP levels, completely blunted nuclear cAMP accumulation, PKA activation, and cell proliferation, while an increase in sAC nuclear expression significantly enhanced cell proliferation. Utilizing novel compartment-specific optogenetic actuators we showed that light-dependent nuclear cAMP synthesis stimulates PKA and CREB triggering cell proliferation. Our results indicate that neither PKA translocation nor cAMP diffusion, but rather nuclear sAC activation represents the rate-limiting step for nuclear PKA activation and downstream events leading to cAMP-dependent proliferation. Thus, sAC-mediated nuclear cAMP accumulation is not only necessary but sufficient for cell proliferation. In the context of these and new unpublished data, we will discuss a new three-wave model of cAMP signaling. Our model proposes that after GPCR-mediated adenylyl cyclase (AC) activation at the PM (first cAMP wave) and the internalization of the signaling complex that continues to signal from intracellular membranes (second cAMP wave), an intermediate factor is synthesized or mobilized. Unlike cytosolic cAMP, this factor can enter the nucleus and activates the local sAC which generates a third cAMP wave that controls cell proliferation.

Analysis of the mechanism of filopodia-based WNT1 Transport

A. M. Villegas-Parra, L. Gallli, L. Burrus; San Francisco State Univeristy, San Francisco, CA.

Wnt gradients regulate cell proliferation and differentiation during embryonic development and adult homeostasis. Uncontrolled production and transport of Wnt proteins can disrupt the Wnt signaling pathway, particularly in cancerous cells. Though much is known about the downstream mechanism of

how Wnt signals are received, less is understood about Wnt gradient production and transport. The production of Wnt ligands requires lipid modification by the acyltransferase Porcupine (PORCN) followed by the binding of Wntless (WLS), a cargo transporter that facilitates Wnt transport from the endoplasmic reticulum to the plasma membrane. Proposed models that explain how lipid-modified Wnts are transported from the producing cell to the receiving cell include diffusion, exosomes, and filopodia. Data from our lab showed that the incubation of Wnt-producing cells with Wnt/β-catenin reporter cells induced over 100-fold more signaling than did the Wnt-conditioned media, suggesting that cell contact is critical for Wnt signaling. Our observation that co-expression of WNT1 with WLS, increases signaling activity, relocalizes WNT1 to the cell membrane, and induces new filopodia projections, further suggests that Wnts could be transported by filopodia, which then contact target cells. As IRSp53, Cdc42, and Ror2 have been implicated in filopodia formation, **I hypothesize that the inhibition of either of these proteins in cells overexpressing WNT1 and WLS will cause a reduction in Wnt signaling.** To test this hypothesis, I created and expressed IRSp53_4k, Cdc42_T17N, and DN Ror2 mutant constructs along with WNT1 and WLS in HEK293T cells. I then measured Wnt signaling activity using a TopFlash luciferase-based assay. I found that none of the inhibitory proteins significantly decreased WNT1 signaling activity. While doing these experiments, we found that WLS promotes the signaling activity of WNT1, but not its so-called functionally redundant sister, WNT3A. Following this differential result, I am assessing differences in the binding of WNT1 and WNT3A to WLS using computational and experimental methods. My findings suggest that neither IRSp53, Cdc42, nor Ror2 appears to be required for WNT1 signaling. Ongoing research includes identifying proteins involved in filopodia induction that are required for Wnt signaling and understanding potential differences in the interaction between WLS and different Wnts.

Why is glucose-stimulated insulin secretion so glucose specific?

F. Firdos[1], T. Pramanik[1], A. Mittal[1,2]; [1]Indian Institute of Technology Delhi, Delhi, India, [2]Indian Institute of Technology, Delhi, Delhi, India

Inability to produce and/or secrete insulin by pancreatic β-cells results in disorders such as Type 1 diabetes in animals. Despite ~50 years of literature on Type 1 diabetes and establishment of Mouse Insulinoma 6 (MIN6) cells (~32 years ago) as an *in vitro* model system for studying glucose-stimulated insulin secretion (GSIS) in pancreatic β-cells, a careful dissection of the roles of glucose molecules distinctly serving as nutrients and as ligands in GSIS is missing. Prevalent views relate ATP generated from glucose metabolism to GSIS; however, this logic fails in absence of GSIS-like regulation of insulin secretion by ATP from other intracellular sources. Interestingly, glucose transport (outside to inside cells) is reported as 10 to 100-fold higher than intracellular phosphorylation of glucose in pancreatic β-cells. There is a surprising absence of literature on the internalized, but non-phosphorylated, glucose. This indicates that glucose not only works as an extracellular stimulator and nutrient but also must have some specific, yet undiscovered, intracellular role(s) in modulating GSIS. In this work, we analyzed differential gene expression in MIN6 cells, exposed to low and high extracellular-glucose-concentrations (EGC), from whole transcriptome data (55467 distinct transcripts of which 14427 were identified as successfully expressed genes). Other than *Gapdh* (downregulated) and *Atp6v0a4* & *Cox20* (upregulated), expression of 154 genes involved in Glycolysis, TCA cycle, and electron transport chain were found to be unaffected by EGC - indicating that glucose consumption as a nutrient is independent of EGC in GSIS. Overall, we found 75 upregulated and 78 downregulated genes at high EGC. Of these, only 3

upregulated genes (*Atp6v0a4, Cacnb4, Kif11*) were identified to have any association with cellular secretion. ATP6V0A4 is required to acidify secretory vesicles, CACNB4 is involved in β-cell insulin secretion, and, KIF11 is a motor protein involved in vesicular transport. Identification of these 3 molecules, in the specific context of GSIS, allowed for directly testing a hypothesis of intracellular glucose molecules serving as a ligand for them. We report strong evidence for glucose binding ability of ATP6V0A4, CACNB4 and KIF11, thereby providing a possibly remarkable discovery of a direct role of intracellular glucose molecules in GSIS for the first time.

B502/P2177

Molecular mechanisms of ADAM17 regulation by iRhom2 in cell signalling

F. Lu, B. Sieber, M. Freeman; University of Oxford, Oxford, United Kingdom

The rhomboid-like protein iRhom2 is an essential regulator of ADAM17, a metalloprotease which cleaves and releases vital signalling molecules and therefore is significantly implicated in cancer and inflammatory diseases. However, the links between iRhom2 and cancer and the molecular mechanisms of ADAM17 activation by iRhom2, are unclear. Here, using a xenograft model, we have established a central role for iRhom proteins in lung tumour cell growth. I also performed a systematic characterisation of a series of cancer-causing mutations (tylosis and oesophageal cancer, TOC) in iRhom2 and found that TOC mutations in iRhom2: 1) potentiate oncogenic KRAS induced ADAM17 activity, 2) confer a growth advantage in KRAS-driven A549 lung cancer cells, and 3) mediate a positive feedback loop in the KRAS signalling pathway. To further investigate the molecular mechanism, combining a biochemical, cell biology and mutagenesis approach, I have identified residues in iRhom2 which are key to its regulation of ADAM17 and I propose a novel model of this regulation. Overall, these findings shed light on the fundamental mechanism of how iRhom2 regulates ADAM17 and its contribution to cancer signalling.

B503/P2178

MALT1 localizes to an aggresome-like structure and sustains NF-κB activation, with limited turnover in T-lymphocytes.

I. Hussain[1], M. Traver[2], L. Campanello[3], C. Huaman[1], S. Paul[4], H. Shriff[2], W. Losert[3], B. Schaefer[1]; [1]Uniformed Services University, Bethesda, MD, [2]National Institutes of Health, Bethesda, MD, [3]University of Maryland College Park, College Park, MD, [4]The Johns Hopkins University, Baltimore, MD

MALT1 and BCL10 are both critical molecular adaptors for T cell receptor (TCR)-dependent NF-κB activation. Shortly after TCR-ligation, BCL10-MALT1 heterodimers cluster to form filament-like structures called POLKADOTS, cytosolic complexes that recruit and activate NF-κB signaling intermediates. Previous work demonstrated that in TCR-activated effector T cells, BCL10 is degraded following POLKADOTS formation, whereas MALT1 levels remain stable over time. Using confocal and super-resolution microscopy, we show that, in activated effector T cells, multiple diffused MALT1 clusters are transported to a perinuclear aggresome-like structure, which is enclosed by a characteristic vimentin cage and near the microtubule-organizing center (MTOC). MALT1 clustering at the aggresome-like structure peaks at 60-90 minutes post-TCR activation and remains stable for at least another hour before beginning to dissociate. Using pharmacological disruption, we demonstrate that the transport and focal accumulation of MALT1 clusters is dependent on microtubules and dynein. By employing a genetic approach, we show that trafficking of MALT1 clusters to the aggresome-like structure is dependent on the autophagy

adapters p62 and NBR1. Surprisingly, however, this focal accumulation of MALT1 is not dependent on expression of HDAC6, suggesting that this structure is not a canonical aggresome. Finally, the trafficking and focal accumulation of MALT1 clusters is necessary to continue signaling to NF-κB by enhancing MALT1 paracaspase activity and promoting persistence of coalesced phospho-IKK complexes. This work highlights two novel findings: 1) MALT1-IKK clusters play a role in extended maintenance of TCR-dependent NF-κB activation and 2) rather than serving as a depot of protein awaiting degradation, the MALT1 aggresome-like structure forms in an HDAC6-independent manner and actively transduces TCR signals.

An in silico investigation of the novel therapeutic targets and cellular pathways against brefeldin a and tunicamycin c in colon cancer

V. Naidoo[1], J. Kandhavelu[2], R. Hull[3], S. Mirza[1], C. Penny[1]; [1]University of Witwatersrand, Johannesburg, South Africa, [2]Georgetown University, Washington, WA, [3]University of Pretoria, Johannesburg, South Africa

BackgroundColorectal cancer (CRC) is a prevalent cancer in South Africa, with a high mortality rate. Glycosylation is an important post-translational modification that plays a role in the development and progression of CRC. The nucleoside antibiotic Tunicamycin C (TunC), inhibits glycoprotein synthesis, reduces proliferation, migration, and invasion of colon cancer cells; while Brefeldin A (BFA) a lactone antiviral, inhibits protein transport from the endoplasmic reticulum to the Golgi complex.**Objective**As both drugs have potential in cancer therapy, using computational approaches, this study assesses the role of these glycosylation inhibitors in cancer signalling pathways and identifying key proteins associated with CRC.**Methods**Using the in silico HTDocking program (www.ebi.ac.uk/chebi/; Chemical Entities of Biological Interest), potential targets were mapped for TunC and BFA. Following this, GO was used for gene ontogeny searches, while both Wiki and KEGG were used for pathway searches to identify their molecular biological role/s in CRC.**Results**With a docking stringency score of 7, this analysis revealed 234 and 168 targets for BFA and TunC, respectively. Pathway analysis showed that Tunicamycin may regulate important signalling pathways, such as gastrin signalling (CDC42, PAK1, SRC, KIT, PPARG, FYN, RAC1, IL2, EGFR), AGE/RAGE signalling (CASP9, CDC42, SRC, RAC1, IRAK4, MMP9, EGFR), tyrosine kinase and leptin signalling (CDC42, SRC, PDE3B, FYN, RAC1, ESR1), Gastrin signalling is known to stimulate the proliferation, invasion, and migration of cancer cells, while AGE-RAGE signalling is involved with cell death machinery during tumorigenesis. Both BFA and TunC were shown to be involved in regulating pathways involved in other cancers and infection pathways. Currently using 3D modelling, we are evaluating binding interactions of selected key target proteins, SRC, CASP9, RAC1, c-Kit and Nuclear receptor co-repressor 2 (NCOR2), with TunC and BFA, respectively. **Conclusion**In summary, the pathways and targets implicated in the anticancer activity of these drugs may in the future lead to the use of glycosylation inhibitors as therapies for colon cancer

Rho-family GTPases

B505/P2180

Lis1 suppresses RhoC by inhibiting LNX1 mediated non-degrading ubiquitination

S. Kholmanskikh, S. Singh, M. Ross; Weill Cornell Medicine, New York, NY.

Non-degrading ubiquitination (NDU) is widespread and plays important functions in the regulation of Ras superfamily proteins. In this study, we tested whether NDU affects Rho proteins. We found that RhoC, but not RhoA, is subject to NDU mediated by LNX1 and LNX2 E3 ligases. The affected lysine residues are homologous to those targeted by NDU in H-Ras and K-Ras, where this modification impairs binding to a GAP and increases activity of those GTPases. We found that RhoC NDU also leads to an increase in activity, but via a different mechanism, namely inhibition of RhoC-RhoGDI interaction. The LNX1-dependent RhoC NDU is physiologically relevant as shown by increased actin stress fiber formation upon LNX1 overexpression, which is inhibited by RhoC knockdown. Furthermore, we found that Lis1 (aka PAFAH1B1) inhibits LNX1-dependent RhoC activation via direct binding to LNX1, thus providing a long sought molecular link between level of Lis1 and activity of Rho GTPases. RhoC NDU is indeed increased in the brains of *Lis1fl/-* animals. Furthermore, knockdown of RhoC, but not RhoA, rescues the cell spreading defect displayed *in vitro* by *Lis1fl/-* astrocytes. In conclusion, we report a novel mechanism of Rho protein regulation that links Lis1 to the activity of Rho GTPases and showed specificity of this novel pathway toward RhoC. The latter has important evolutionary and therapeutic implications. Both LNX1 and RhoC are vertebrate specific, while Lis1 is present in all eukaryotes. This suggests that Lis1 regulation of Rho GTPases is an evolutionarily new function of an ancient protein. Hyperactivity in the Rho signaling pathway is associated with multiple human diseases including cardiovascular, cancer, and neurodegenerative disorders. Yet, indiscriminate targeting of Rho pathway has been disappointing due to its intolerable side effects. Discovery of a RhoC selective upstream regulatory mechanism provides an opportunity for design of a more targeted way of manipulating Rho signaling to therapeutic benefit.

B506/P2181

Spatiotemporal crosstalk of Rap1A-RhoA GTPases regulates breast cancer cell motility

C. Sanchez, A. Muesch, L. Hodgson; Albert Einstein College of Medicine, Bronx, NY.

During cancer dissemination and metastasis, cells undergo an epithelial-mesenchymal transition (EMT), which induces cell adhesion remodeling and migration that are regulated by p21 family of small GTPases. Rap1A, a member of the Ras subfamily, is aberrantly expressed in a number of breast cancer cell types but a specific role for this isoform in controlling the dynamic balance of cell adhesions and motility has not been elucidated. Here, we identified a pathway regulating the Rap1A-RhoA antagonism, important for breast cancer cell adhesion dynamics and migration. The spatiotemporal coordination and modulation of adhesion structures play essential roles in cancer. The loss of intercellular cadherin contacts drives signals that induce integrin-based focal adhesion and actin cytoskeletal rearrangement leading to cell motility. Since Rap1A and RhoA appear to have an antagonistic role in controlling cell adhesion and motility, elucidating how these two GTPases are coordinating the cell adhesion dynamics and the balance of regulatory cues to produce transient, localized effects is critically important, yet clearly difficult using conventional approaches. Here, we designed new Förster resonance energy transfer (FRET)-based single-chain biosensors, including near-infrared (NIR) FRET biosensor for RhoA and a cyan-yellow FRET biosensor for Rap1A. Importantly, the NIR miRFP670nano1-miRFP720 fluorescent

protein FRET pair allows direct multiplex imaging with our new CFP-YFP Rap1A biosensor with practically zero spectral overlap, enabling simultaneous imaging. The new multiplex FRET imaging approach allowed us to directly visualize and quantify the Rap1A-RhoA coordination during cell motility and adhesion remodeling. Our data show that there is a localized, antagonistic balance, both in space and time, of the activity of Rap1A versus RhoA within both cell-cell and cell-extracellular matrix adhesion structures. Furthermore, the assembly and disassembly of focal adhesion and cell-cell adhesion components have differential, dynamic-dependence on the spatiotemporal regulation of Rap1A activity. Moreover, upstream regulation of Rap1A activity by C3G and SIPA1, Rap1A-GEF and -GAP respectively, has a direct impact on the activity of RhoA at cell adhesion structures and on cell motility. Importantly, we show here that one of the primary functions of Rap1A at these adhesion structures is to recruit and to control the regulators of cytoskeletal RhoA activity to the sites of adhesion remodeling, which in turn, induce actin cytoskeleton rearrangement and cell motility. Our results point to an important molecular pathway of antagonistic crosstalk between Rap1A and RhoA, controlling EMT and cell motility, which is found to be upregulated during early tumor dissemination.

ARHGAP17 regulates the spatiotemporal activity of Cdc42 at invadopodia

G. Kreider-Letterman[1], A. Castillo[1], E. Mahlandt[2], J. Goedhart[2], A. Rabino[1], S. Goicoechea[1], R. Garcia-Mata[1]; [1]University of Toledo, Toledo, OH, [2]University of Amsterdam, Amsterdam, NETHERLANDS.

Cancer cells form actin-rich protrusions called invadopodia that can degrade the extracellular matrix and facilitate tumor invasion and intravasation. Invadopodia, like podosomes, are typically organized with a core region comprised of actin, actin nucleators, and scaffolding proteins, and a surrounding ring comprised of adhesion and adapter proteins. The formation of invadopodia is tightly regulated by the Rho family of GTPases. Rho GTPases function as molecular switches that are turned on by guanine-nucleotide exchange factors (RhoGEFs) and turned off by GTPase-activating proteins (RhoGAPs). However, the molecular mechanisms of RhoGEF and RhoGAP signaling at invadopodia are poorly understood. In particular, almost nothing is known about the role of RhoGAPs at invadopodia. Here, we have identified ARHGAP17, a RhoGAP specific for Cdc42, as a key regulator of invadopodia in breast cancer cells. Using a wide range of fixed and live microscopy approaches, including TIRF, STORM, and Cdc42 sensors, we dissected a novel ARHGAP17-mediated signaling pathway that regulates the spatiotemporal activity of Cdc42 at invadopodia. Our results show that during invadopodia assembly, ARHGAP17 localizes to the invadopodia ring and restricts the activity of Cdc42 to the invadopodia core, where it promotes invadopodia growth. Invadopodia disassembly starts when ARHGAP17 translocates from the invadopodia ring to the core, in a process that is mediated by its interaction with the Cdc42 effector CIP4. Once at the core, ARHGAP17 inactivates Cdc42 to promote invadopodia disassembly. Our results in invadopodia provide new insights into the coordinated transition between the activation and inactivation of Rho GTPases.

B508/P2183

Rhob gtpase function during breast cancer invasion

S. Pagano, L. Hodgson; Albert Einstein College of Medicine, Bronx, NY.

RhoGTPases are molecular switches that cycle between active (GTP-bound) and inactive (GDP-bound) states. RhoGTPases regulate many biological processes, including cell motility and adhesion, and are

essential in both normal and disease physiologies, including cancer progression. RhoB is a close paralog of the canonical RhoA and is an important yet poorly characterized GTPase involved in the endosomal recycling and targeting of cell surface receptors, including integrins and growth factor receptors that are important for tumor invasion and dissemination. Moreover, very few studies to date have highlighted the role of RhoB in breast cancer invasion.Our work focuses on the role of RhoB in cell migration and invasion in breast cancer. We address a hypothesis that RhoB may play a key role in these processes by modulating integrins and membrane receptors at the cell surface. We show that the genetic depletion of RhoB impacts invadopodia functions in mammary adenocarcinoma cells and this appears to be modulated through localized, RhoB-targeting of vesicular structures at invadopodia. Reduction in the functional phenotype of invadopodia upon RhoB depletion did not alter cell invasion through Matrigel coated filters, pointing to a mechanism in which a balance between the extracellular matrix degradation and the cell motility may be regulated by RhoB. We are investigating whether changes in cell motility in response to RhoB depletion could compensate for the reduced matrix degradation at invadopodia. The balance between motility and degradation regulated by RhoB through controlling the endosomal recycling requires activation/deactivation of RhoB to properly target the endosomes. To probe this dynamic of RhoB regulation, we have developed and optimized a FRET based RhoB biosensor to visualize the RhoB activity status in living cells.Our results show an involvement of RhoB in invadopodia regulation and its implication in metastatic dissemination through fine-tuning the balance of matrix degradation and cell motility. It is likely that RhoB may coordinate together with other canonical members of the RhoGTPases to regulate this dynamic balance. Ultimately, our investigations will focus into this dynamic coordination of Rho family GTPases in regulating the invasion and dissemination of tumor cells during metastasis, in which RhoB may play an important yet unidentified role.

Regulation of cell wall integrity in mating *Saccharomyces cerevisiae*

E. Curtis, C. Robertson, D. Lew; Duke, Durham, NC.

To survive in a hypoosmotic environment, yeast cells are surrounded by a cell wall. The wall is remodeled to allow cell growth, which can lead to dangerous wall thinning with potential for catastrophic lysis (Clark-Cotton, Jacobs, and Lew 2022). However, a “Cell Wall Integrity” (CWI) stress response pathway is thought to ensure that the wall remains intact in the face of environmental conditions that threaten wall integrity (Levin 2011; Levin 2005). Nevertheless, when two yeast cells mate, they are able to degrade the intervening cell walls, suggesting that CWI protections are either turned off or over-ridden (Philips and Herskowitz 1997). This study aims to identify whether and how the CWI pathway is regulated during mating in *Saccharomyces cerevisiae*. A key component of the CWI is the kinase Pkc1p, which is activated upon binding to Rho1-GTP at the cell surface (Kamada et al. 1996). Using surface localization of Pkc1 as a reporter of CWI activation, we examined pathway activity during pheromone exposure and mating. We found that Pkc1 was recruited to the polarity site (shmoo tip) in cells exposed to high levels of synthetic pheromone. However, in mating cells Pkc1 was often absent from the polarity site. We observed short visits to the vicinity of the polarity site but Pkc1 localization was much less sustained than it was in shmoos. Expression of an activated Pkc1 mutant delayed the degradation of intervening cell wall during mating. Our results suggest that the CWI pathway is to some degree inactivated in mating cells, presumably to allow cell wall degradation.

MLK3-dependent Membrane Repair against Cholesterol-Dependent Cytolysins is not Activated by Rho-family small GTPases.

V. G. Kayejo, P. A. Keyel; Biological Sciences, Texas Tech University, Lubbock, TX.

Necrotizing soft tissue infections (NSTIs) exhibit a rapid disease progression characterized by substantial local tissue loss, which results in significant morbidity and mortality rates despite optimal treatment. The causative agents of NSTIs are *Streptococcus pyogenes* and *Clostridium perfringens,* which produce the cholesterol-dependent cytolysins (CDCs) streptolysin O (SLO) and perfringolysin O (PFO), respectively. These CDCs are resisted by mammalian membrane repair activated by Mixed-Lineage Kinase 3 (MLK3) and Mitogen-activated protein kinase kinase (MEK) signaling. However, the upstream activator of MLK3 remains unknown, as is the redundancy of MEK1/2 in membrane repair. Here, using selective GTPase inhibitors and siRNA, we tested the role of Rho-family small GTPases in membrane repair to CDCs and MEK redundancy. Inhibition of cdc42, Rac, or ROCK1/2 in HeLa cells did not increase cell sensitivity to SLO and PFO, nor block the downstream phosphorylation of MLK3 or MEK, as confirmed by western blotting. Using siRNA knockdown in HeLa cells, we tested the redundancy between MEK1 and MEK2 in repair against CDCs. We found that MEK2 siRNA, but not MEK1, increased cell sensitivity about 2-fold to SLO and PFO. We conclude that MEK2 is the critical downstream kinase activated for HeLa cell survival against CDCs, while the upstream activator of the MLK3-MEK2 repair signaling pathway to CDCs is unlikely to be a Rho-family small GTPase.

B511/P2186

C9orf72/SMCR-8 negatively regulates *C. elegans* EGFR signaling via the Arf6 GTPase.

A. Sabbir, A. Sobhani, S. Deng, K. Gauthier, C. Rocheleau; Research Institute of the McGill University Health Centre, Montreal, QC, Canada

An expansion of hexanucleotide repeats in the first intron of C9orf72 is the most prevalentgenetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). RNA andprotein aggregates resulting from the hexanucleotide repeats and C9orf72 haploinsufficiencymay cause disease. Thus, knowing the normal biological functions of the C9orf72 protein isimportant to understand how loss of C9orf72 might contribute to disease progression. C9orf72forms an obligate complex with SMCR8 and they have been implicated in several aspects ofendolysosomal and autolysosomal function. Recent structural and biochemical data indicate thatC9orf72 and SMCR8 function as a Rab and Arf GTPase Activating Protein (GAP) *in vitro*. In *C.elegans*, C9orf72 and SMCR8 protein complex has been proposed to affect the lysosomalhomeostasis. However, the *in vivo* targets of C9orf72/SMCR8 have not been identified.We previously demonstrated in *C. elegans* that the ARF-1 and RAB-7 GTPases are strong negativeregulators of Epidermal Growth Factor Receptor (EGFR)-mediated vulva cell fate specification.We find that C9orf72 and SMCR-8 are also strong negative regulators of EGFR-mediated vulvainduction. RAB-7 promotes EGFR trafficking to the lysosomes and loss of RAB-7 results in EGFRaccumulating in endosomes. ARF-1 targets EGFR trafficking to the apical membrane of the vulvaprecursor cells; away from the EGF ligand localized at basolateral membrane. Loss of ARF-1results in an increased trafficking of EGFR to the basolateral membrane. We found that C9orf72is unlikely to function with either RAB-7 or ARF-1 as loss of C9orf72 does not result in EGFRaccumulating in either endosomes or the basolateral membrane. Instead, we found *C9orf72*mutants have increased level of EGFR on both the apical and basolateral membranes suggestingthat C9orf72 and SMCR8 are involved in

EGFR sorting into the recycling and degradativepathways.ARF-6 promotes endosomal recycling. We found that *arf-6* gain-of-function mutation antagonizesEGFR-mediated vulva induction, and that ARF-6 is required for C9orf72 to negatively regulateEGFR signaling. Our data consistent with C9orf72/SMCR8 functioning as an ARF-6 GAP to inhibitEGFR recycling to the plasma membrane. In a broader perspective, the increased ARF-6 activityand increased cargo delivery to the plasma membrane because of human C9orf72 loss couldcontribute to ALS and FTD development.

B512/P2187

BAG6 regulates stress fiber formation via controlling RhoA ubiquitination

M. Miyauchi, H. Kawahara; Biological Sciences, Tokyo Metropolitan University, Tokyo, JAPAN.

Dynamics of the actin cytoskeletal architecture are regulated at the level of actin polymerization. The Rho family of small GTPases are key regulators of distinct steps of cytoskeletal actin polymerization, which control cell shape, adhesion, migration, and division. They act as molecular switches controlled by GEFs/GAPs, which stimulate GTPase cycling between active (GTP-bound) and inactive (GDP-bound) form. Rho GTPases also associate with cytosolic chaperone proteins known as guanine-nucleotide dissociation inhibitors (GDIs), which maintain the GTPase in its inactive conformation. Binding of GTP induces a conformational change, which allows to interact and activate effector proteins.
Recently, posttranslational modifications such as ubiquitination were also reported to regulate the activity and stability of Rho GTPases. However, regulatory mechanisms how ubiquitination of Rho-family proteins are controlled remains elucidate to date. Previous study suggested that BAG6 interacts with GDP-associated Rab GTPases and recruits it to ubiquitin-dependent degradation (Takahashi et al., 2019). BAG6 is a chaperone/holdase that interacts with hydrophobic polypeptides. BAG6 prevents the excess accumulation of inactive Rab family proteins, whose accumulation impairs intracellular membrane trafficking. However, it is unknown whether BAG6 targets other family of small GTPases. The hydrophobic residues of the SwitchI region of Rab8a are essential for its interaction with BAG6. When we compared the amino acid sequence of SwitchI region of small GTPases, we found that Rho proteins are the most similar to Rab8a. In addition, BAG6 knockdown induced change in cell shape, we hypothesized that BAG6 might regulate Rho proteins.
Our finding in this study was that deficiency of BAG6 resulted in destabilization of cell endogenous RhoA protein that is rapidly degraded by the proteasome, leading to abrogation of stress fiber formation. Strikingly, restoration of RhoA expression through a transient overexpression rescued defects in stress fiber formation induced by BAG6 depletion, bypassing the requirement of BAG6. BAG6 is also necessary for appropriate assembly of focal adhesions as well as cell migration events. These findings reveal a crucial role of BAG6 in maintaining the integrity of actin fiber polymerization by preventing ubiquitination of RhoA small GTPases.

Mechanotransduction

B514/P2188

Regulation of membrane homeostasis by TMC1mechanoelectrical transduction channels

A. Ballesteros, K. J. Swartz; NINDS-NIH, Bethesda, MD.

The mechanoelectrical transduction (MET) channel in auditory hair cells converts sound into electrical signals,enabling hearing. Transmembrane-like channel 1 and 2 (TMC1 and TMC2) are implicated in

forming the pore ofthe MET channel. Here, we demonstrate that inhibition of MET channels, breakage of the tip links required forMET, or buffering of intracellular Ca... induces pronounced phosphatidylserine externalization, membraneblebbing, and ectosome release at the hair cell sensory organelle, culminating in the loss of TMC1. Membranehomeostasis triggered by MET channel inhibition requires Tmc1 but not Tmc2, and three deafness-causing mutationsin Tmc1 cause constitutive phosphatidylserine externalization that correlates with deafness phenotype. Ourresults suggest that, in addition to forming the pore of the MET channel, TMC1 is a critical regulator of membranehomeostasis in hair cells, and that Tmc1-related hearing loss may involve alterations in membrane homeostasis.

Nanoscale substrate deformation triggers fast Ca^{2+}transient via mechanosensitive cation channels

H. Peussa[1], C. Fedele[2], H. Tran[1], E. Mäntylä[1], A. Priimägi[2], S. Nymark[1], **T. O. Ihalainen**[1]; [1]Faculty of Medicine and Health Technology, Tampere University, Tampere, FINLAND, [2]Faculty of Engineering and Natural Sciences, Tampere University, Tampere, FINLAND.

Cells in our bodies are constantly subjected to mechanical stimuli such as stretch, compression, osmotic stress, or shear. The mechanical information cells receive from their physical environment co-regulates their form and functions, thus allowing cells to adapt to their niche. The physical cues rising from the environment are often locally sensed by specific and highly dynamic protein assemblies at the cell membrane, e.g., in integrin-rich focal adhesions or by large mechanosensitive (MS) ion channel complexes.Calcium-mediating MS ion channels like Piezo1 are particularly interesting for local mechanosensing due to the dual function of calcium. In addition to affecting the electrical potential difference of the cell membrane, calcium also acts as a universal second messenger, participating in numerous cellular signaling pathways, such as contraction, proliferation, secretion, vesicle trafficking, protein synthesis, and apoptosis. However, studies of these fast cellular mechanosensitive responses have proven to be difficult, partly due to the lack of proper tools to locally manipulate the cells. Light responsive materials offer an interesting approach to study how local mechanical perturbation affects cells. Azobenzene-containing light-controllable materials have been recently proposed as smart biointerfaces, as their topography can be precisely manipulated via visible light. Photopatterning such materials with different sinusoidal microtopographies has shown to be very effective in driving cellular morphology and migration.Herein, we exploit the dynamical properties of a light responsive azobenzene-based molecular glass (disperse red 1 molecular glass – DR1-glass) as a dynamic cell culturing substrate for the mechanically activated calcium dynamics in epithelial monolayer. We first optimized the light-induced formation of topographical features by tuning irradiation parameters of a common confocal microscope. We show that local nanoscale material deformation and deformation dynamics cause strong calcium transient in the cells. Based on pharmaceutical experiments, we propose that Piezo1 channels are involved in sensing this deformation. Finally, the flexibility of this approach helped reveal that cells respond distinctively to direct mechanical stimuli and to signals rising from neighboring cells, thus highlighting the role of cell-to-cell communication in the tissues' complex mechanoresponses.

Contractility and the LINC complex mediate unlocking of the Neurectoderm Lineage Gene Sox1 During Early Differentiation in Mouse Embryonic Stem Cells

M. S. Hamouda[1,2], C. Labouesse[2], G. Wylde[2], Y. Miroshnikova[3], S. Basu[2], K. Chalut[2], C. Waterman[1]; [1]Cell and Tissue Morphodynamics, National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, [2]Wellcome-MRC Cambridge Stem Cell Institute, Cambridge, UNITED KINGDOM, [3]Section on Nuclear Mechanotransduction and Cell Fate Dynamics, Laboratory of Molecular Biology, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD.

During development, cell differentiation often involves morphogenic transformations that shape and organize tissues. Emerging evidence suggests that the LINC complex may transduce the actomyosin-mediated cellular forces of morphogenesis through the nuclear envelope to chromatin. This nuclear mechanoresponse can effect gene expression and epigenetic changes during differentiation, thereby influencing or instructing cell fate determination. We studied the role of the LINC complex and actomyosin activity in neurectoderm lineage specification in mouse embryonic stem cells (mESCs) in an *in vitro* model of exit from naïve pluripotency. This models early embryogenesis, where disorganized cells of the pre-implantation epiblast undergoes a polarization morphogenesis to form a cup-like epithelium in the post-implantation epiblast. We found that mESCs induced to exit naïve pluripotency *in vitro* recapitulated some features the apical constriction morphogenesis that occurs *in vivo. In vitro* colonies formed apical actin rings containing phosphorylated myosin light chain, indicating contractile activity, and radially taught actin cables that severely deformed nuclei. To determine the role of LINC and contractility in lineage specification, we utilized inducible expression of dominant negative LINC and pharmacological perturbation of myosin II. We found that the timely downstream expression of the master neurectoderm lineage transcription factor, SOX1, required an intact LINC complex or myosin II activity during the apical constriction time window. 3D DNA FISH revealed the *Sox1* locus residing at the apical nuclear envelope during this time window. Notably, pluripotency transition was unaffected by LINC decoupling, suggesting an epigenetic basis of *Sox1*'s sensitivity to LINC function. Supporting this, we observed LINC-dependent changes in the levels and nuclear distributions of histone modifications known to be associated with *Sox1* transcriptional regulation and epigenetic poising. CHIP-qPCR revealed that gain of H3K27me3 on the *Sox1* promoter required an intact LINC complex during the apical constriction time window. Together these data suggest that morphogenesis-associated cytoskeletal contractility signals the LINC complex to instruct appropriate chromatin changes that poise *Sox1* for timely downstream expression, effecting cell fate determination during early development.

B517/P2191

Investigating Nuclear Mechanotransduction by Mapping Changes in Genome-Wide Transcription and Chromatin Accessibility After Mechanical Stretch

J. T. Long[1,2], J. Morival[1,2], J. T. Lis[3], J. Lammerding[1,2]; [1]Meinig School of Biomedical Engineering, Cornell University, Ithaca, NY, [2]Weill Institute of Cell and Molecular Biology, Cornell University, Ithaca, NY, [3]Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY.

Cells can mediate tissue maintenance and growth through mechanotransduction, i.e. the translation of mechanical forces into biochemical signals. Whereas multiple mechanotransduction pathways have been identified at the plasma membrane and cytoplasm, the role of the cell nucleus in mechanotransduction remains unclear. Proteins at the nuclear envelope such as nuclear lamins and the

LINC complex connect cytoplasmic forces directly to the genome with the potential to influence genome organization and transcriptional regulation. It is not yet known whether mechanical forces could therefore result in the opening of genomic regions to influence the transcription of mechanoresponsive genes. Here, we seek to address this gap by developing a system to induce mechanical stress in fibroblasts and map genome-wide changes in transcription and chromatin accessibility temporally and at high resolution. To examine differential gene expression, we performed precision nuclear run-on sequencing (PRO-seq). Unlike RNA-seq which measures the quantity of total cellular RNA, PRO-seq captures nascent RNA for genome-wide temporal observation of early transcription events at base-pair resolution with high signal to noise ratio. We performed PRO-seq to detect early differential gene expression after subjecting human fibroblasts to cyclic stretch. To probe the effect of short-term mechanical stress on genome organization, we also performed the Assay for Transposase-Accessible Chromatin with high-throughput sequencing (ATAC-seq) on stretched fibroblasts. PRO-seq experiments detected a rapid increase in polymerase activity within the gene body of several genes encoding for transcription factors associated with cell proliferation, survival, and stress response after mechanical stretch as early as 10 minutes. Cross-referencing PRO-seq data with ATAC-seq revealed that the promoter regions of mechanically induced genes were already accessible before mechanical stretching was induced, and genome-wide chromatin accessibility did not increase with mechanical stretch. These findings suggest that genomic regions associated with mechanoresponsive genes are primed for gene activation to trigger polymerase pause release and elongation. Future work will investigate the role of nuclear lamins and LINC complex proteins in this phenomena and how disruption of these proteins perturbs the cellular mechanotransduction pathways.

B518/P2192

Elevated Extracellular Viscosity Redistributes Mitochondria and Microtubules in Cells

D. Yan[1,2,3], M. Pittman[1,2,3], H. Qureshi[1,2,4], Y. Chen[1,2,3]; [1]Department of Mechanical Engineering, Johns Hopkins University, Baltimore, MD, [2]The Institute for NanoBioTechnology, Johns Hopkins University, Baltimore, MD, [3]Center for Cell Dynamics, Johns Hopkins University, Baltimore, MD, [4]Department of Classics, Johns Hopkins University, Baltimore, MD.

A large proportion of the human tissue is covered by extracellular fluids that are viscous in nature, such as mucus in the airway and the GI tract. Yet little is known regarding how cells behave at various viscosities. We previously found that adherent cells with active ruffling lamellipodia can sense extracellular viscosity levels. At increased viscosity, single cells with ruffles flatten, and focal adhesion turnover increases, counterintuitively resulting in faster migration. However, how cells at high viscosity migrate in the context of wound healing, where cells collectively migrate to close wounds, remains unknown. Wound healing requires persistency in migration direction, which is regulated by microtubules. Wound healing also requires energy from mitochondria. On one hand, active proliferation and extracellular matrix repair are required, both of which are energy-consuming processes mainly localized in the cell's center. On the other hand, traction forces generated by cells increase at high viscosity, implying higher energy demands at the cell's leading edge. Mitochondria traverse along microtubules. To gain insights into how microtubules facilitate mitochondrial re-distribution to satisfy the growing energy demands at both the cell edge and center, we employed live-cell fluorescence confocal microscopy to study the dynamics of mitochondria and microtubules at various viscosity values. Upon the medium viscosity changing from low to high, we observed a minority of microtubules extending to the cell edge, following the protruding actin cortex, while most microtubules stalled at the

lamella circumference. We simultaneously observed a small subpopulation of mitochondria treading along the long extending microtubules to the cell edge. Furthermore, we found that the flattened nucleus at high viscosity was in closer contact with the ventral side of the cell membrane, while the membrane tension decreased significantly. Our results suggest that at high viscosity microtubules redistribute and guide mitochondria to the cell edge, albeit a small proportion. This redistribution might correlate with decreased membrane tension, allowing microtubules to push far onto the cell edge, as well as repositioning of the nucleus, reorganizing the spatial distribution of perinuclear organelles.

B519/P2193

Altered patterns of cell migration during wound healing at abnormal viscosity

H. Qureshi[1], M. Pittman[2], Y. Chen[2]; [1]Department of Classics, Johns Hopkins University, Baltimore, MD, [2]Department of Mechanical Engineering, Johns Hopkins University, Baltimore, MD.

Wound healing involves rapid cell migration to the site of injury, relying on fibroblasts and epithelial cells to replenish the extracellular matrix and restore damaged tissue. The speed and directionality of cell migration can be altered in response to various chemical and physical cues, including chemoattractant gradients, substrate stiffness, and extracellular fluid (ECF) viscosity. Yet the mechanical effects of ECF viscosity on healthy and aberrant wound healing are underexplored. A recent finding from our research group demonstrated that single cells with actively ruffling lamellipodia can sense and respond to elevated ECF viscosity and migrate up to twice as fast in viscous medium. However, wound healing involves collective migration within the epithelium, and the effect of viscosity on collective cell motility has not been closely examined. I aim to address this unexplored question and extend our knowledge to how viscosity affects interactions between cell types in the context of wound healing. A 2-D co-culture system consisting of human GM00637 fibroblasts and HaCaT keratinocytes was constructed to model skin wound healing. After incubating co-culture wells overnight, the wells were scratched down the middle, and the cells were imaged as they migrated into the wound site. I found that the two cell types displayed starkly contrasting behaviors when immersed in viscous medium (0.4 Pa·S). In particular, collective migration and proliferation were both decreased in keratinocytes, while fibroblasts exhibited no significant changes in their migration or proliferation. This resulted in predominantly fibroblasts occupying the wound site. Since coordinated arrival of these cells at the wound site is necessary for effective re-epithelialization, disruptions to the relative timing of this migration can lead to fibrosis. In summary, these findings provide insights into the etiology of fibrosis during wound healing and demonstrate the important role of mechanosignaling in pathology.

B520/P2194

DNA repair in soft and stiff contexts

M. Locatelli[1], A. Hinds[2], J. Holmes[2], G. Chang[3], J. Liu[3], Q. Song[2], **P. Vidi**[4]; [1]UNC, Chapel Hill, NC, [2]Wake Forest University School of Medicine, Winston-Salem, NC, [3]IUPUI, Indianapolis, IN, [4]Institut de Cancérologie de l'Ouest, Angers, FRANCE.

Cells feel and respond to the physical properties of their microenvironment. We asked if the stiffness of the extracellular matrix (ECM) regulates DNA repair. Using breast organoid models and mammary epithelial cells cultured on polyacrylamide gels of defined stiffness, we found that the response to DNA damaging drugs and ionizing radiation (IR) is amplified in stiff contexts. This effect could not be explained by cell cycle imbalance. IR induced similar levels of DNA breaks in soft and stiff conditions,

pointing to mechanogenomic regulation of the DNA damage response. Mechanistically, this effect was dependent on the structural continuum spanning integrins at the plasma membrane and the LINK complex at the nuclear envelope. ECM stiffness affected DNA repair by homologous recombination and non-homologous end joining. Cell survival to DNA breaks was also influenced by ECM stiffness. These findings may partly explain elevated breast cancer risk associated with high mammographic density (MD), which reflects high fibrillar collagen and stiff breast tissue. Using public transcriptomic data of normal breast tissue, we found a two-fold higher mutation burden in women with high MD compared to women with low MD. We propose that a mechano-stimulated DNA damage response in stiff tissue promotes survival of cells with DNA lesions at the expense of apoptosis, leading to the propagation of somatic mutations.

Optogenetic activation of microtubule acetylation elucidates its role in actomyosin dynamics and directional cell migration

A. Deb Roy, C. Saez Gonzalez, E. Yadav, F. Shahid, X. Wang, T. Inoue; Johns Hopkins University, Baltimore, MD

Acetylation of α-tubulin at lysine-40, solely catalysed by α-TAT1, is implicated cell migration and mechanosensing. However, the precise role of microtubule acetylation in these events is not well understood, partly due to a limited understanding of α-TAT1 regulation and lack of tools to specifically actuate microtubule acetylation. Here we report that cytoplasmic localization of α-TAT1 is critical for its function, and that such localization is mediated by its C-terminal region through a combination of nuclear export, phospho-inhibited nuclear import and 14-3-3 mediated cytoplasmic retention. Based on this model of spatial regulation of α-TAT1 function, we developed an optogenetic tool to control microtubule acetylation in live cells to probe its relationship with actomyosin contractility. We modified the previously described Light-inducible nuclear export system (LEXY) to reduce its dark-state activity and tethered the catalytic domain of α-TAT1 to it. This tool, named optoATAT1, was predominantly nuclear in dark and was rapidly shuttled to the cytoplasm upon blue light stimulation in a reversible manner. Hela cells expressing optoATAT1 exposed to blue light showed a robust increase in microtubule acetylation compared to those kept in dark, validating the functionality of the tool. Mouse embryonic fibroblast (MEF) cells from α-TAT1 knock-out (KO) mice showed severe defects in chemotaxis, although they are highly motile compared to wild-type (WT) MEF cells. In addition, the KO MEFs showed defects in cell polarity, actin cytoskeleton and Myosin-II activity. Using a FRET-based Vinculin Tension-sensor, we further show that compared to WT, α-TAT1 KO MEF cells exert little mechanical forces on focal adhesions. Stimulation of optoATAT1 induced rapid activation of actomyosin contractility as evidenced by increased actin stress fibers, Myosin-Light chain accumulation and maturation of focal adhesions. These effects of optoATAT1 on the actin cytoskeleton were dependent on its catalytic activity as well as ROCK signaling, thus establishing a causal relationship between microtubule acetylation and ROCK-mediated actomyosin contractility. To summarize, we have identified a previously unknown regulatory function of the α-TAT1 C-terminal region and based on our finding of spatial regulation of α-TAT1 function, we have developed optoATAT1, a powerful optogenetic tool to control microtubule acetylation that will provide new insights in the role of microtubule acetylation in mechanotransduction and directional cell migration.

B522/P2196

Linking cell mechanics and metabolism in endothelia

N. Cronin; Biochemistry and Molecular Biology, University of Iowa, Iowa City, IA.

Mechanisms for protecting or restoring endothelial function have been the subject of intense scrutiny. These efforts have revealed that fluid shear stress, from proper blood flow, activates signal transduction pathways that allow the cell to reorganize its actin cytoskeleton to withstand tension. Other groups have identified metabolic changes in response to shear and disturbances in regions of disrupted blood flow. These cytoskeletal and metabolic changes are often viewed as being disparate functions - an understanding for how the mechanical properties and behavior of cells to shear stress (i.e. mechanics) is linked to metabolism is incomplete. Here I provide evidence that cell-cell adhesion proteins located at the adherens junctions are directly responsible for sensing fluid shear stress and signal for the activation of AMP-activated Protein Kinase (AMPK), a master regulator of cell metabolism. I determine that the activation of AMPK shifts the metabolic state of these cells to promote energy production, which is necessary to sustain the cellular mechanics needed to withstand fluid shear stress. Furthermore, disruption of this signaling pathway leads to aberrant endothelial function, cell-cell junction stability, and cellular alignment to fluid shear stress. These data confirm that cell mechanics and metabolism are linked in endothelia and may provide insights into endothelial regulation and cardiovascular health and disease.

B523/P2197

Endothelial Glycocalyx in High- and Low-Flow Regions in the Trabecular Outflow Pathway of Bovine Eyes

N. Liu, S. Sosnowik, H. Li, H. Gong; Boston University, Boston, MA.

Intraocular pressure (IOP) plays an important role in the function of the eye, and is maintained through a dynamic balance of production and drainage of aqueous humor. Elevated IOP due to increased resistance in the outflow pathway is a primary risk factor for glaucoma, a leading cause of blindness. The trabecular outflow pathway is the primary pathway for aqueous outflow, and consists of the trabecular meshwork (TM), Schlemm's canal (aqueous plexus (AP) in bovine eyes), collector channels (CCs), and episcleral veins (ESVs). Flow along the pathway is segmental, with areas of varying resistance, resulting in high- and low-flow regions. The pressure gradient across the TM to the AP results in the formation of giant vacuoles (GVs) along the endothelium of the AP. Larger GVs form pores, which serve as pathways for aqueous humor to enter the AP. Glycocalyx is a hair-like structure that can be found covering the endothelium of the outflow pathway and filling some pores, however its role in contributing to or regulating outflow resistance has not been well studied. This study investigated the morphological differences of the glycocalyx in different flow regions along the trabecular outflow pathway in normal bovine eyes.

Six enucleated bovine eyes were perfused at 15 mm Hg for 30 minutes to measure baseline outflow facility, perfused with fluorescein to identify high- and low-flow regions of the outflow pathway, then perfusion- and immersion-fixed with Alcian Blue 8GX to label glycocalyx. Radial wedges of high- and low-flow regions of the anterior chamber angles were dissected and embedded. Ultra-thin sections (70nm) were cut and imaged with a transmission electron microscope. Coverage and thickness of glycocalyx was measured using ImageJ. The thickness and percentage coverage of glycocalyx, and the percentage of pores completely filled with glycocalyx was compared in high- and low-flow regions.

Glycocalyx thickness increased proximally to distally from the TM to ESVs, with glycocalyx covering ESVs being significantly thicker than that on the surface of the TM (P=0.01) and AP (P=0.02) in high-flow regions alone. No significant differences in glycocalyx coverage, glycocalyx thickness and percentage of pores filled with glycocalyx were found between high- and low-flow regions. Glycocalyx was also observed lining the inside of the majority of GVs with pores but not the inside of the majority of GVs without pores. Our results suggest that variations in shear stress play a role in determining glycocalyx morphology in different outflow pathway locations. Further studies are warranted to understand the role of glycocalyx in regulating or restricting aqueous outflow.

Adaptation of peristaltic pumps allows for cellular behavior analysis in response to flow forces *in vitro*

J. Abello[1], S. Raghavan[2], Y. Y. Yien[3], A. Stratman[1]; [1]Cell Biology and Physiology, Washington University in St. Louis, St. Louis, MO, [2]Department of Biomedical Engineering, Texas A&M University, College Station, TX, [3]Pittsburgh Heart, Lung and Blood Vascular Medicine Institute and Department of Medicine, University of Pittsburgh, Pittsburgh, PA.

Adaptation of peristaltic pumps allows for cellular behavior analysis in response to flow forces *in vitro*

Javier Abello[1], Shreya Raghavan[2], Yvette Y. Yien[3], and Amber N. Stratman[1]
1.Department of Cell Biology and Physiology, Washington University in St. Louis School of Medicine, St. Louis, MO 631102.Department of Biomedical Engineering, Texas A&M University, College Station TX 778433.Pittsburgh Heart, Lung and Blood Vascular Medicine Institute and Department of Medicine, University of Pittsburgh, Pittsburgh, PA 15261

The vascular system is subjected to mechanical forces that influence its function and architecture. Blood flow forces differ depending on the type of vessel, vessel size, and proximity to the heart (i.e. laminar or pulsatile flow). Studying the effect of mechanical forces on endothelial cells *in vitro* is important to understanding the molecular pathways that regulate the interactions between the different components of the vascular system. However, *in vitro* studies require the implementation of sophisticated equipment to generate flow that effectively resembles the natural blood flow rates and patterns. These kinds of equipment are expensive and can present a challenge for many laboratories that must adhere to a budget. Here we present our inexpensive adaptation of a conventional peristaltic pump to produce both laminar and pulsatile flow. To corroborate the effectiveness of our design we acquired timelapse videos of cell cultures under different flow conditions and compared cellular motility, alignment, and persistence. We further evaluated the differences in VE-Cadherin expression and assessed actin filament orientation and assembly under flow patterns by immunostaining. This study introduces an easy-to-use, cost-effective, and reproducible platform for the study of flow forces *in vitro*, which will allow us to mechanistically dissect the role of mechanical forces on the architecture and functionality of the vascular system.

Piezo1-mediated Mechanochemical Signaling Regulates Centriole Number in Multiciliated Cells

V. Narayanan, V. G. Rao, S. Kulkarni; Department of Cell Biology, University of Virginia, Charlottesville, VA.

How cells regulate organelle number is an outstanding question in cell biology. Unlike cycling cells that restrict centrioles to two copies per cell, highly specialized multiciliated cells (MCCs) deviate from the strict regulation as a part of the developmental program. MCCs that line the airway epithelium undergo massive amplification of basal bodies (specialized centrioles) to assemble an apical array of motile cilia and promote mucociliary clearance. Mutations that affect the number of centrioles/cilia are associated with impaired MCC function and can result in respiratory diseases, demonstrating that synthesizing the "right" number of centrioles/cilia is critical. Yet, how MCCs count and control centriole number remains a key gap in our understanding. Recent studies have shown that centriole number scales with MCC apical area. By artificially stretching the multiciliated epidermis, we demonstrated that mechanical forces calibrate MCC apical area and trigger centriole amplification via a mechanosensitive (MS) cation channel, Piezo1. However, how stretch-induced Piezo1 activation translates into more centrioles remains unresolved. To address this question, first, we demonstrate that Piezo1 acts a MS Ca^{2+} channel to regulate MCC centriole amplification. Inhibition of Piezo1-mediated Ca^{2+} signaling via Gd^{3+}, a potent inhibitor of stretch-activated Ca^{2+} channels, or intracellular Ca^{2+} chelation using BAPTA-AM, blocked centriole amplification in MCCs. Moreover, we show that Piezo1-mediated Ca^{2+} influx acts through protein kinase C (PKC) to activate Erk1/2 signaling and control MCC centriole number. Erk1/2 signaling, in turn, leads to the nuclear accumulation of a mechanosensitive transcriptional co-activator, Yap1, in MCCs. Strikingly, depleting Yap1 reduces the expression of Foxj1, a master regulator of motile ciliogenesis, suggesting Foxj1 is a target of Yap1 to regulate centriole number. Indeed, Foxj1 depletion affects centriole amplification in a tension-dependent manner. Interestingly, Yap1 and Foxj1 also control the expression of Piezo1, demonstrating a feedforward mechanism to control centriole number in MCCs. Together, our work indicates that Piezo1-mediated Ca^{2+} signaling regulates MCC centriole amplification in a tension-dependent manner via the Erk1/2 - Yap1 - Foxj1 signaling axis. Collectively, our work addresses a significant knowledge gap in mucociliary physiology and uncovers the central role of mechanochemical signaling in regulating organelle numbers to maintain tissue homeostasis.

All models are wrong: *Xenopus* embryonic epithelial sheets under strain transmit tension perpendicular to apical junctions with little transmitted along junctions.

J. Yang[1], L. A. Davidson[2]; [1]Bioengineering Department, University of Pittsburgh, Pittsburgh, PA, [2]Bioengineering Department, Developmental Biology Department, Computational and Systems Biology, University of Pittsburgh, Pittsburgh, PA.

Contemporary mechanical models and force inference methods of epithelial morphogenesis assume transmission of stress and strain occurs primarily along cell-cell junctions and that the mechanics of epithelial sheets is dominated by tension carried along the lengths of spring-like apical junctional complexes. In these models, contributions of tension across the medio-apical cortex are commonly lumped into an isotropically-actin pressure term. Here we test those assumptions with a unique tissue stretcher that combines high resolution live-cell imaging with the application of morphogenesis-scale strain rates. *Xenopus* embryos establish a mature apical junctional complexes replete with tight-,

adherens-, and desmosomal-junctions by blastula stage and develop high transepithelial electrical resistance reminiscent of simple epithelia in organs such as those found in the gastrointestinal tract. To track these structures in *Xenopus* we express cell membrane and apical junctional reporters together with a vinculin tension sensor widely used as a reporter of tension at the cadherin/catenin adhesion complex. Reporter expressing organotypic explants of gastrula stage ectoderm are cultured on a fibronectin-coated polydimethylsiloxane (PDMS) substrate attached to an interchangeable custom cassette. The stretcher is a multipiece 3D-printed microscope stage insert with two motorized actuators that operate on the cassette to achieve > 100% uniaxial strain at the level of the apical junctional complex. The small size and low mass of the stretcher enable the use of piezo- and galvo-based z-focus to track individual cell- and junction-strain and biophysics of apical junctional complexes. Surprisingly, we observed few cell rearrangement events; rather, we observed heterogeneous cell-to-cell deformation. Segmenting junctions around the perimeter of each cell allowed us to analyze the tension between cell vertices and assess how well these correlate with junction length changes. We quantified vinculin intensity along individual cell junctions in these samples, where we expected to see vinculin recruited as the tissue responses to the high strain. Surprisingly, we found no positive correlation between vinculin recruitment and apical junction length increase. We next sought to evaluate the level of tension across junctions. We were also surprised to observe no vinculin recruitment to sites that were parallel to the uniaxial stretch axis, but a significant increased vinculin recruitment to junctions perpendicular to the stretch axis. These findings suggest current vertex-based models and force inference methods may need significant revision if they are to be used as interpretive models of epithelial morphogenesis in tissues with substantial medio-apical junctions.

A New Computational Model for Mechanosensing and Mechanotransduction of Neuronal Growth Cones

L. Pulido[1], A. Athamneh[1], Y. Efremov[2], A. Raman[2], T. Kim[3], D. M. Suter[1]; [1]Biological Sciences, Purdue University, West Lafayette, IN, [2]School of Mechanical Engineering, Purdue University, West Lafayette, IN, [3]School of Biomedical Engineering, Purdue University, West Lafayette, IN.

Neuronal growth cones are highly motile structures at the tip of the axons and dendrites, which sense a variety of cues including chemical and mechanical to establish functional connections during nervous system development. Substrate-cytoskeletal coupling is an established model for adhesion-mediated growth cone advance through the application of traction force. However, the detailed molecular and biophysical mechanisms underlying the mechanosensing and mechanotransduction process remain to be elucidated. For this reason, we developed a new computational model to better understand the changes in cytoskeletal dynamics, traction force, and substrate deformation when the growth cone interacts with adhesion substrates of different stiffnesses. To achieve this, we have modified an existing motor-clutch model by including both motor and clutch reinforcement with increasing substrate stiffness. Furthermore, we have added an actin flow threshold that indicates when the growth cone is strongly coupled to the substrate. Our modeling results are in good agreement with experimental data from *Aplysia* growth cones with respect to substrate deformation behavior. Modeling also shows that strong coupling is achieved faster on soft substrates suggesting that growth cones prefer softer substrates when given the choice.

Mechanical cues tune the differential localization of LIM domain proteins

S. Seetharaman[1], T. Chmiel[1], J. Devany[1], J. Winkelman[1], Y. Fang[2], M. Gardel[1]; [1]James Franck Institute, Department of Physics, University of Chicago, Chicago, IL, [2]Department of Medicine, Biological Sciences Division, University of Chicago, Chicago, IL.

The actomyosin network is coupled to mechanosensitive adhesion components such as focal adhesions and adherens junctions, and can generate forces to maintain overall tissue homeostasis. A ubiquitous family of LIM (Lin11, Isl- 1, and Mec-3) domain proteins is associated with stress fibers and adhesions; however, the precise mechanisms of their localization and force-sensing remain unknown. Here, we demonstrate tunability of LIM domain protein localization by altering various intracellular and extracellular mechanical cues in endothelial cells. We show that actomyosin contractility, an intrinsic mechanical stimulus, triggers the shuttling of several members of the LIM family including Zyxin, Paxillin, FHL2 and LIMD1 to stress fibers, focal adhesions, or the nucleus. Specifically, local tension in stress fibers recruits the LIM regions of 18 different LIM proteins to these strain sites. We also show that different external mechanical stimuli can tune LIM protein localization in cells. Interestingly, Zyxin, which predominantly localizes to stress fibers and focal adhesions, can be redirected to adherens junctions and tricellular vertices by altering matrix rigidity-induced cell-cell adhesion signaling. In addition, stretching and shear stresses experienced by vascular endothelial cells drive the differential localization of Zyxin and FHL2. Using RNAseq, we identified that FHL2 is enriched in cells experiencing disturbed shear stresses mimicking atherosclerosis. Under these conditions, FHL2 strongly accumulates at stress fibers and focal adherens junctions, but not linear adherens junctions. Altogether, we have identified and described the intracellular and extracellular mechanical cues that trigger the differential localization of LIM domain proteins. This force-dependent localization can be exploited to study the specific functions and mechanotransduction pathways downstream of LIM domain proteins.

B529/P2203

Differential roles of extracellular matrix on primary and metastatic pancreatic cancer cells in 2d and 3d systems

O. Usman[1], S. Kumar[1], R. Walker III[1], G. Xie[1], L. J. Dooling[2], Y. Wang[1], J. Irianto[1]; [1]Florida State University, Tallahassee, FL, [2]University of Pennsylvania, Philadelphia, PA.

Pancreatic ductal adenocarcinoma (PDAC) has a poor prognosis, and it is one of the leading causes of cancer death, with less than five percent 5-year survival rate. PDAC is characterized by high stromal deposition of different extracellular matrix (ECM) proteins which contribute to its resistance to both chemo- and radiotherapies. The ECM being a meshwork of different proteins, elucidating the role of the individual proteins in the ECM is important to the understanding of the disease. Here, by using multiple PDAC lines derived from both primary and metastatic tumors, we investigate the role of several ECMs commonly found in PDAC tumors: collagen I, fibronectin, vitronectin, and laminin, in both 2D and 3D culture systems. Surprisingly, when cells were cultured on a 2D system, only the PDAC lines derived from the primary tumors show differential growth and cellular morphology between the different ECM proteins. Both fibronectin and vitronectin increase cell proliferation rate by 3 folds and promote cell spreading. Transcriptome analysis of one of the primary tumor PDAC lines shows a significant differential expression of genes involved in cell-cell and cell-matrix adhesion. When the cells were cultured in the polyethylene glycol 3D culture system, all of the PDAC lines grow at a similar rate when

exposed to the four different ECMs. However, when focal adhesion kinase (FAK) was experimentally overexpressed in one of the primary tumor PDAC lines, it rescues the sensitivity to the different ECMs in the 3D culture system. In summary, these findings suggest differential ECM response for PDAC lines derived from primary and metastatic tumors, and for cells cultured in 2D and 3D culture systems.

Multiplexed mechanical mapping reveals macrophage mediated remodeling of brain in vivo

W. So[1], B. Johnson[1], P. B. Gordon[1], G. Scarcelli[2], K. Tanner[1]; [1]National Cancer Institute (NIH), Bethesda, MD, [2]University of Maryland - College Park, College Park, MD

Colony stimulating factor 1 receptor (CSF1R) plays a major role in central nervous system development especially for microglia formation as CSF1R loss in mammalian systems halts macrophage and microglia development. In humans, variants in CSF1R may also cause contribute to developmental disorders associated with brain morphological abnormalities and pathologies involving neurodegeneration. In mice, Csf1r deficiency results in embryonic or perinatal death. Thus, examination of the role of CSF1R in brain homology is challenging. Due to high homology with zebrafish, we specifically looked at a role of csf1ra (a paralogue of the mammalian CSF1R) on the regulation of brain mechanical homeostasis of larval zebrafish *in vivo*. RNA-Seq data analysis revealed alterations in pathways associated with angiogenesis and development of the innate immune system. Using intravital imaging, we observed abnormal brain morphology with an increase in fluid filled ventricles and altered neuron morphology in mutant fish. We then asked if mechanical properties are impaired as tissue mechanics play a crucial role in tissue development and neural stem cell behavior. Using two different microscale mechanical mapping techniques, we quantified the mechanical heterogeneities of different brain regions: fore-, mid-, and hind- brain. In wild type fish, the fore brain is stiffer than that of the mid and hind brain, As the brain develops, all regions become stiffer where the greatest increase in stiffness is measured in the hind brain. In comparison, the brain of the mutant zebrafish showed more homogeneous stiffness across all brain regions. Similar to the mammalian systems, csf1ra depletion in zebrafish will have delay or deficiency in microglia/macrophages within the brain. We then perturbed microglia/macrophage in wild type fish to further delineate the role of macrophage in mechanical homeostasis during brain development. We employed two methods of macrophage depletion using clodronate liposomes and tissue specific ablation using a genetic background NTR coupled to macrophages. In both alterations, the zebrafish brains were softer after treatment compared to the control siblings. We observed altered neuronal and acetylated tubulin structure of the mutant fish following in these treated fish. Our data demonstrates the importance of macrophage remodeling during brain development. It may also be relevant to the possibility that microglia contribute to synaptic plasticity and therefore function. Moreover, our data shows that mechanical properties can be used to identify phenotypes that result due to macrophage mediated tissue remodeling in brain morphogenesis.

B531/P2205

Stiff substrates localize myosin regulatory light chain in nucleus to suppress apoptosis

O. Katsuya[1], I. Seiichiro[1], T. Masayuki[1], A. Enomoto[2], H. Haga[1]; [1]Hokkaido University, Sapporo, Japan, [2]Nagoya University, Nagoya, Japan

Cells respond to physical stimuli, such as substrate stiffness. However, the response mechanism is not well known. Previous research showed that stiff substrates promote di-phosphorylation of myosin

regulatory light chain (MRLC) and as a result increase cellular contraction. It is also reported di-phosphorylated MRLC (2P-MRLC) performs transcriptional regulation in nucleus. These results indicate that MRLC mediates cellular responses to substrate stiffness via transcriptional activation itself. In this study, we aim to clarify the mechanism by which the cells that sense stiffness trigger cellular responses via MRLC. Previous research showed that 2P-MRLC localizes not only to the nucleus but also to the cytoplasm. Thus, we investigated whether substrate stiffness regulates the nuclear localization of 2P-MRLC. First, we prepared soft and stiff substrates of polyacrylamide gels, which are 0.4 kPa and 271 kPa, respectively. Then, human cervical cancer cells (HeLa cells) were cultured on each substrate and MRLC localization was observed. As a result, it was found that 2P-MRLC localized to nucleus in Hela cells on stiff substrates, whereas 2P-MRLC was localized to cytoplasm in the cells on soft substrates. This result revealed that substrate stiffness promoted nuclear localization of 2P-MRLC. Next, we aimed to identify the genes that regulate the nuclear-localized 2P-MRLC in response to substrate stiffness. Specifically, we performed qPCR screening and explored the genes which are up- or down-regulated by both a stiff substrate and MRLC. We found that MafB expression is downregulated by a stiff substrate and MRLC expression. Previous research showed MafB promotes apoptosis in limb morphogenesis. Thus, we hypothesized that suppression of MafB expression, which is induced by the nuclear localization of 2P-MRLC in response to substrate stiffness, restricts apoptosis. We examined the level of cleaved-caspase3, an apoptosis marker, in negative control cells, MRLC-knockdown (KD) cells and MRLC and MafB double-KD cells. MRLC-KD cells exhibit promoted cleaved-caspase3 levels, whereas knock down of MafB rescued the phenomena in MRLC-KD cells. These results indicate that the nuclear localization of 2P-MRLC, in response to substrate stiffness suppresses MafB expression to restrict apoptosis. These findings may provide new insight into how cells respond to substrate stiffness.

B532/P2206

Investigating Roles of Cytoskeletal Genes in *C. elegans* Sex Myoblast Development

M. A. Fitian[1], M. Razi[1], S. A. Shehzad[1], O. B. Ahmed[2], T. L. McKnight[1], A. Fang[2], T. V. Gibney[3], A. M. Pani[3], D. Q. Matus[2], R. C. Adikes[1]; [1]Siena College, Loudonville, NY, [2]Stony Brook University, Stony Brook, NY, [3]University of Virginia, Charlottesville, NY

The cytoskeleton plays integral mechanical roles in cell migration, division, and morphogenesis during animal development. However, our understanding of how cytoskeletal behaviors are regulated *in vivo* remains limited compared to our knowledge of mechanisms *in cellulo*. Here, we set out to characterize developmental roles of candidate genes associated with the cytoskeleton using an *in vivo* model system. To do this, we investigated development of the sex myoblast (SM) cells in *C. elegans*. The SM cells are descendants of the M mesoblast cell and are born in the posterior region of the L1 larva. SMs then travel anteriorly until they reach the gonad at the center of the worm. Upon arrival, the SM cells re-enter the cell cycle, divide three times and differentiate into the uterine and vulval muscle cells, which are required for egg laying. Mutations that impact SM cell migration, division, and/or differentiation can lead to lower egg counts that can be quantified at the plate level. Cytoskeletal regulatory proteins are likely to be important for multiple aspects of SM development including migration, division, and regulation of membrane protrusions that appear after migration is complete. To investigate functions for candidate cytoskeletal regulators in SM development, we are performing a targeted RNAi screen of ~120 genes associated with the cytoskeleton using M-lineage specific RNAi to bypass essential and/or pleiotropic functions for key genes. *C. elegans* were grown on RNAi plates and scored as young adults for phenotypes including sterility, larval growth slow, protruded vulva, uncoordinated, lethal, dumpy,

and bag of worms. We used brood size as a proxy for egg-laying ability with the hypothesis that reduced brood sizes likely indicate defects in SM development. Preliminary data show depletion of *cdc-42*, *ced-10* (*Rac*), *unc-73* (*RhoGEF-kinase*), *arx-2* (*Arp-2/3*), *wsp-1* (*WASP*), *unc-60* (*Cofilin*), and *ani-2, ani-3* (*Anillin*) impact development and brood size. These data suggest that key actin regulators are required for proper SM cell development. Future experiments will investigate the types of defects underlying these phenotypes through further RNAi experiments and imaging. In conclusion, we can take advantage of the unique attributes of the SM cell lineage to dissect how the cytoskeleton is required for development *in vivo*.

B533/P2207

Plectin linkages are mechanosensitive and facilitate nuclear translocation during cell migration through 3D matrices

B. R. Hewitt; Drexel University, Philadelphia, PA

Migrating cells have the remarkable capability of sensing and responding to their environment by switching their mode of migration. Cells migrating in a linearly elastic 3D environment concentrate actomyosin contractility in front of the nucleus to pull the nucleus forward, which increases the interior pressure at the front of the cell. High pressure in front of the nucleus creates cylindrical protrusions called lobopodia. This mode of migration, known as the nuclear piston, relies on contractility and adhesion where actomyosin filaments transmit force onto vimentin intermediate filaments that act as molecular tow cables for the nucleus by docking into the nuclear envelope protein nesprin 3. While best characterized in human primary fibroblasts, the nuclear piston has also been observed in primary human chondrocytes, human fibrosarcoma, and human breast adenocarcinoma. It is unclear how actomyosin filaments connect to vimentin filaments to transmit force to the nucleus to help pull it forward in 3D matrices. We hypothesized that the cytoskeletal cross-linking protein plectin couples actomyosin and vimentin intermediate filaments. Proximity ligation assays (PLA) on 2D glass and FRET imaging in 3D matrices showed that vimentin and actin interact in both a plectin dependent and ROCK-NMII dependent manner. Additionally, plectin interacts with vimentin in response to NMII contractility and substrate stiffness, suggesting that the association of vimentin and plectin complex is mechanosensitive. We found that plectin expression slows migration on 2D glass but is critical for both nuclear piston migration in 3D cell-derived matrix (CDM) and lamellipodial migration in 3D collagen. Finally, we found that plectin is required for the polarization of both NMII and vimentin in front of the nucleus. Taken together, our findings suggest that matrix stiffness and NMII activity govern assembly of vimentin, plectin, and actin. Once assembled, this interconnected cytoskeletal machinery can be activated in 3D matrices to help pull the nucleus forward to generate compartmentalized pressure and lobopodial protrusions.

B534/P2208

Effect of Mechanical Dose on Characteristics of Cartilaginous Matrix Production

S. Jang[1,2], J. Jeong[1], T. Oh[3], B. Song[2], E. Lee[4,2]; [1]Graduate School, Kyung Hee University, Seoul, Korea, Republic of, [2]Akrocell Biosciences, Inc., Seoul, Korea, Republic of, [3]School of Medicine, Kyung Hee University, Seoul, Korea, Republic of, [4]Kyung Hee University, Seoul, Korea, Republic of

For the reconstruction of functional fibrocartilage tissue, induction of ECM alignment and cartilaginous matrix production is essential. Although tensile stimulation is the most effective approach to induce

tissue alignment, recent studies showed that mechano-transduction interferes with the upstream signaling pathway of chondrogenesis. To overcome the anti-chondrogenic effect exerted by mechanical stimulation, we established an optimized fibrocartilage formation protocol by investigating the effect of tensile stimulus mechanical dose on meniscal chondrocytes (MCs). To induce tissue alignment, cable-form tissues constructed with MCs were subjected to 10% static tension for various duration. The state of mechano-transduction was confirmed by YAP nuclear translocation status. We confirmed that mechanical memory in MCs, both induced by surface stiffness and tensile stimulation, did not show irreversibility and lasted less than 24 hours based on YAP localization status. The established uni-axial tissue anisotropy and its retention was confirmed with alignment of actin cytoskeleton and type I collagen. The mechanical stimulation applied for more than 7 days resulted in the maintenance of tissue anisotropy up to 5 days after the tension release. Applying tensile stimulation only for initial 7 days of 3-week chondrogenesis resulted in production of fibrous matrix as well as GAGs matrix, while continuous static tension compromised cartilaginous matrix production. In conclusion, these findings suggest that the optimization of tensile dose can modulate the characteristics of cartilaginous matrix production, which can lead to the successful reconstruction of fibrocartilage in its similarity to natural tissues.

Phosphoinositide Metabolism by Actin-Regulatory Protein in Cancer

A. Orenberg[1], D. Gau[1], L. Ohayon[1], M. Ricci[1], Y. Bae[2], G. Hammond[1], P. Roy[1]; [1]University of Pittsburgh, Pittsburgh, PA, [2]University of Buffalo, Buffalo, NY

Profilin1 (Pfn1) is an actin polymerization regulatory protein that conventionally promotes cell migration in physiological contexts. Yet, in breast cancer and several other invasive adenocarcinomas, Pfn1 downregulation leads to increased migration and invasion of cancer cells. We previously discovered that increased accumulation of plasma membrane phosphoinositide (PPI) $PI(3,4)P_2$ (a PPI generated downstream of activated PI3-kinase) at the leading edge and subsequent recruitment of $PI(3,4)P_2$-interacting pro-migratory protein complexes is responsible for the hyper-motile phenotype of breast cancer cells during Pfn1 depletion. The aim of this study is to gain fundamental molecular insights into the Pfn1-dependent regulation of PPI metabolism in cells. We combined biochemical techniques, immunofluorescence, and live-cell imaging of PPI reporters to investigate the effect of perturbation of Pfn1 on $PI(3,4)P_2$ dynamics and upstream PPIs including PIP_3 and $PI(4,5)P_2$. Our knockdown and overexpression studies collectively demonstrated that Pfn1 positively and negatively regulates the cellular levels of $PI(4,5)P_2$ and PIP_3, respectively, but does not affect phospholipase C (PLC)-mediated hydrolysis of $PI(4,5)P_2$ in cells. Therefore, the elevation of PI3K-derived PPIs upon Pfn1 depletion is not a secondary consequence of alteration to $PI(4,5)P_2$ hydrolysis. Live imaging of a $PI(3,4)P_2$-specific fluorescent reporter demonstrated that Pfn1 depletion enhances $PI(3,4)P_2$ synthesis in cells. We are currently exploring whether Pfn1 plays a role in modifying the activity of lipid-modifying enzymes to enrich our understanding of the unconventional functions of Pfn1 beyond its direct regulation of actin cytoskeletal rearrangement.

From Single-Protein to Single-Cell: a unique platform that combines optical tweezers and fluorescence microscopy for the study of Cytoskeletal Processes and Cell Mechanics

S. Dutta[1], T. Simpson[1], B. Groen[2]; [1]Lumicks B.V., Waltham, MA, [2]Lumicks B.V., Amsterdam, Netherlands

Cells and protein filaments such as microtubules, actin and intermediate filaments are highly dynamic structures that constantly interact with each other and their surroundings. The forces governing these interactions play fundamental roles in essential biological processes like cell division, motor transport, protein signaling or cell migration. Therefore, being able to study the mechano-chemical and mechano-biological pathways governing these interactions is essential to better understanding their nature. Force spectroscopy on a single-molecule and single-cell level permits exploring and manipulating these complex interactions. Our force-spectroscopy platform, the C-Trap, integrates optical tweezers, fluorescence microscopy, and an advanced microfluidics system in a truly correlated manner. It enables live, simultaneous, and correlative visualization and manipulation of molecular interactions for a wide range of forces (from picoNewtons to a nanoNewton) and with high temporal resolution (microseconds). Here we present our experiments visualizing and quantifying the elastic properties of protein filaments, the motility of cytoskeletal molecular motors, the characterization of forces exerted by filopodia, or the force-triggered activation of membrane receptors using the C-Trap system. These experiments show that the technological advances in hybrid single-molecule and single-cell methods can be turned into an easy-to-use and stable instrument that opens new venues in many research areas.

B537/P2211

Comparative Cell-Generating Tractional and Intracellular Force Analyses of Acrylamide-Based And Methacrylated Gelatin-Based Techniques for Understanding the Mechanotransduction

S. Hur[1], J. Jeong[1], K. Noh[1], J. Park[2], J. Chung[2], Y. Hwang[1]; [1]Soonchunghyang Institute of Medi-Bio Science (SIMS), Soonchunhyang University, Cheonan, Korea, Republic of, [2]Soonchunhyang University Cheonan Hospital, Cheonan, Korea, Republic of

Cell-generating tractional and intracellular forces within physiological and pathological microenvironments and their transduction to regulate various cell behaviors have been of great interest. Although these mechanical forces exerted cells have been traditionally analyzed by utilizing polyacrylamide (PAAm) hydrogel-based traction force microscopy (TFM) due to its good linear elastic and transparent optical properties, PAAm hydrogel was failed to support three-dimensional (3D) cell encapsulation to understand the cellular forces within 3D microenvironment. Here, we aim to develop a novel method to assess cell-matrix (traction) and intracellular (and intercellular) stresses using an alternative candidate, methacrylated gelatin (GelMA), to overcome the current limitations. Our preliminary results demonstrated that viscoelastic and elastic properties of both PAAm and GelMA-based hydrogels were successfully matched, which were confirmed by measuring Young's modulus, dynamic modulus (G', G'', and tanδ), stress relaxation, and strain revery. Next, we evaluated various cell-generatiing forces of either tonsil-derived stem cells in a single cell level or conjunctiva-derived epithelial cells as a monolayered cell sheet using GelMA-based traction force microscopy (TFM), intracellular force microscopy (IFM), and monolayer stress microscopy (MSM), where the results were also compared and validated using PAAm-based methods. Our initial findings indicate that our GelMA-based TFM, IFM, and MSM methods exhibited cell-generating forces and mechanotransduction in a spatio-temporal manner. Taken together, these results suggest GelMA can be a good candidate for the cell-ECM and intracellular

stress measurement platform and this technique can offer insight into the important roles of dynamic cell-matrix and intracellular stresses in regulating stem cell lineage commitment and disease progression within 3D microenvironments.

B538/P2212

Septin characterization in neonatal cardiomyocytes

A. Vallopra[1], S. Balasubramanian[1], E. T. Spiliotis[2], A. V. Kwiatkowski[1]; [1]University of Pittsburgh, Pittsburgh, PA, [2]Drexel University, Philadelphia, PA

Cardiomyocyte function requires precise, dynamic, and carefully regulated organization of the proteins and organelles within them. The non-contractile cytoskeleton in cardiomyocytes - including cortical actin, microtubules, and intermediate filaments - helps establish and maintain this complex organization. In developing cardiomyocytes, the septin cytoskeletal family of proteins has also been implicated in regulating cellular organization. Septins function in multiple biological processes, including cell division, cell polarity, and membrane remodeling. Septins are expressed in the developing and adult heart; however, their role in cardiomyocyte organization is not well understood. Here we describe our efforts to characterize septins (SEPT)-2,6,7,9 and 11 expression and localization in cultured cardiomyocytes. Since changes in substrate stiffness can impact cardiomyocyte organization, we cultured neonatal cardiomyocytes on PDMS (polydimethylsiloxane) gels of varying stiffnesses (soft to stiff) and coated with either fibronectin or collagen I to create a range of microenvironments. Cardiomyocytes were cultured for 72 hours, fixed, and stained using specific anti-septin antibodies. SEPT7 and SEPT6 localized to discreet areas along the membrane, whereas SEPT11 was largely cytoplasmic. Notably, SEPT6 was present in the nuclei of most, but not all, cardiomyocytes and the only septin that showed nuclear localization. On the collagen I substrates, we observed similar septin localization patterns across all tested stiffnesses. Our results show that multiple septins are expressed in neonatal cardiomyocytes with unique and specific localization patterns that are largely unaffected by substrate stiffness. We speculate that septin membrane and nuclear localization reflects multiple roles in cardiomyocyte organization.

Plasma Membrane Damage Contributes to Syncytia Formation after Laser Ablation

J. Hua, J. T. O'Connor, A. D. Pumford, L. Nassar, J. White, M. Hutson, A. Page-McCaw; Vanderbilt University, Nashville, TN

Restoration of tissue integrity after injury is essential to the survival of all organisms. We use *Drosophila* pupal notum damaged by laser ablation as a model system to study the wound healing mechanisms. Starting about 10 minutes after laser ablation, mononuclear cells of the pupal epidermis fuse and form multinucleated syncytia to assist with re-epithelialization. The objective of this study is to investigate the mechanisms of wound-induced syncytia formation.

All trauma wounds generate a mixture of damage, but pulsed laser ablation creates a highly reproducible pattern of cellular damage and response. An expanding cavitation bubble is generated within microseconds after wounding, exerting shear mechanical force on cells under its footprint, damaging their plasma membranes and allowing an influx of extracellular calcium within milliseconds after ablation. Concentric to the zone of plasma membrane damage is the area of nuclear membrane damage and cell lysis. Interestingly, syncytia form only after this type of ablation, called single-shot

ablation, during which the notum is hit once by a high-power pulsed laser; syncytia are absent after scanning ablation, when cells are destroyed by a low power laser scanning multiple times over a selected area of cells. Using Ca^{2+} entry as a proxy for plasma membrane damage in single-shot ablation, we reveal that approximately 96% of fused cell borders co-localize with traces of Ca^{2+} captured as early as 30 ms after wounding, and all fused cell borders are surrounded by elevated level of Ca^{2+} within 60 ms of single-shot ablation. In contrast, scanning ablation does not induce plasma membrane damage, as demonstrated by the voltage indicator ArcLight. Surprisingly, overexpression of the TMEM16F scramblase does not enhance wound-induced syncytia formation, suggesting that altered phosphatidylserine exposure pattern on the outer cell leaflet is not contributing to syncytia formation. We conclude that plasma membrane damage primes wound-induced cell fusion.

Dynamics of Focal Adhesions and Invadosomes

B540/P2214

Regulating mechanical properties of focal adhesion through protein liquid liquid phase separation

X. Cheng, L. Case; Biology, Massachusetts Institute of Technology, Cambridge, MA.

Integrin based focal adhesions (FA) are supramolecular complexes at the cell surface that are important for cell adhesion. They anchor the cell to the extra cellular matrix through transmembrane integrin receptors. Talin, vinculin and tensin are present at mature focal adhesions and have important function for linking integrin to the actin cytoskeleton. Despite past discoveries on the genetic and biochemical level, how the protein composition of focal adhesions contribute to the physical property of focal adhesion is not well understood. Recent studies have described certain proteins possess the innate property of going through liquid-liquid phase separation in the cytoplasm, creating mesoscale biomolecular condensates. These condensates form chemical compartments that gives rise to many membraneless organelles. Studies from my lab have describe that several nascent focal adhesion proteins phase separate. With the correct protein composition, we can in vitro reconstitute minimal nascent FA condensates that can cluster integrin on supported lipid bilayers. The multivalency of vinculin binding sites in talin, as well as the large intrinsic disordered region in tensin make them great candidates for phase separation. Overexpression of constitutively active vinculin or tensin lead to cytoplasmic condensates formation, confirming their ability to go through phase separation. These condensates contain focal adhesion kinase and paxillin, both are FA proteins essential to the formation of minimal nascent FA condensates. We hypothesize that the recruitment of talin, vinculin and tensin to the focal adhesion increase the physical strength of the FA condensate, making it able to bear stronger force. To study the mechanical property changes of adhesion condensates, I will introduce these proteins to reconstituted nascent FA condensates to form compositional mature FA condensates. This technique is a significant technical advancement that allows us to precisely control the amount and timing for recruitment, also enables me to use biophysical approaches such as microrheology to analyze the material property of these condensates. I will confirm my results by expressing talin, vinculin and tensin variants used for reconstitution in live cells, and measure FA number, size, protein dynamics and cell migration changes. These are important experiments linking in vitro observations to in vivo physiological events. Together, my results will shed light on how the physical properties of protein compartments lead to specific cellular phenotype.

Substrate Stiffness Regulates Focal Adhesion Kinase Alternative Splicing in Breast Cancer

M. Millet, E. Pic, C. Luthold, G. Bourriquen, G. Khelifi, B. Trudel, S. Hussein, F. Bordeleau; Université Laval, Québec, QC, CANADA.

Altered alternative splicing is considered as a hallmark of cancer. In fact, alternatively splice protein variants can differentially influence cellular processes such as cell migration and invasion. We have shown previously that increased matrix stiffness in tumors regulates alternative splicing events through increased cell contractility. Interestingly, the focal adhesion kinase (FAK), a protein central to matrix stiffness mechanosensing in focal adhesion, has several isoforms that promote tumor progression. In this context, we hypothesized stiffness-mediated alternative splicing could regulate the expression of FAK splice variants and influence tumor progression. We first investigated FAK mRNA splicing as a function of matrix stiffness using RNAseq. Our data identified stiffness-mediated alternative splicing events in FAK exon 4 exclusion (FAK^{4-}). PCR data from *in vitro* experiments confirmed FAK^{4-} expression was modulated by substrate stiffness, reaching a maximum at around 1, 5 and 10 kPa in MCF10a, MCF7 and MDA-MB-231 cells respectively. Of note, FAK^{4-} expression at these stiffnesses was reduced upon contractility inhibition. To investigate FAK^{4-} clinical relevance, we characterized FAK^{4-} expression as function of the tumor stage as a proxy of tumor stiffness in patients (TCGA). Notably, we found that patients with higher proportions of FAK^{4-} had significantly worst survival odds than patient with lower FAK^{4-} expression. Finally, preliminary data suggest FAK^{4-} expression is regulated by tumor stiffness. Taken together, our data revealed FAK alternative splicing is regulated by matrix stiffness both in patients and *in vitro*. Moreover, the stiffness at which the maximum FAK^{4-} expression is observed is higher in the more invasive MDA-MB-231 cells. Overall, our results show FAK splicing is modulated by tumor mechanics, raising the possibility of an existing interplay between stiffness-driven alternative splicing and FAK-mediated mechanoregulation. Importantly, our data suggest FAK^{4-} could have an important clinical significance.

A hard path to follow: The LKB1-AMPK axis in mechanosensing and durotaxis

A. K. Howe, J. B. Patterson; Pharmacology, University of Vermont, Burlington, VT.

Cellular metabolism is regulated at the scale of subcellular space and this regulation can couple to structures and events involved in cell migration. Migration is a complex process and is directionally guided by various types of gradients - concentration gradients of diffusible factors drive chemotactic migration while concentration gradients of immobilized extracellular matrix cues drive haptotactic migration. Previously, our laboratory demonstrated that mitochondria are recruited to the leading edge of migrating cells in manner that couples lamellipodial dynamics to local energy status and that is dependent on AMPK, a master sensor and regulator of metabolism. In addition, silencing the expression of LKB1, the major upstream activator of AMPK, decreases the directionality of migrating cells. Recently, we've have investigated whether metabolism also contributes to mechanosensing and mechanically-gated cell migration, known as durotaxis. We've found that mitochondria are recruited towards acute durotactic stretch. Moreover, LKB1 is locally activated in response directional increases in cell-ECM tension. Finally, silencing LKB1 expression disrupts Golgi reorientation and polarization in cells plated on substrates with graded rigidity and inhibits directional, durotactic cell migration. Thus, LKB1, a nutrient-sensing signaling hub, also senses mechanical cues and is required for proper durotaxis. These

observations provide an impetus and a foundation to further explore the molecular mechanisms linking metabolism, migration, and mechanobiology.

T cells switch between integrin-dependent and integrin-independent migration modes to migrate in complex environments

A. Caillier[1], D. Oleksyn[2], J. F. Miller[2], P. W. Oakes[1]; [1]Cell & Molecular Physiology, Loyola University Chicago, Maywood, IL, [2]Program for Advanced Immune Bioimaging, University of Rochester Medical Center, Rochester, NY.

Lymphocyte migration is essential to ensure a quick and efficient immune response. As they screen the body for antigen presenting cells, they are exposed to different complex environments composed of various extracellular matrix (ECM) components, architectures, and density. While previous work in vitro has shown that immune cells can migrate without integrin-dependent adhesion, other studies in vivo have shown that integrin-dependent adhesion is required to induce the migration of lymphocytes. This suggests that lymphocytes have multiple mechanisms of migration and can adapt to their environment, fluctuating between integrin-independent to integrin-dependent migration as needs of the environment demand.

Using primary t cells, we find that confinement is necessary to induce rapid and robust migration, independent of ECM composition. The presence of ECM proteins, however, does lead to a subtle but significant difference in migration speed and persistence. We also find in the presence of ECM proteins, T cells form focal adhesions that include clusters of integrins and adaptor proteins such as vinculin. When T cells are confined between two deformable surfaces, we can see that focal adhesions coincide with regions of traction stress as measured using Traction Force Microscopy. We find that traction stresses are exerted on both surfaces, though on occasion cells will pull only on one side, while pushing the other surface out of the way. Finally, using micropatterned surfaces we find that cells can switch between integrin-independent to integrin-dependent migration modes depending on whether the ECM coating is present.

Together these data illustrate that t cells are able to effortlessly switch between integrin-dependent and integrin-independent migration to maintain efficient migration, navigate a wide range of complex environments, and facilitate effective an immune response.

Elucidating Ca^{2+} effects on cell migration by resolving Ca^{2+}-adhesion interactions

H. Chen; National Taiwan University, Taipei, TAIWAN.

<META NAME="author" CONTENT="厚任 陳">Ca^{2+} is important for cell migration. However, whether Ca^{2+} augments or suppresses cell migration has remained controversial. One possibility is that Ca^{2+} help focal adhesion (FA) dynamics by improving both formation and degradation of FA complexes. Altering Ca^{2+} changes the balance between formation and degradation of FA, resulting in the increase or decrease of cell migration depending on basal adhesion status within the cell. Based on this hypothesis, we developed a mathematical model to predict cell migration using its levels and activities of Ca^{2+} and adhesion proteins. Then we used several cell lines to verify this model by perturbing their Ca2+ and adhesion molecules. Our preliminary data supported the validity of this model in head and neck cancer SAS cells, and in ovarian cancer JHOC-9 and OVTOKO cells, under genetic and pharmacological

perturbations of store-operated Ca^{2+} entry, ROCK and paxillin. We are now working on the examination of FA dynamics in these cell lines under various perturbations of Ca^{2+} and adhesion, with the ultimate goal to build an unified model explaining Ca^{2+} effects on cell migration.

Tks5 promotes lamellipodia and invadopodia formation to drive cancer metastasis

H. JUI-YU; National Taiwan University, Taipei, TAIWAN.

The malignant tumor is notorious for the abnormal growth and invasion into nearby tissue of cancer cells. It has been reported that Tks5, a critical scaffold protein of invadopodia, is highly expressed in many types of cancer cells. Tks5 binds to PI(3,4)P2 and interacts with many proteins responsible actin polymerization, leading to the speculation that Tks5 may have functions other than promote invadopodia formation, critical for cancer cell growth and metastasis.In this study, we found that Tks5 localizes not only to invadopodia, but also at lamellipodia, which is a branched actin-rich structure and is important for cell migration. To decipher Tks5 function in cancer cells, firstly we knockdown Tks5 in HT1080 and found a decrease of invadopodia and lamellipodia area. Similar effects were observed in cells stablely expressing or overexpression of Tks5 SH3A and SH3E domain in HT1080. Moreover, we demonstrate that the stably expressing or treatment of SH3 penetrating peptides can reduce migration velocity and extracellular matrix degradations well as their invasion ability. Our preliminary result also show that Tks5 is required for anchorage-independent growth of cancer cells. Taking together, we anticipate that Tks5 individual domain can compete against endogenous Tks5 for their binding partners and disturb the branch actin polymerization in both lamellipodia and invadopodia, and that makes treating cancer cell with Tks5 individual domain a potential therapeutic way to deal with invasive cancer cells.

B546/P2220

Pressure and stiffness sensing together regulate vascular smooth muscle cell phenotype switching

P. Swiatlowska[1], B. Sit[1], Z. Feng[2], X. Zhou[3], Q. Xiao[3], C. Shanahan[4], C. Yu[2], **T. Iskratsch**[1]; [1]School of Engineering and Materials Science, Queen Mary University of London, London, UNITED KINGDOM, [2]Hong Kong University, Hong Kong, HONG KONG, [3]Queen Mary University of London, London, UNITED KINGDOM, [4]King's College London, London, UNITED KINGDOM.

Atherosclerosis is considered the major underlying cause of cardiovascular diseases. Vascular smooth muscle cells (VSMCs) play a central role in the onset and progression of atherosclerosis. In pre-atherosclerotic lesions, VSMCs switch from a contractile (healthy) to a synthetic (disease) phenotype and subsequently remodel the microenvironment, leading to further disease progression. Several factors have been investigated that regulate this process, but the impact of the mechanical forces acting on the VSMCs has not been studied closely. However, especially, ageing and associated mechanical changes of the extracellular matrix - as well as hypertension are major risk factors for atherosclerosis. Consequently, we sought here to systematically study the impact of mechanical forces on VSMC phenotypic switching, by modulating individually and in combination the stiffness and hydrodynamic pressure. Phenotypic changes of primary human and bovine VSMCs and the A7r5 VSMC line were evaluated using quantitative proteomics, cell morphological and functional analysis (e.g. extracellular matrix degradation), as well as cell mechanical testing. Additionally, we confirmed our findings, using a mouse neointima model (after complete ligation of the left common carotid artery (LCCA)), where we

compared disease state, local tissue stiffness and protein expression and activity pattern.
Thereby, we surprisingly find that hemodynamic pressure and matrix compliance individually affect the VSMCs. However, only the combination of hypertensive pressure and matrix compliance result in a full phenotypic switch that leads to extensive cytoskeletal changes, podosome formation, extracellular matrix remodelling, and overall included 123 differently regulated proteins related to atherosclerosis, cytoskeletal organisation and podosome formation.
We further analyse the molecular mechanism in stiffness and pressure sensing and identify a regulation through different pathways, both converging on the same effector protein, cofilin. Downstream of stiffness sensing, the RhoA-ROCK-LIMK signalling pathway leads to increased cofilin activity, while on the other hand, hydrodynamic pressure induces podosome formation through an increase in intracellular Ca^{2+} concentration that regulates slingshot-dependent cofilin phosphorylation. Using knock down, small molecule inhibitor and activator treatment, we further find that the mechanosensitive Ca2+ influx depends on Piezo1 and activation of Piezo1 directly affects the phenotypic switching.
Altogether, our findings show that pressure and stiffness sensing regulate the VSMC phenotype through different pathways that converge on cofilin, ultimately promoting a switch to a synthetic phenotype in diseased conditions.

B547/P2221

Lipid-driven 2D phase separation of focal adhesion proteins

T. Litschel[1,2], C. Kelley[2], P. Schwille[2]; [1]Harvard University, Cambridge, MA, [2]Max Planck Institute of Biochemistry, Martinsried, Germany

Focal adhesions form liquid-like assemblies around activated integrin receptors at the plasma membrane. Made up of hundreds of proteins, focal adhesions are dynamic structures which can assemble and disassemble quickly, withstand strong actomyosin-applied forces, and form highly stable complexes. How they achieve these flexible characteristics is not well understood. Here, we use recombinant focal adhesion proteins to reconstitute the core structural machinery in vitro, with the goal of understanding the underlying protein dynamics and interactions. We observe liquid-liquid phase separation of the core focal adhesion proteins talin and vinculin for a spectrum of conditions and in combination with several interaction partners. Intriguingly, we show that membrane binding triggers phase separation of these proteins adjacent to the membrane, which in turn induces the enrichment of integrin in the clusters. We also introduce a novel experimental setup to probe talin-membrane interactions down to the single protein level. Our results suggest that membrane composition triggers condensate assembly at the membrane, a regulatory mechanism which could widely apply to membrane-localized biomolecular condensates and provide a pathway of how spatial organization of lipids within the membrane can couple into the cytosol.

B548/P2222

TIRF FRET Imaging of Adhesion ERK Activity

A. Shepherd, M. Mendoza; University of Utah, Salt Lake City, UT

Cell migration is a fundamental cellular process essential for development and wound healing. Unregulated cell migration also drives cancer metastasis. Most epithelial tumor cells move via mesenchymal model cell migration. Mesenchymal-mode migration begins with the advancement of the lamellipodia, where actin polymerization pushes against the cell edge and adhesions transmit traction

against the substrate as membrane tension increases. Extracellular signal-regulated kinase (ERK) has been found to control actin assembly and adhesion turnover, the key mechanisms of cell migration. Our objective in this project is to understand how fluctuations in ERK activity control adhesion dynamics. To do this, we developed a targeted FRET biosensor to detect ERK activity within nascent and focal adhesions. We have shown that the novel EKAREV-FAT biosensor localizes to adhesions. We found that EKAREV-FAT can be used to measure ERK FRET activity in adhesions in live cells using TIRF imaging. The probe responds to ERK activation and inhibition. We have determined the biosensor detects ERK activity on a timescale relevant to adhesion assembly/disassembly and protrusion/retraction of the lamellipodia. We have tracked and quantitatively analyzed adhesions, allowing us to classify adhesion size, turnover, orientation, and proximity to the edge while also measuring the FRET signal from each adhesion. By probing the spatially localized kinase activity signal, we will better understand how different signals to the actin cytoskeleton and adhesions are integrated during cell migration.

Cadherins and Cell-cell Interactions

Junctional endothelial F-actin bundles regulate size-selective permeability of the vascular barrier

M. Gronloh, W. VanderMeer, A. VanStalborch, J. VanRijssel, **J. Van Buul**; Amsterdam UMC, Amsterdam, NETHERLANDS.

At the interface of the circulation and the underlying tissue, the vascular endothelium forms a semi-permeable barrier that allows the regulated passage of small solutes, macromolecules, and immune cells. However, many cardiovascular and inflammatory diseases are characterized by reduced vascular integrity, demonstrated by reduced barrier function, leading to organ failure and ultimately death. To restore vascular integrity, intervention is directed to promote endothelial cell-cell junctions, although it is not clear how junction stability is regulated. Here we show that junction stability of endothelial cells is regulated by tensile junctional F-actin bundles, resulting in linear junction phenotype and increased barrier function. This increase in the barrier is independent of VE-cadherin. Mechanistically, we show that tight junction proteins Claudin-5 and ZO-1 are recruited by the guanine nucleotide exchange factor (GEF) Trio in a Rac1 and RhoG-dependent manner, to stabilize cell-cell junctions and regulate the passage of small molecules specifically. We propose that by bringing opposing membranes in close contact, these tensile actin-rich bundles support tight junctional pore assembly and the formation of a semi-permeable, size-restricted vascular barrier.

Podoplanin (PDPN) Enables Transformed Cells to Migrate and Escape Growth Control Mediated by Cadherin Junctions with Adjacent Nontransformed Cells

E. P. Retzbach[1], S. A. Sheehan[1], H. Krishnan[2], Y. Shen[1], J. P. Trama[3], H. Zheng[4], **G. S. Goldberg**[1]; [1]Rowan University, Stratford, NJ, [2]Stony Brook University, Stony Brook, NY, [3]Medical Diagnostic Laboratories, Hamilton, NJ, [4]Rutgers University, Piscataway, NJ.

Oncogenic Src tyrosine kinase activity induces PDPN expression to promote cell migration. However, effects of Src in the absence of PDPN expression has remained unexplored. We analyzed the effects of an inducible Src kinase construct on migration and anchorage independent growth of cells with and without PDPN expression. These data indicate that Src promotes anchorage independent cell growth in

the absence of PDPN expression. However, Src is not able to promote cell migration in the absence of PDPN expression. Phosphoproteomic analysis identified 28 proteins that are phosphorylated in Src transformed cells in a PDPN dependent manner. In addition, continued Src kinase activity is required for cells to assume a transformed morphology since cells reverted to a nontransformed morphology upon cessation of Src kinase activity. Nontransformed cells can also normalize the growth and morphology of neighboring Src transformed cells. Transformed cells must escape this process, called "contact normalization", to become invasive and malignant. However, junctions responsible for this process have not been defined. We found that N-cadherin (N-Cdh) can mediate contact normalization. Cells that express N-Cdh inhibit the growth of neighboring transformed cells in culture, while cadherin deficient cells do not inhibit the growth of these cells. Results from RNA-seq analysis indicate that about 10% of the transcripts affected by contact normalization rely on cadherin mediated communication, and this set of genes includes PDPN. In contrast, cadherin deficient cells do not inhibit PDPN expression or normalize the growth of adjacent transformed cells. These data indicate that nontransformed cells form heterocellular cadherin junctions to inhibit PDPN expression in adjacent transformed cells. Moreover, cadherin competent cells fail to normalize the growth of transformed cells expressing PDPN under a constitutively active exogenous promoter. Therefore, PDPN enables transformed cells to override contact normalization in the face of continued N-Cdh expression. Taken together, these results indicate that nontransformed cells form cadherin junctions with adjacent transformed cells to decrease PDPN expression in order to inhibit tumor cell proliferation, and that PDPN enables transformed cells to migrate and overcome growth inhibition by contact normalization.

B552/P2225

Translational Regulation by Desmosomes

D. Hlavaty[1], K. Badu-Nkansah[1], G. Bjerke[2], R. Yi[3], T. Lechler[1]; [1]Duke University, Durham, NC, [2]University of Colorado Boulder, Boulder, CO, [3]Northwestern University, Evanston, IL.

Desmosomes are cell-cell adhesion complexes that provide tissues with mechanical integrity. Desmosomal disruption results in severe blistering in the epidermis as well as cardiomyopathies. In addition to their canonical adhesive function, desmosomes have many emerging non-canonical functions such as regulating diverse signaling pathways and integrating cytoskeletal networks in keratinocytes. Recent work from our lab revealed a surprising recruitment of both translational machinery and the RNA-induced silencing complex (RISC) to the cell cortex by desmosomes. Using two distinct techniques, we observed that the cell cortex is a site of active translation in keratinocytes and that this localized translation requires desmosomes. We found that mRNAs for translational machinery were also enriched at the cell cortex. These transcripts share a 5'TOP motif, which can be bound by LARP1, a novel desmosome component also identified by our proteomics. We additionally identified the RISC-associated mRNAs using CLEAR-CLIP analysis which showed an enrichment for genes involved in wound healing and cell adhesion. Further, both in vitro and in vivo wound healing assays reveal that the RISC becomes depleted from the cell cortex of keratinocytes near the site of injury. Our results define a new function for desmosomes in translational regulation and suggest that they may act as sensors of adhesion integrity which can directly influence the cell's translatome to quickly restore homeostasis when it is disrupted.

Epidermal Stratification Requires Retromer-Mediated Desmoglein-1 Recycling

M. Hegazy[1], J. L. Koetsier[1], A. L. Huffine[1], J. A. Broussard[1], B. M. Godsel[1], E. Cohen-Barak[2], E. Sprecher[3], L. M. Godsel[1], K. J. Green[1]; [1]Northwestern University, Chicago, IL, [2]Emek Medical Center, Afula, ISRAEL, [3]Tel Aviv Medical Center and Tel Aviv University, Tel Aviv, ISRAEL.

Sorting transmembrane cargo is essential for tissue development and homeostasis. However, mechanisms of transmembrane sorting and trafficking during the development and regeneration of the stratified epidermis are not well characterized. Here, we describe a novel role for the endosomal trafficking complex, the retromer, in regulating epidermal differentiation and stratification. Through a BioID screen, we identified an interaction between the retromer component, VPS35, and the desmosomal cadherin, Desmoglein-1 (Dsg1), and validated this interaction through proximity ligation assay and co-immunoprecipitation. Dsg1 is first expressed in basal keratinocytes as they commit to differentiate and transit into the superficial layers of the epidermis. We previously showed that when properly localized on the plasma membrane of basal keratinocytes, Dsg1 promotes stratification. Here we show that VPS35 promotes recycling of Dsg1 from the endo-lysosomal system to the plasma membrane to promote basal keratinocyte transit into the next superficial layer. Increasing retromer stability and function with a small molecule chaperone, R55, enhanced retromer association with and plasma membrane localization of Dsg1 and a trafficking-deficient Dsg1 mutant that results in a systemic inflammatory condition called Severe dermatitis, multiple Allergies, and Metabolic wasting (SAM) syndrome. R55 also enhanced the ability of SAM-Dsg1 to induce stratification. Using a Dsg1 knockout mouse and SAM patient skin, we found Dsg1 disruption is associated with increased glucose transporter 1 (GLUT1) plasma membrane localization and retromer association. GLUT1 is a well known retromer cargo that regulates proliferation in basal keratinocytes and is upregulated in the inflammatory skin disease, psoriasis. Dsg1 overexpression results in the cytoplasmic accumulation of GLUT1 raising the possibility that the onset of Dsg1 expression during epidermal differentiation may initiate a switch in retromer cargo trafficking to decrease GLUT1 activity. Our work provides the first evidence for retromer function in epidermal regeneration, identifying it as a potential therapeutic target for epidermal diseases.

B554/P2227

Novel Mechanosensitive Junction Interactor Gish is Required for Apical Constriction and Epithelial Folding

R. Koran, M. Weng; University of Nevada Las Vegas, Las Vegas, NV.

Adherens junctions, the Cadherin-based cell-cell junctions that resist physical tension, often mediate mechanosensitivity during morphogenesis. During the internalization of Drosophila mesoderm, contractile actomyosin on the apical cortex drives apical constriction and epithelial folding. Strong adherens junctions are required in this process to connect actomyosin in individual cells into a supracellular network as well as protect tissue integrity. Our previous studies show that adherens junctions not only connect to but also are strengthened by actomyosin contraction, through growing in packing density and size. However, the molecular mechanism that mediates this junction strengthening is unknown. We have identified Drosophila casein kinase I gamma, Gilgamesh (Gish), as a potential mechanosensitive junction interactor. We found that in the resting state, Gish uniformly localizes to cell membrane. However, upon apical myosin activation in mesoderm cells, Gish appears to be recruited to

junction clusters. Myosin knockdown abolishes such cluster recruitment of Gish, while ectopic myosin activation is sufficient to recapitulate the recruitment. Gish cluster localization also depends on adherens junctions, since Gish can no longer be recruited into clusters in mutant embryos that lose core junction components such as alpha-catenin. Importantly, in Gish mutants, adherens junctions in the mesoderm cannot form large clusters in response to apical myosin contraction and appear to be diffuse on the apical surface. Additionally, large quantities of membrane tethers and blebs accumulate on the apical surfaces of these mesoderm cells. At the tissue levels, apical constriction cannot occur efficiently, leading to failure of epithelial folding. These data suggest Gish is a mechanosensitive junction interactor essential for epithelial tissue folding.

Investigating the Interaction of Inflammation-Associated Fibroblasts (IAFs) with Colon Epithelial Cells in Inflammatory Bowel Disease (IBD)

Y. Dong, B. Johnson, T. Larman, R. Li; Johns Hopkins University School of Medicine, Baltimore, MD.

Inflammatory Bowel Disease (IBD) is a chronic inflammatory disease that affects the epithelial lining of the gastrointestinal tract. Recent single cell RNA-sequencing (scRNA-seq) studies suggested that inflammation-associated fibroblasts (IAFs) play important roles in the disease pathogenesis and drug resistance. To elucidate IAF's role in IBD, we isolated fibroblasts from patients with IBD and profiled their responses to a panel of pro-inflammatory cytokines. We found a cocktail of the cytokines can induce IAF marker genes in the patient-derived fibroblasts. These cytokine-stimulated fibroblasts recapitulate many characteristics of IAFs, including increased ECM and chemokine secretion. Furthermore, when co-cultured with colon organoids, the cytokine-stimulated fibroblasts induce phenotypic changes in epithelial cells that mimic disease-related features of IBD. We are currently investigating the mechanisms underlying the observed IAF-epithelial cell interaction and will further validate the in vitro observations using biospecimens obtained from IBD patients.

B556/P2229

Mechanosensitive recruitment of Vinculin maintains junction integrity and barrier function at tricellular junctions in vertebrate epithelia

L. Van Den Goor, J. Iseler, A. L. Miller; Molecular, Cellular, and Developmental Biology, University of Michigan, University of Michigan, MI.

Epithelial tissues are critical for generating compartmentalized barriers to ensure proper organ function and prevent pathogen invasion. Apical cell-cell junctions, including adherens junctions (AJs), and tight junctions (TJs), must adhere cells to one another and regulate selective permeability at both bicellular junctions (BCJs) and tricellular junctions (TCJs). Although several specialized proteins are known to localize at TCJs, it remains unclear how actomyosin-mediated tension transmission at TCJs contributes to maintenance of junction integrity and barrier function at these sites. Here, we show that at baseline tension in the *Xenopus laevis* embryonic epithelium, Vinculin is localized in three "spots" surrounding the TCJ. When tension is increased, Vinculin is mechanosensitively recruited to TCJs, and the spots expand to form three elongated "spokes" around the TCJ. Vinculin is known to reinforce the connection between AJs and actomyosin under high tension. As TCJs are sites of locally increased tension in epithelial sheets, we predicted that Vinculin's mechanosensitive recruitment at TCJs anchors actomyosin bundles, and this organization might be important for maintaining junction integrity at TCJs. We first

investigated this idea using fluorescence recovery after photobleaching (FRAP) of mNeon-Vinculin. At baseline tension, Vinculin is more stable at TCJs than BCJs. Under increased tension, Vinculin's stability at BCJs increases such that it is similar to Vinculin's stability at TCJs. Furthermore, in Vinculin knockdown (KD) embryos both junctional and medioapical actomyosin are decreased and disorganized at TCJs. Additionally, Angulin, a key protein for regulating barrier function at TCJs, exhibits reduced stability by FRAP in Vinculin KD embryos compared with controls, suggesting that Vinculin helps stabilize the TCJ and that barrier function could be affected when Vinculin is depleted. To assay Vinculin's role in epithelial barrier function, we used ZnUMBA, a live imaging barrier assay that detects barrier leaks with high spatiotemporal resolution. Our preliminary data reveals increased barrier leaks at TCJs in Vinculin KD embryos compared to controls. Together, these experiments indicate that mechanosensitive recruitment of Vinculin to TCJs is essential for maintaining junction integrity and barrier function at TCJs.

B557/P2230

On the Formation of Ordered Protein Assemblies in Cell-cell Interfaces

N. Boni[1], G. Wiseglass[1], L. Shapiro[2,3], B. Honig[2,3,4,5], Y. Wu[6], R. Rubinstein[1,7]; [1]School of Neurobiology, Biochemistry and Biophysics, Tel Aviv University, Tel Aviv, ISRAEL, [2]Zuckerman Mind, Brain and Behavior Institute, Columbia University, New York, NY, [3]Department of Biochemistry and Molecular Biophysics, Columbia University, New York, NY, [4]Department of Systems Biology, Columbia University, New York, NY, [5]Department of Medicine, Division of Nephrology, Columbia University, New York, NY, [6]Department of Systems and Computational Biology, Albert Einstein College of Medicine, Bronx, NY, [7]Sagol School of Neuroscience, Tel Aviv University, Tel Aviv, ISRAEL.

During neural development, billions of neurons generate a complex network of interactions. Self-avoidance is one of the underlying mechanisms that support this process. Self-avoidance allows each neuron to self-recognize, thereby driving neurons to only interact with non-self neurons. In vertebrates, clustered protocadherins (cPcdhs) are a family of transmembrane proteins composed of approximately 60 different isoforms that mediate the self-avoidance process. Each neuron expresses a random set of approximately 10 isoforms. It is unclear how such a small set of isoforms allows self-recognition and non-self discrimination between billions of neurons. Recent studies suggest that an alternated homophilic interaction between cells (*trans*) and promiscuous interactions on the same cell (*cis*) results in the formation of one-dimensional zipper-like arrays of cPcdhs in the cell-cell interface. In this model, when both membranes express the same set of isoforms they form long one-dimensional zipper-like arrays. In contrast, a mismatch between those sets of isoforms prevents long zipper formation by chain termination. The objective of my research is to understand if these proposed zipper assemblies provide a platform with sufficient diversity required for neuronal self-avoidance. To accomplish this, I use a mesoscopic computer simulation that allows quick testing of numerous conditions. Our results indicate that the combination of *cis* and *trans* interactions leads to the formation of long zipper assemblies. Surprisingly, we found that zipper assemblies spontaneously stack into two-dimensional arrays. Such ordered organizations of proteins have been observed in previous studies that used cryo-tomography and our current results suggest that those two-dimensional arrays form without additional interaction sites. Since zipper-like assemblies have been observed in many other cell-adhesion proteins, these results might be of general relevance.

SGEF, a RhoG specific GEF, regulates E-cadherin stability, turnover, and transcription in epithelial cells

A. F. Rabino, R. Garcia-Mata; University of Toledo, Toledo, OH.

The canonical Scribble polarity complex, comprised by Scribble, Dlg1 and Lgl, plays a key role in the regulation of epithelial junctions and apical-basal polarity. However, little evidence is available regarding the molecular mechanisms that control its function. We have recently shown that SGEF, a RhoG specific GEF, forms a ternary complex with Scribble and Dlg1, and functions in the regulation of epithelial permeability and adherens junction (AJ) formation. Interestingly, when we silenced SGEF expression in MDCK cells, we observed a striking reduction of E-cadherin protein levels. Here, we characterized the molecular mechanisms that control the SGEF-mediated regulation of E-cadherin expression. Our results show that the exchange activity of SGEF is essential for the regulation of E-cadherin levels. In addition, we demonstrate that the activity of SGEF needs to be targeted to the basolateral membrane to efficiently regulate E-cadherin expression. Additionally, we observe a Src-dependent increase in p120 catenin phosphorylation in the absence of SGEF, which has been previously associated with increased internalization of E-cadherin. Supporting these results, we show that E-cadherin protein levels can be rescued by inhibiting Clathrin mediated endocytosis in SGEF KD cells. E-cadherin downregulation in SGEF KD cells appears to be mediated in part by proteasomal degradation, as inhibiting the proteasome partially rescued this phenotype. However, degradation did not completely account for the severity of E-cadherin downregulation. Besides proteasomal degradation, E-cadherin transcription is drastically reduced SGEF KD cells and correlates with an upregulation of its transcriptional repressor Slug. Taken together, our results suggest that the interaction with the Scribble complex, targets SGEF to the basolateral membrane in epithelial cells, where it mediates the localized activation of RhoG. This in turn regulates the stability, endocytosis, and transcriptional regulation of E-cadherin, and thus the formation and stability of AJ.

***Ctnnd2*controls layer-specific astrocyte morphogenesis by astrocyte-neuron cadherin interactions**

C. X. Tan[1], D. S. Bindu[1], N. Allen[2], P. Arlotta[3], C. Eroglu[1]; [1]Duke University, Durham, NC, [2]Salk Institute for Biological Studies, La Jolla, CA, [3]Broad Institute of MIT and Harvard, Cambridge, MA.

The brain is often perceived as a large network of interconnected neurons. A chemo-affinity code of cell adhesion molecules and diffusible cues specify which neurons synapse together to form circuits. However, the brain is composed of more than just neurons. Astrocytes are the most abundant glial cells of the brain. Astrocytes dramatically increase their morphological complexity during a critical window of cortical development overlapping with a period of peak circuit formation. A morphologically complex astrocyte has thousands of fine processes that can directly contact neurons and dynamically provide instructive cues for circuit formation, maturation, and function. However, little is known about the mechanisms underlying how astrocytes identify their specific neuronal partners. By conducting a candidate-based reverse genetic screen, we found that *Ctnnd2* (protein: δ-catenin) is expressed abundantly by astrocytes and is robustly required for neuron contact- dependent astrocyte morphological maturation. Prior to this, δ-catenin was widely assumed to be a neuron-specific protein. Knockdown of δ-catenin specifically in astrocytes results in a dramatic loss of astrocyte processes both *in vitro* and *in vivo*. Introduction of *CTNND2* autism mutations in rescue experiments implicated cadherin family of cell adhesion proteins to work upstream of δ-catenin. Cadherins are critical for circuit assembly

because they provide specificity information which enables correct matching of pre- and post-synaptic neurons. Our ongoing work is indicating that astrocytes utilize the neuronal cadherin code to establish astrocyte-neuron *trans*-interactions. These interactions are necessary for astrocyte morphogenesis in a cortical layer-specific manner. This study answers vital knowledge gaps in astrocyte biology by giving insight into the molecular mechanisms underlying astrocyte morphological complexity during development and how astrocyte-neuron interaction functionally specifies cortical heterogeneity. It also sheds light into the causes of synaptic defects and cognitive impairments observed in *CTNND2* autism mutations.

Topographical analysis of immune-cell contacts reveals the segregation of mechanical activities across immunity

M. De Jesus[1], A. Settle[1], D. Vorselen[2], M. Galiano[3], E. Santosa[1], P. Shah[4], J. Theriot[2], M. Huse[1]; [1]Department of Immunology, Sloan Kettering Institute, New York, NY, [2]Department of Biology, University of Washington, Seattle, WA, [3]Department of Developmental Biology, Sloan Kettering Institute, New York, NY, [4]Department of Cell & Developmental Biology, University of California, Los Angeles, Los Angeles, CA.

Autonomously acting immune cells execute their protective functions across vastly different tissue architectures in the body. We hypothesized that this challenge is met in part by the segregation of efferent immune-mechanical activities into discrete mechanotypes that correlate with distinct immune functions. To this end, we developed a novel experimental system to facilitate three-dimensional mechanical profiling of immune-cell targets: cells interacting with biomimetic hydrogel spheres are imaged by super-resolution microscopy, and the topographies induced by cells on these deformable targets are analyzed. We developed analysis approaches that: (1) identify mechanical features of interest for morphometry, (2) generate an average “radial mechanical profile” of a cell population, (3) cluster single-cell mechanical patterns by spatial frequency (Fourier) analysis, or (4) determine mechanical pattern complexity. This battery of biophysical analyses was applied to compare ontogenically and functionally distant leukocytes (i.e., phagocytes vs. synapse-formers), ontogenically close but functionally distinct leukocytes (i.e., cytotoxic vs. helper T cells), as well as a single functional subset of leukocytes across its developmental states (i.e., CD8+ cells throughout an infection to terminal exhaustion). By radial profiling, phagocytosis and synapsis could be classified as mechanically opposite patterns for the first time. Furthermore, different T-cell synapses exhibited different degrees of protrusive activity, with cytotoxic CD8+ T cells at the peak of infection exerting the most numerous and strongest pockets of concavity on their targets. Interestingly, the actin nucleation-promoting factor *WASp* appeared to differentiate lytic from non-lytic T-cell synapses, indicated by *WASp*-less CD8+ topographies clustering with CD4+ topographies. Lastly, different T-cell subsets and developmental states could be arranged along hierarchies of strength and pattern complexity, implying that dynamic mechanical complexity could help maximize perforin-mediated cytolysis. We found in each of these comparative cases differences in strength and mechanical patterning, suggesting that immune lineages also develop their own idiosyncratic mechanotypes. Together, these findings imply that distinct efferent mechanical activities contribute to overall immune protection.

Cellular Crowd Control: internal collective cell mechanics compete with external migration cues

G. Shim[1], I. Breinyn[1], A. Wolf[1], T. Zajdel[2], D. J. Cohen[3]; [1]Princeton University, Princeton, NJ, [2]Electrical and Computer Engineering, Carnegie Mellon University, Pittsburgh, PA, [3]Princeton Bioengineering Institute; Mechanical Engineering, Princeton University, Princeton, NJ.

Coordinated cellular migration, emerging from the interplay of cell-substrate and cell-cell forces, is as fundamental to multicellular life as it is beautiful, and underpins foundational processes spanning embryonic development, regeneration, and disease invasion. Given this importance, tools to program or 'herd' large-scale cell migration and tissue growth over thousands of cells in living tissues and organisms have great value. Our group is working on several strategies using external cues to reprogram and 'herd' collective cell migration. For instance, we routinely harness the 'electrotaxis'—directed cell migration along naturally occurring ionic gradients—to program large-scale cell migration using our SCHEEPDOG bioreactor. By manipulating electric fields similar to those found *in vivo (*1 V/cm), we can program both the speed and direction of collective cell migration. Here, we discuss how the internal, collective mechanobiology of the tissue appears to create a tug-of-war with the external 'command'. Our key observation was that tissues became more difficult to control with increasing cell-cell adhesion mediated by E-cadherin. Low levels of E-cadherin enabled smooth and stable migration control, while tissue with high levels of E-cadherin dramatically ripped themselves apart with high levels of cell death. Using inhibitory antibodies against E-cadherin, we proved that briefly disrupting E-cadherin coupling shortly before applying electrical stimulation rescued the tissue response, enabling strong migratory control with no cytotoxicity or mechanical damage and stable growth and expansion post-stimulation. Using this strategy, we were able to demonstrate accelerated healing of a scratch assay in a mature primary mouse skin monolayer. Further evidence of mechanobiological tug-of-wars between external and internal migration cues came when we evaluated both the spatiotemporal and relaxation responses of large tissues undergoing electrotaxis. Where cells are in a tissue determines how well they respond to an electrotactic command, with the greatest issues arising in regions known to possess high traction stresses. Moreover, we found that the stimulated tissue continued to move in the direction of the electric field, albeit more weakly, for hours after the field had been removed, indicating a large-scale reprogramming of the mechanical state of the tissue. While this work was performed using electrotaxis, there are numerous instances in natural systems where achieving appropriate or desired group behaviors requires dynamically tuning mechanical coupling amongst individuals, whether humans in a crowd or cells in a tissue.

Classical cadherins expressed in the central nervous system show higher evolutionary constraints and negative selection in primates as compared to non-neuronal cadherins

M. Petersen, F. Reyes-Vigil, **J. Bruses**; Mercy College, Dobbs Ferry, NY

Classical cadherins (CDH) comprise a family of single-pass transmembrane proteins that participate in tissue morphogenesis by regulating cell-cell adhesion, cytoskeletal dynamics, and gene expression. Their extracellular domain (ED) forms high-affinity homo and hetero trans-dimers between apposed cell membranes, and the cytoplasmic domain (CD) regulates the actin cytoskeleton and cell signaling through the binding to p120- and beta-catenin. CDHs are grouped into type I (CDH 1, 2, 3, 4 and 15) and type II (CDH 5, 6, 7, 8, 9, 10, 11, 12, 18, 20, 22, and 24) based on differences in ED folding. *CDHs* are

exclusively found in metazoans and their evolutionary origin and expansion coincide with the emergence of multicellularity and vertebrates respectively. This study examined the evolutionary rates of amino acid and nucleotide substitutions of *CDH* orthologs in fourteen species of primates representing tarsiers, old and new world monkeys, lesser and great apes, and humans covering ~60 million years of evolution. All *CDHs* have been under negative (purifying) selection; however, analysis of the ratio of non-synonymous nucleotide substitutions per non-synonymous sites (dN) over synonymous substitutions per synonymous sites (dS) show that the EDs of *CDH2* and *CDH4* have been under significantly higher negative selective pressure than *CDH1* (a type I prototype). The EDs of *CDH5*, *CDH19*, and *CDH24* have been under lower negative selection as compared to *CDH11* (a type II prototype), while the EDs of *CDH7*, *CDH8* and *CDH10* have been under higher negative selection. In contrast, the CDs of *CDH3*, *CDH6*, *CDH12*, *CDH18*, *CDH19*, *CDH22*, and *CDH24* have been under lower negative selection suggesting that some substitutions have been beneficial. These results show that trans-dimerization and regulation of cytoskeletal dynamics have been under independent selective pressures. Substitution rates in type I *CDHs* introns show no significant differences among *CDHs*, indicating that differences in selective pressure observed in protein coding sequences are not due to gene location. A Spearman's correlation analysis shows no significant correlation between gene essentiality and dN/dS ratios. In contrast, *CDHs* expression levels in various human and mouse tissues show a significant negative correlation between dN/dS ratios and *CDH's* expression in the central nervous system. These results suggest that the differences in negative selective pressure observed among classical cadherins is primarily driven by their role in neural development and synapse formation and their significance for the fitness of the organism.

B563/P2236

Determining the molecular interactions of the asymmetric planar cell polarity bridge

A. Goh, D. Devenport; Princeton University, Princeton, NJ

Planar cell polarity (PCP) is an evolutionarily conserved phenomenon in which cells collectively align their polarities across great distances along a single plane of a tissue during development. A defining feature of PCP is the asymmetric localization of its core components, where Frizzled localizes to one side of the cell and Vangl localizes to the other. A transmembrane cadherin, Celsr, localizes to both sides and engages in homophilic adhesion to stabilize Frizzled and Vangl between cells. In order to understand how the polarity is generated within a cell and subsequently propagated to millions of cells, the molecular interactions of PCP components must be characterized. To monitor the intracellular and intercellular protein-protein interactions necessary for the formation of the asymmetric PCP bridge, a junctional recruitment assay was utilized to dissect the mechanism of PCP protein localization, where primary mouse keratinocytes are transfected with PCP protein(s) tagged with a fluorescent protein to observe their localization at cell junctions between transfected neighboring cells after forming an epithelial sheet. In this system, overexpression of Celsr selectively recruits the Celsr-Frizzled PCP subcomplex to the cell-cell border in the adjacent cell, suggesting that unpaired Celsr is in a configuration that has higher affinity for Celsr-Frizzled than Celsr-Vangl.

The desmoglein 2 interactome in primary cardiomyocytes

Y. Li, **A. P. Campbell**, X. Zeng, N. A. Yates, A. V. Kwiatkowski; University of Pittsburgh, Pittsburgh, PA

Mechanical coupling and chemical communication between cardiomyocytes are accomplished through a specialized adhesive structure called the intercalated disc (ICD). The ICD is formed from three junctional complexes: adherens junctions (AJs) and desmosomes, both of which physically link apposing cardiomyocytes, and gap junctions that electrically couple cells. AJs and desmosomes connect the actin and intermediate filament (IF) cytoskeletons, respectively, of adjoining cells at the ICD and provide structural integrity and mechanical strength. The cardiomyocyte adhesive system is formed from a complex arrangement of molecular components with unique mechanical and signaling properties. How this system is organized at the molecular and cellular level to maintain adhesive homeostasis remains unclear. Previously, we used proximity proteomics to define the N-cadherin (CDH2) interactome in primary neonatal cardiomyocytes and identified adaptor and adhesion proteins that promote AJ specialization. Building from this work, we describe our efforts to define the desmosome interactome in cultured cardiomyocytes. We first measured protein dynamics using fluorescent recovery after photobleaching (FRAP) and show that desmosomal proteins are stable with dynamic properties similar to their AJ counterparts. We then combined quantitative mass spectrometry and proximity labeling to identify proteins associated with desmosomal cadherin desmoglein 2 (DSG2). We found over 300 proteins in the DSG2 interactome, and over half are shared with the CDH2 interactome. Shared hits include two proteins that associate with AJs and desmosomes, plakoglobin and plakophilin 2. Notably, plakoglobin and plakophilin 2 are among the most abundant proteins in both DSG2 and CDH2 interactomes, suggesting that the two proteins may coordinate adhesive complex formation along the ICD. Proteins unique to the DSG2 interactome include the gap junction protein connexin 43 as well as members of the plakin family of cytolinker proteins - desmoplakin, periplakin, and plectin. In contrast to the CDH2 interactome in neonatal cardiomyocytes, the DSG2 interactome is largely devoid of unique secondary scaffolding, adaptor, and/or cytoskeletal proteins that might assist in mechanical adhesion. We suggest that the desmosome core - desmosomal cadherins, plakophilin 2, plakoglobin, and desmoplakin - is sufficient for desmosome function and ICD organization in neonatal cardiomyocytes. In summary, our analysis of the DSG2 interactome adds a critical new dimension to the proteomic atlas of molecular complexes that regulate cardiomyocyte adhesion.

Exploring the function of Canoe's intrinsically disordered region in linking cell junctions to the cytoskeleton during morphogenesis

N. J. Gurley; University of North Carolina At Chapel Hill, Chapel Hill, NC

Noah J. Gurley[1], Rachel A. Szymanski[1], Kia Perez-Vale[2], Kristi Yow[1], Amber Butcher[1], Emily McParland[1], and Mark Peifer[1,3]Department of Biology[1], Curriculum in Genetics and Molecular Biology[2], Lineberger Comprehensive Cancer Center[3], University of North Carolina at Chapel Hill, North Carolina 27599-3280, USA

The remarkable ability of cells to change shape and move without disrupting tissue integrity is a hallmark of embryonic development. To do so, cells must link the contractile actomyosin cytoskeleton to cell-cell and cell-matrix junctions, and this linkage must be robust and dynamic. We have focused on the multidomain scaffolding protein Canoe (Cno), homologue of mammalian Afadin, which links the

cadherin-catenin complex to actin. It includes two N-terminal Ras-association (RA) domains – which bind the small GTPase Rap1 – followed by Forkhead-associated (FHA) , Dilute (DIL) and PSD95-Disc large-ZO-1 (PDZ) domains. These are separated from the C-terminal F-actin binding domain by a long intrinsically disordered region (IDR). IDRs are now recognized as important players in the multivalent interactions that assemble multiprotein complexes, including those that form phase-separated biomolecular condensates. One of our tasks is to define Canoe's mechanistic role, by taking it apart as a machine. We began by exploring the roles of its PDZ and F-actin binding domains, thinking they provided the direct linkage between cadherin and actin. However, deleting each domain had only modest effects on protein function. In contrast, the Rap1-binding RA domains were critical for Cno function. We now have returned to this analysis, exploring a surprising result from earlier work—protein null alleles of *canoe* have a milder zygotic phenotype than some "canonical" *canoe* alleles, whose defects in dorsal closure gave the gene its name. To explore this, we have sequenced a series of 22 EMS-induced *canoe* alleles; most result from premature stop codons arrayed across the coding sequence. Intriguingly, the strongest "canonical" alleles carry a stop codon early in the IDR. We suspect these alleles may encode a truncated protein that act in a dominant negative fashion, interfering with maternally contributed, wildtype Canoe protein. To test this, we are now exploring the function of this diverse set of Canoe proteins, examining both zygotic and maternal/zygotic mutants. In parallel, we are creating a new series of CRISPR-based mutants at the *cno* locus, including independent deletions of the IDR and DIL domains. Together, these approaches will help define the role of Canoe's IDR in protein function.

B566/P2239

Defining alpha-T-catenin interactions with plakophilin 2

E. Porter, J. Heier, A. Kwiatkowski; University of Pittsburgh, Pittsburgh, PA

Plakophilin 2 (PKP2) is a core component of the desmosome, a junctional complex that connects the intermediate filament cytoskeletons of neighboring cells. In cardiomyocytes, PKP2 is abundant at the intercalated disc (ICD), a specialized junction formed from desmosomes, adherens junctions, and gap junctions that permits adhesion and electrical signaling between cardiomyocytes. PKP2 mutations in humans are linked to arrhythmogenic ventricular cardiomyopathy (AVC), but relatively little is known about the function, the associations with other ICD proteins, and the pathogenesis of heart degradation in AVC. Alpha-T-catenin is an actin-binding protein that connects the cadherin-catenin complex to the actin cytoskeleton to form the adherens junction. Similar to PKP2, mutations in alpha-T-catenin are linked to AVC in humans. Past work has shown that alpha-T-catenin binds directly to PKP2. It is believed that alpha-T-catenin recruits PKP2 to the cadherin-catenin complex to create a unique hybrid junction. We hypothesize that the interaction between alpha-T-catenin and PKP2 functions to coordinate and strengthen intercellular adhesion in cardiomyocytes. To define the binding interface between alpha-T-catenin and PKP2, we constructed, expressed, and purified various fragments of the PKP2 in order to test their binding interactions with alpha-T-catenin using size exclusion chromatography (SEC) and pulldown experiments. Our results revealed that the binding interface in PKP2 lies within amino acid (aa) 73-229, in the unstructured N-terminus. In parallel, we expressed various fragments of PKP2 fused to EGFP in cardiomyocytes and assessed localization. Notably, full-length EGFP-PKP2 and endogenous PKP2 protein were not restricted to the desmosome in cardiomyocytes. Instead, this showed a broad distribution at cell-cell contacts and colocalized with adherens junction proteins. The PKP2 N-terminus (aa73-348) was required and sufficient for recruitment to cell-cell junctions whereas the armadillo region (aa341-837) was not. We speculate that PKP2 is recruited to the adherens junction through

alpha-T-catenin at cardiomyocyte cell-cell contacts to coordinate junctional and cytoskeletal organization.

Bioengineering of Cell-matrix Interactions

Biophysical programming and phenotypic switching of fibroblasts in tissue remodeling

H. Xiao[1], K. Sylla[1], B. Wilkowski[1], E. Mintah[1], D. Zhang[1], A. Zheng[1], X. Gong[1], E. Herzog[2], M. Mak[1]; [1]Department of Biomedical Engineering, Yale University, New Haven, CT, [2]Department of Medicine (Pulmonary, Critical Care and Sleep), Yale University, New Haven, CT.

Fibroblasts are versatile master regulators that can assemble, degrade, and remodel the extracellular matrix (ECM) in connective tissues. Although excessive tissue repair is associated with most fibrotic diseases, tissue destruction is observed in many end-stage lung diseases including idiopathic pulmonary fibrosis (IPF), termed honeycombing. However, it is not well understood how fibroblasts can be systematically programmed and tuned to transition between tissue maintenance and tissue destruction phenotypes. Our objective is to demonstrate that the biophysical states of fibroblasts are directly programmable and reversible, leading to tunable macroscopic tissue behaviors. We encapsulated fibroblasts in collagen and used molecular screens and gel compaction assay to dissect cell features including invadopodia, protrusions, and contractility. We further determined the impact of matrix properties including boundary conditions, collagen concentration, and crosslinking. Finally, we demonstrated clinical relevance via bioinformatic analyses of healthy vs. IPF patients. Our results showed that lung fibroblasts from both healthy and diseased individuals had the ability to produce holes and this process was upregulated by cytokines such as TGF-β. With high-resolution imaging, we showed that fibroblasts migrated through, densified, and ruptured collagen gels. We used correlation analyses and showed that MMPs were required for hole formation, and cellular contractility mediated hole enlargement. Denser, ribose-crosslinked, or non-anchored gels led to a reduction in hole sizes. We demonstrated that wound healing (hole closure) could be initiated by MMP inhibition and required myosin and ROCK. Finally, we leveraged bioinformatics and showed that many MMPs and invadopodia-related genes could be clinically relevant factors in IPF patients. In conclusion, our study details the phenotypic versatility and switching between tissue destruction and repair by fibroblasts and highlights remodeling events with implications for lung fibrotic disease. Our results suggest that fibroblast activities--the actomyosin machinery and MMP-related degradation--can be tuned to modulate fibrotic diseases and potentially restore tissue homeostasis.

Mechanical Memory Acquisition of Oral Squamous Cell Carcinoma (OSCC) and Biological Pathways Involved in the Process

S. Moon[1], P. S. Campos[2], B. F. Matte[2], J. K. Placone[3], V. G. Zanella[2], M. D. Martins[2], M. L. Lamers[2], A. J. Engler[1]; [1]University of California San Diego, La Jolla, CA, [2]Federal University of Rio Grande do Sul, Porto Alegre, BRAZIL, [3]West Chester University, West Chester, PA.

Oral cancer and oropharyngeal cancers' 5-year survival rate is 85% according to American Cancer Society, but it significantly decreases with regional or systemic metastasis. Oral squamous cell carcinoma (OSCC) accounts for 95% of all oral cancers. To improve prognosis of this cancer type, it is important to

study OSCC cell's metastatic features throughout the invasion process. In the previous study, we have shown that even non-invasive OSCC cell lines - FaDu and Cal27 - can demonstrate epithelial-to-mesenchymal transition (EMT)-like responses after being conditioned on stiff matrix (20 kPa polyacrylamide gel). To metastasize to the secondary tumor site, tumor cells must disseminate from stiffened tumor tissue and invade through surrounding softer parenchyma. Accordingly, we hypothesized that OSCC cells can acquire "mechanical memory" and the invasive features they have learned from stiffness can be maintained as EMT in the new niche. Cal27 cells were conditioned either by matrix stiffness or by contractility modulation with contractile agonists to acquire EMT markers, and then moved to a new niche (0.48 kPa PA gel) to mimic tumor cells facing softer tissue as they disseminate. Both stiff matrix and enhanced cell contractility allowed cells to have less localization of E-cadherin (epithelial marker) at the edge of the cell, higher expression of non-muscle myosin II A (NMMIIA), and higher migration speed than those without mechanical memory either due to absence of learning source or due to contractility inhibition by Blebbistatin. Phospho-kinase array indicated the possibility of AKT and FAK signaling pathways being involved in "learning" and "recovering" mechanical memory respectively, and inhibition of the pathways supported such possibility. Transcriptomic difference between cell populations with and without "mechanical memory" was identified by RNA sequencing. 822 deferentially expressed genes (DEGs) were identified, and 6 most significant up-/down-regulated genes (SDC4, ICAM1, FN1, ITGAV are up-regulated in the cells with memory, and RhoD and FSCN1 are down-regulated) were listed based on their expression rate. Stratifying TCGA patient data according to their genetic profile of 6 given genes, we could see that patient group whose genetic profile is closer to OSCC cells with mechanical memory has lower progression free interval and overall survival rate.

B569/P2242

Molecular Regulation of Hyaluronan Degradation in the Human Vocal Fold Fibroblasts under Stress

K. Basu, L. Mongeau; McGill University, Montreal, QC, CANADA.

Objective: Vocal fold (VF) scarring alters viscoelastic properties of the VF, and causes dysphonia. Hyaluronic acid (HA), a key polysaccharide is present in the lamina propria and regulates VF viscoelasticity, stiffness, and osmosis to initiate and maintain phonation. Thus, HA-based injectable biomaterials and hydrogels are in demand for vocal fold repair. However, one major drawback to using HA in composite biomaterials is its short residence time within VF. HA degradation releases low molecular weight (LMW) HA and HA oligosaccharides that may trigger inflammation in VF. Thus, the purpose of the current study was to understand the molecular steps regulating HA degradation and HA catabolic enzyme hyaluronidase and how HA degradation releasing LMW HA orchestrates vocal fold inflammation under stress. **Method:** The immortalized hVFF cell line was exposed to cigarette smoke extract (CSE). WST-1 assay determined cell survivability and the half maximal inhibitory concentration (IC_{50}) was calculated. qPCR and western blot assessed gene and protein expression respectively. CD44/HYAL2 interaction was studied by co-immunoprecipitation. **Results:** CSE suppressed the growth of hVFF in a dose-dependent manner and the upregulation of ECM marker (collagen) and inflammation marker (TGFβ1) confirmed the effectiveness of hVFF cells in CSE to mimic injured vocal fold. Significant upregulation of *HAS3* synthesizing LMW HA and *HYAL2* catabolizing HA ($p \leq 0.05$), suggests accumulation of LMW HA in the injured hVFF. Upregulation of HA receptor CD44 suggested that CD44 might play an important role in regulating HA catabolism. HYAL2 binds to CD44 ectodomain and CD44/HYAL2 interaction regulates HA degradation inside the cell. The enzymes (MT1-MMP and ADAM10) regulating

cleavage of CD44 ectodomain were upregulated in hVFF in CSE. Regulation of CD44 cleavage, CD44/HYAL2 binding, and inhibition of lysosomal degradation of HA was thought to regulate HA degradation in hVFF under stress. **Conclusion:** The study identified the principal steps regulating hyaluronidase activity and HA degradation in the VF inflammation. This is important to make a strategy to increase the stability of the HA-based biomaterials and hydrogel for VF and control inflammation.

Conductive Electrospun Polymer Platforms Improve Stem Cell-Derived Cardiomyocyte Function and Maturation

G. Gonzalez[1], A. C. Nelson[1], A. J. Whitehead[1], E. LaMontagne[1], R. Vatsyayan[2], S. Dayeh[2], A. J. Engler[1]; [1]Bioengineering, University of California, San Diego, San Diego, CA, [2]Electrical and Computer Engineering, University of California, San Diego, San Diego, CA.

Despite efforts to mature human pluripotent stem cell-derived cardiomyocytes (PSC-CMs) for disease modeling and high throughput screening, cells remain immature and may not reflect adult biology. Recent advancements utilize electro-mechanical and paracrine stimulation to functionally mature cardiomyocytes but continue to lack mature electrical conduction. Conductive matrices may facilitate electrical maturation between gaps in sparse PSC-CM clusters or between PSC-CMs that model conduction defects; hence, we electrospun and crosslinked poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) blended with 8% w/v poly(vinyl alcohol) (PVA) scaffolds. Matrix fiber structure remained stable over 4 weeks in buffer, stiffness remains near cardiac stiffness *in vivo,* and electrical conductivity scaled with PEDOT:PSS concentration. Electrically excitable PSC-CMs were cultured sub-confluently or as a monolayer. Cells adhered to all scaffolds, with increased desmoplakin (DSP) localization on conductive scaffolds, indicating an improvement in the mechanical stability of our PSC-CMs. Sarcomere organization also scaled with increasing PEDOT:PSS concentration, even in the absence of a uniform monolayer, suggesting that improved organization of the contractile machinery in these cells was due to the electrical condition of the matrix. Calcium handling indicated higher calcium flux with a shorter time to peak, further suggesting improved electrical maturity, even when sub-confluent. Taken together, these data suggest that PEDOT:PSS/PVA scaffolds are stable, of a stiffness relevant to cardiomyocytes, and supportive of electrical coupling even in the absence of a monolayer, which may improve cardiac disease modeling and drug development.

RGD peptide and glutamic acid crosslinked chitosan hydrogel promotes salivary gland cell acinar formation

K. Hozumi[1], C. Takahashi[2], M. Nomizu[3]; [1]Shigakkan University, Obu, JAPAN, [2]Kitasato Junior College of Health and Hygienic Science, Minamiuonuma, JAPAN, [3]Tokyo University of Pharmacy and Life Sciences, Hachioji, JAPAN.

Extracellular matrix (ECM) provides suitable biochemical and structural support to the tissue mimicked cell culture platforms, such as Matrigel. Designing the cell culture platforms mimicking the environment of the cells in vivo is useful strategy to develop the cell culture materials, and many materials have been used to mimic the structural and biological functions of basement membrane and ECM. Chitosan-based biomaterials have been used to perform as cell culture platforms. Here, we crosslinked chitosan, a polysaccharide containing many free amine groups, using dicarboxylic acids and conjugated ECM

derived active peptides to the chitosan hydrogel. Ten dicarboxylic acids were examined to obtain the chitosan solution and found that seven liner saturated dicarboxylic acids could solve the chitosan to the water. Adipic acid effectively generated transparent 3D hydrogels through the chitosan crosslinking. Dicarboxylic amino acids of glutamic acid (Glu) and aspartic acid (Asp) did not promote chitosan hydrogel by crosslinking, but mixed adipic acid/Glu generated hydrogels and its stiffness was regulated by the mixing ratio of adipic acid and Glu. These suggest that the stiffness of chitosan hydrogels is related and can control by the amount of Glu. Next, we conjugated ECM peptides to the chitosan hydrogel and examined its biological activities. We used ECM derived five ECM receptor specific binding peptides, such as fibronectin derived RGD (integrin alpahvbeta5 binding peptide), laminin alpha1 derived AG10 (integrin alpah6beta1 binding peptide), and laminin alpha1 derived AG73 (syndecan binding peptide). The peptide-chitosan/dicarboxylic acid hydrogel effectively promoted human salivary gland cell attachment. The biological activities of peptide-chitosan/dicarboxylic acid hydrogels were different depending on the ECM derived active peptide. After cell attachment, we cultured salivary gland cells for seven days on the peptide-chitosan/dicarboxylic acid hydrogel, RGD-chitosan/dicarboxylic acid hydrogel promoted differentiation and formation of acinar like structure as salivary gland cells cultured on Matrigel. The peptide-chitosan/dicarboxylic acid hydrogel could use to analyze the cellular functions mediated by specific cell surface receptors and have the potential to use as cell culture matrices of salivary gland cells.

The shape of a microfabricated scaffold can control cell protrusion and migration direction

H. Sunami; Faculty of Medicine, University of the Ryukyus, Okinawa, JAPAN.

The present study demonstrates unidirectional cell migration using a novel three-dimensional microfabricated scaffold, as revealed by the uneven sorting of cells into an area of 1 mm x 1 mm. To induce unidirectional cell migration, it is important to determine the optimal arrangement of three-dimensional edges, and thus, the anisotropic periodic structures of micropatterns were adjusted appropriately. The cells put forth protrusions directionally along the sharp edges of these micropatterns, and migrated in the protruding direction. There are three advantages to this novel system. First, the range of applications is wide, because this system effectively induces unidirectional migration as long as three-dimensional shapes of the scaffolds are maintained. Second, this system can contribute to the field of cell biology as a novel taxis assay. Third, this system is highly applicable to the development of medical devices. In the present report, we describe unique three-dimensional microfabricated scaffolds that provoked unidirectional migration of NIH3T3 cells. The three-dimensional scaffolds could provoke cells to accumulate in a single target location, or could provoke a dissipated cell distribution. Because the shapes are very simple, they could be applied to the surfaces of various medical devices. Their utilization as a cell separation technology is also anticipated.

Biomimetic extracellular matrix nanofibers electrospun with calreticulin promote synergistic activity for tissue regeneration

S. Mishra[1], M. E. Stack[2], M. P. C. Ratnamani[2], H. Wang[2], H. Wang[2,2,2], L. I. Gold[1]; [1]NYU Langone Health, New York, NY, [2]Stevens Institute of Technology, Hoboken, NJ

Electrospun nanofibers (NFs) are engineered to simulate extracellular matrix (ECM) scaffolds that provide biophysical and biochemical cues to elicit cellular responses favoring wound repair. Polycaprolactone-collagen I (PCL-Col1) NFs were electrospun with calreticulin (CRT; CRT-NFs), a protein that possesses numerous vulnerary effects including functioning as a chemoattractant for keratinocytes, fibroblasts and macrophages, the most important cells for wound healing. CRT potently enhances the rate and quality of wound healing in porcine and diabetic murine models; mice treated with CRT demonstrated tissue regeneration of excisional wounds marked by epidermal appendage neogenesis and lack of scarring. Poor healing chronic wounds, such as diabetic foot ulcers, is an unmet need due to lack of successful treatments. A major problem associated with chronic wounds is the paucity of granulation tissue from lack of cellular recruitment/migration, cell proliferation and ECM induction required for resurfacing and reconstructing the wound defect. We proposed that CRT sequestered into NFs would offer tunable delivery of CRT and protect the protein from proteolytic digestion by the abundant enzymes in wounds. Results show that following electrospinning 100 ng fluoresceinated CRT (Fl-CRT) into PCL-Col1 NFs, the NFs are architecturally unaltered with release kinetics of 50% in 24h, 77% in 96h with sustained release. Remarkably, CRT-NFs retained the ability to induce migration and proliferation of human keratinocytes and fibroblasts seeded onto the CRT-NFs equal to, or with statistically higher potency than CRT added exogenously to NFs. In addition, the dynamic expression of ECM proteins and integrins for migration was observed by fibroblasts seeded onto CRT-NFs: TGF-β1, TGF-β3, fibronectin, elastin, integrin β1, and integrin α5. Furthermore, NFs protected sequestered CRT from proteolytic digestion by common wound enzymes, Cathepsin G, elastase, lysozyme, and subtilisin [from bacteria] as shown by release of Fl-CRT electrospun into NFs compared Fl-CRT alone. Notable synergistic effects of CRT-NFs compared to NFs or exogenous CRT alone were CRT-NFs effect on basal exposure to fibroblasts and keratinocytes, which adapted a clear elongated migratory phenotype with increased expression of vinculin, stress fibers, and abundant migrasomes released by the cells. CRT within NFs is released over time, protected from proteolysis, and together CRT-NFs have synergistic activities providing a potentially improved topical therapeutic for tissue regeneration to compensate the lack of granulation associated with difficult to heal chronic wounds. In summary, we show that CRT can be electrospun into PCL-Col1 NFs without loss of wound healing related biological activities.

cRGD Surface Activity - How It Can Be Quantified, Compromised, and Controlled for Live-Cell Experiments

M. Robitaille[1], J. Christodoulides[1], P. Calhoun[2], J. Byers[1], M. Raphael[1]; [1]US Naval Research Laboratory, Washington, DC, [2]Nanocrine, Inc., Frederick, MD

RGD peptides play a crucial role in diverse areas of biological research, yet their applications in terms of surface functionalization are typically based on a set of assumptions rather than directly measured. To address this, we outline a methodology that can quantitatively measure the amount of RGD available to interface with cells (surface activity) and show that surface activity 1) can be significantly reduced by in-

vitro media constituents irrespective of RGD surface concentration, 2) directly influences cell behavior with regards to adhesion and migration, and 3) can be preserved/regenerated. First, surface activity is quantified by using identical surface functionalization protocols on a Surface Plasmonic Resonance (SPR) chip to serve as a concurrent control. Recombinant $\alpha_V\beta_3$ integrins serve as cell-free sensors to quantify cyclic RGD (cRGD) surface activity in a reliable and reproducible manner via SPR. Next, we show that commonly used agents in-vitro such as Bovine Serum Albumin (BSA), PLL-g-PEG, and Fetal Bovine Serum (FBS) are effective blocking molecules cRGD surface activity, highlighted by the addition of 1% FBS reducing cRGD surface activity 33-fold. We show that SPR surface activity measurements reflect the behavior of MDA-MB-231 cells atop similarly functionalized surfaces/environments in-vitro, in which changes in surface activity alter their migration and adhesion. Finally, we show that cRGD activity can be preserved in the presence of blocking molecules by utilizing recombinant $\alpha_V\beta_3$ integrins as a protective cap in-vitro.

Suspended Nanonets for Quantitative Cell Biology

N. E. Grega Larson, B. Behkam, A. Nain; Virginia Tech, Blacksburg, VA

Cell migration is defined as the directed movement of a cell or group of cells in response to chemical and/or mechanical signals. The extracellular matrix (ECM) acts as the “track” on which cells extend protrusions that sense these signals, and is comprised of individual and bundles of protein fibers that vary in diameter (nanoscale-to-microscale), orientation (random-to-aligned), and mechanical stiffness (soft-to-stiff). Thus, the ECM presents various curvatures and other topographical cues that in some cases lead to the initiation of cell migration. While the process of cell migration is essential for physiological and pathological processes in development, wound healing, the clearance of infections, and cancer metastasis, our understanding of how cell migration is controlled by the physical properties of the ECM is still lacking. Here, we demonstrate the ability to quantitatively measure protrusive, migratory, and force response behaviors of cells attached to various patterns of ECM-mimicking suspended fibrous nanonets, which are fabricated using our non-electrospinning Spinneret-based Tunable Engineered Parameters (STEP) platform. By visualizing cells cultured on suspended nanonets, we discovered that the tips of cell protrusions *wrap around* ECM fibers, termed coiling, and the amount of coiling and the size of protrusions increase as fiber diameter increases. Furthermore, differences in directed cell migration can be measured as a function of ECM architecture by depositing fiber networks in various organizations (aligned vs. crosshatched). For example, we observe differences in cell behavior on suspended nanonets versus flat 2D culture in contact inhibition of locomotion and chemotaxis, suggesting that differences in the physical attachments a cell makes with its surroundings are sufficient to control its behavior. Finally, we have pioneered Nanonet Force Microscopy (NFM) to measure cell forces originating at focal adhesion sites that direct along actin stress fibers. NFM data show that force increase with fiber diameter due to an increase in both focal adhesion cluster length and stress fiber number. Overall, our low-cost, well-defined and repeatable, and high throughput platform quantitatively evaluates cell behavior at single-cell resolution, and better recapitulates the environment that cells experience *in vivo* as compared to flat 2D culture methods.

Developing Decellularized Plant Scaffolds as a 3D in vitro Cell Culture Platform

C. A. Sword, K. E. Kubow; James Madison University, Harrisonburg, VA

Current 3D in vitro cell culture models are typically simple gels of biological and/or synthetic components or precisely structured synthetic scaffolds. While both approaches have benefits, the former are often too structurally simplistic while the latter require equipment and expertise not typically found within biological laboratories. One simpler and more easily accessible option is to create cellulose-based scaffolds with complex 3D structures by decellularizing plant tissues. Our aim was to develop such a scaffold from the tissue of the stem of a common broccoli plant. We selected broccoli stem because of its open mesh structure, which could provide a mimetic for connective tissue. The scaffolds were produced by decellularizing thin slices of broccoli stem with concentrated sodium dodecyl sulfate, followed by washing and sterilization in a series of water, ethanol, and PBS solutions. The successful removal of plant cells was assessed by staining with a live/dead stain (calcein AM and propidium iodide). Only a small number of plant cell nuclei remained along the edges of the scaffolds, likely due to the thicker exterior tissues of the stem. These areas were easily trimmed. The scaffolds consisted of a meshwork of pockets with diameters of 24.4 +/- 5.9 µm (mean +/- standard deviation) as assessed using calcofluor stain and confocal microscopy. Rheological measurements revealed that the scaffolds had a bulk shear modulus on the order of kilopascals.We cultured MEFs (mouse embryonic fibroblasts) on the cellulose-derived scaffolds for up to one week to demonstrate the scaffolds' ability to support cell growth. The cells colonized the pockets left behind by the broccoli cells and remained viable. Although most cells were localized to the outer edges of the scaffold, we found that minor mechanical disruption of the scaffold structure enabled greater cell attachment and invasion. Future experiments will include optimizing cell seeding and studying extracellular matrix deposition.

Regulation of Aging

Determining Parkinson's Disease causing variants in PRKN using a pooled FACS-based screen

A. J. Gilsrud, J. A. Thayer, D. P. Narendra; NINDS, NIH, Bethesda, MD.

Parkinson's disease (PD) is the second most common neurodegenerative disease after Alzheimer's Disease. The characteristic motor symptoms in PD are due to degeneration of dopamine neurons within a region of the midbrain called the *substantia nigra pars compacta*. Approximately 500,000 Americans are diagnosed with PD. 5-10% of Parkinson's disease cases are caused by genetic mutations, with loss of function mutations in *PRKN* (coding for the protein Parkin) being the most common cause of autosomal recessive Parkinson's disease. The pathogenicity of many *PRKN* missense variants, however, remains unknown. Indeed, we recently found that approximately 1% of individuals carry a rare *PRKN* missense variant of unknown significance, complicating genetic counseling (Zhu et al., in press). To resolve this uncertainty, we generated a pooled cDNA library of all rare Parkin missense variants in publicly available databases as well as alanine substitutions of critical Parkin residues (599 variants in total). The Parkin variants in the library were additionally tagged with YFP. Therefore, the effect of each mutation on Parkin stability can be determined. Finally, we developed a novel FACS based screening approach to resolve the functional status of each variant, using a single-cell reporter of Parkin function. As an initial assessment of feasibility, we single cell sorted the high and low Parkin activity populations and grew up

the resulting single cell clones. As expected, all (3/3) of the high single-cell clones had Parkin function, whereas 60% (3/5) of the low function single-cell clones did not. From four of these clones, we identified two novel loss of function Parkin variants and two benign Parkin variants. We are now developing a next-generation sequencing approach to test the library as a pool to differentiate benign mutations from loss of function mutations. The structural relationship of these variants will be assessed by mapping them onto the solved structures of Parkin in its auto-inhibited and active states. We anticipate the results of this study will help resolve the functional consequence of *PRKN* variants in the population and additionally reveal novel structural requirements for Parkin activity.

Lewy-body associated proteins suppress α-synuclein toxicity under respiratory growth

B. Gillespie, R. P. Almazan, A. P. Almazan, P. Shirahatti, R. Santhanakrishnan, I. Haider, Z. Paxhia-poppaw, E. Manishimwe, S. Ju, Q. Zhong; Wright State University, Dayton, OH.

A pathological hallmark of Parkinson's disease is the formation of Lewy bodies, primarily composed of abnormal protein aggregates of α-synuclein. The accumulation of α-synuclein in neurons causes dosage-dependent cytotoxicity. This toxic phenotype has been recapitulated in a simple eukaryote, *Saccharomyces cerevisiae.* Genetics screens using yeast models have led to the discovery of several hundred modifier genes and critical cellular processes driving α-synuclein toxicity. Most of these yeast models rely on the use of the *GAL1* promoter to induce gene expression. The *GAL1* promoter is activated by a fermentable carbon source, galactose. Yeast cells do not require full mitochondrial function, such as oxidative phosphorylation, to grow on galactose. Accumulating evidence supports a role of mitochondrial dysfunction in neurodegenerative disease. The dispensable mitochondria in yeast models grown on galactose represents a missing cellular context for studying the toxicity of α-synuclein. Here, we developed a new yeast model to express α-synuclein when cells are forced to respire on a non-fermentable carbon source. We found that α-synuclein is more prone to form aggregated cytoplasmic structures and to induce mitochondrial damage and cell death under respiratory growth. We reasoned that previous genetic screens in yeast have not uncovered the full spectrum of genetic modifiers of α-synuclein toxicity. By performing a genome-wide overexpression screen, we identified a set of Lewy-body associated proteins and their corresponding yeast homologs exhibiting conserved protective effects on cells against α-synuclein toxicity. These Lewy-body associated proteins are not uncovered in previous genetic screens. Expression of these proteins also reduces the accumulation of cytoplasmic structures and mitochondrial defects induced by α-synuclein. Our data support that mitochondrial function is a critical cellular context for understanding α-synuclein pathology.

Relevance of Rhomboid-like Protease-4 mediated Amyloid Precursor Protein Processing in Alzheimer's Disease.

Y. Penalva, S. Recinto, L. Munter; McGill University, Montréal, QC, CANADA.

Alzheimer's disease (AD) is a neurodegenerative disorder characterized by progressive impairments in cognitive functions and affects 32 million people worldwide. Autosomal dominant inherited mutations causatively link the amyloid precursor protein (APP) to AD and one of its proteolytic cleavage products via the canonical amyloidogenic pathway, Aβ peptides, is a hallmark of AD. While APP's relevance in the pathogenesis of the disease is clear, its physiological functions remain poorly characterized. Unveiling

APP's functions and defining the triggers leading to Aβ production are crucial to determining the cellular conditions underlying AD. We have discovered a novel processing pathway of APP mediated by the endoplasmic reticulum resident rhomboid-like protease-4 (RHBDL4). We have shown in Human Embryonic Kidney 293T (HEK293T) cells that RHBDL4 cleavage results in decreased total APP and Aβ levels. In this study, we aim to determine the physiological relevance of this pathway in AD. We crossed an AD mouse model expressing a mutated form of APP only in neurons (hAPP J20) to a RHBDL4 global knockout (KO) mouse. hAPP J20 mice show cognitive defects at 4 months of age and increased hippocampal Aβ production starting 6 to 36 weeks of age. We assessed cognition using the Y maze and the Novel Object Recognition (NOR) test and found a rescue of cognition in female hAPP J20 mice in the absence of RHBDL4 at 5 months of age. Interestingly, when we quantified total APP and Aβ levels from brain samples using western blot and Enzyme Linked Immunosorbent Assay (ELISA) respectively, we found a significant increase for both when knocking out RHBDL4 in the hAPP J20 females. These results confirmed the absence of correlation between Aβ and cognition, but most importantly RHBDL4's relevance for APP physiology *in vivo*. We aim to further confirm the effect of RHBDL4 on APP total levels and processing as well as on cognition using RHBDL4 KO and knockdown models in mouse embryonic fibroblasts (MEFs) and HEK293T cells. Specifically, we have shown in RHBDL4 KO MEFs that β-catenin protein expression is increased, possibly hinting at a greater activation of the Wnt/β-catenin pathway whose decreased signaling has been published to underlie cognitive defects in the hAPP J20 model. Herein, we propose to use RHBDL4 as a new tool to further our knowledge on APP's functions and AD pathology.

Reduced expression of the cell intrinsic clock protein Bmal1 in myeloid cells accelerates cognitive decline and alters microglial function in aging mice

C. Iweka, E. Seigneur, A. Latif-Hernandez, S. Herrera Paredes, M. Cabrera, E. Blacher, Q. Wang, F. Longo, L. DeLecea, K. Andreasson; Stanford University, Stanford, CA.

Neuron-microglia interactions are critical to maintaining neural circuitry and function. Microglia are myeloid-lineage cells that possess an intrinsic time-keeping system that regulates its function to anticipate changes in its external environment. This time-keeping system, the circadian clock, diminishes with aging, and disruption of the circadian rhythmicity impairs neuroinflammatory responses in microglia. Several studies have demonstrated that tissue-specific deletion of Bmal1, a transcription factor and regulator of circadian rhythms, can accelerate aging, for example the development of sarcopenia in muscle, bone calcification in bone and cataracts in the eye. Here, we tested the hypothesis that Bmal1-deficient microglia disrupts essential neuron-microglia interactions that ultimately impair neuronal circuits and function in aged mice. We show increased microglial activation with decreased expression of lysosomal proteins, CD68 and LAMP1. Bmal1-deficient microglia also exhibited alterations in expression of complement proteins, C1q and C3. Altogether, this resulted in decreased microglia-mediated synaptic engulfment and consequently increased dendritic spine density in the hippocampus that caused deficits in LTP and cognitive impairment. Furthermore, the sleep-wake cycle, critical for synaptic remodeling was significantly impaired. These results highlight the significance of maintaining the cell-intrinsic circadian clock system in myeloid cells, and its contribution to neuron-microglia interactions.

Exploiting age-dependent biomechanical features of single cells for disease detection and prevention.

S. Hinz[1], M. Miyano[1], A. Manousopoulou[1], R. W. Sayaman[1,2], K. Y. Aguilera[3], M. E. Todhunter[1], J. C. Lopez[1], L. D. Wang[1], L. L. Sohn[4], M. A. LaBarge[1]; [1]City of Hope, Duarte, CA, [2]University of California, San Francisco, CA, [3]David Geffen School of Medicine at UCLA, Los Angeles, CA, [4]University of California at Berkeley, Berkeley, CA.

Age is the major risk factor in most carcinomas, yet little is known about the specific reasons aging increases cancer susceptibility. In mammary gland, luminal epithelial cells are thought to be the breast cancer cell of origin. Dysregulation of keratin intermediate filament proteins is a hallmark age-dependent change in luminal cells, which implicates mechanical states that are unique to cancer susceptible cells. We implemented mechano-node-pore sensing (mechano-NPS), which is a powerful tool in multi-parametric single-cell analysis that simultaneously measures cell diameter, resistance to compressive deformation, transverse deformation under constant strain, and recovery time after deformation. We identified mechanical phenotypes that distinguish human mammary epithelial cells by lineage, age, and cancer progression stage. A machine learning model accurately predicted the chronological age of average risk epithelial cells based exclusively on mechanical properties of single cells. Application of the model to cells from women who are germline carriers of high-risk cancer-causing mutations showed that they are mechanically old irrespective of their chronological age, suggesting that mechanical states could be a window into detection and prevention of cancer susceptible states. Mass spectrometry and cell-based functional assays were used to dissect the molecular underpinnings of age-dependent changes in the mammary epithelium. Cytoskeleton related proteins keratin 14 (KRT14) and pseudopodium enriched atypical kinase 1 (PEAK1) were key drivers of the age-dependent mechanical signatures. Pharmacological and gene silencing approaches that targeted KRT14 and PEAK1 were able to modulate the mechanical age of HMEC and, in the case of PEAK1 modulation, ablate luminal epithelial cells in an age and lineage dependent manner. Our work has assessed the intersection between mechanical phenotypes and novel age-dependent proteins that can be exploited to assess breast cancer susceptibility and reveal vulnerabilities that can be exploited for prevention.

Missorting of Plasma miRNAs in Aging and Alzheimer's Disease

M. Čarna[1], J. S. Novotný[1], N. Dragišič[1], H. Slavik[2,3], K. Sheardova[1,4], Y. E. Geda[5], M. Vyhnalek[1,6], J. Laczo[1,6], J. Hort[1,6], Z. Mao[7], R. A. Rissman[8], M. Hajduch[9], E. B. Dammer[10], G. B. Stokin[1,11,12]; [1]International Clinical Research Centre, St. Anne's University Hospital, Brno, Czech Republic, St. Anne's University Hospital Brno, Brno, CZECH REPUBLIC, [2]Institute for Molecular and Translational Medicine, Faculty of Medicine and Dentistry, Palacky University Olomouc, Olomouc, CZECH REPUBLIC, [3]Department of Neurology, University Hospital Olomouc, Olomouc, Czech Republic, Olomouc, CZECH REPUBLIC, [4]1st Department of Neurology, Masaryk University, Brno, Czech Republic, Brno, CZECH REPUBLIC, [5]Department of Neurobiology, Barrow Neurological Institute, Phoenix, AZ, USA, Phoenix, AZ, [6]Memory Clinic, Department of Neurology, 2nd Faculty of Medicine, Charles University and Motol University Hospital, Prague, Czech Republic, Prague, CZECH REPUBLIC, [7]Department of Pharmacology and Chemical Biology, Emory University School of Medicine, Atlanta, GA, USA, Atlanta, GA, [8]Department of Neurosciences, University of California San Diego, La Jolla, CA, USA, San Diego, CA, [9]nstitute for Molecular and Translational Medicine, Faculty of Medicine and Dentistry, Palacky University Olomouc, Olomouc, CZECH

REPUBLIC, [10]Department of Biochemistry, Emory University School of Medicine, Atlanta, GA, USA, Atlanta, GA, [11]Division of Neurology, University Medical Centre, Ljubljana, Slovenia, Ljubljana, SLOVENIA, [12]Department of Neurosciences, Mayo Clinic, Rochester, MN, USA, Rochester, MN.

Aging is the greatest risk factor for Alzheimer's disease (AD)[1], a pervasive cognitive disorder with unsettled etiology. The precise role of aging in AD, however, remains poorly understood. Accumulating evidence documents the dysregulation of circulating microRNAs (miRNA) separately in aging[2,3] and AD[4]. Considering miRNAs play a role in aging and longevity[5,6], we comprehensively test which aging-associated miRNA changes are observed in AD, and change in AD beyond aging in the circulating miRNA network. Here we show that plasma miRNAs in aging are downregulated and preferentially targeted to extracellular vesicle (EV) content, while in AD, miRNAs are further downregulated and of exclusive EV origin. We further show that miRNAs in AD display altered proportions of motifs relevant to their loading into EVs[7,8] and secretion propensity[9]. Considering endosomes play a role in the genesis of EVs[10,11] and are compromised early in AD[12], these findings implicate endosomal pathology underlying the AD plasma miRNA profile and its potential as a mechanistic AD biomarker. Striking similarities between plasma miRNA profiles in aging and AD further suggest that the AD miRNA network profile reflects a pathological exacerbation of the aging process whereby physiological suppression of AD pathology by plasma miRNAs becomes insufficient.

Effect of fine particles driven pollution combined to UV exposure on keratinocytes 2D culture and reconstructed 3D skin models

E. Leblanc-Noblesse, L. Sobilo, J. Sage, K. Pays, C. Nizard; LVMH Recherche, Saint Jean de Braye, FRANCE.

INTRODUCTION: Skin is the largest and outermost organ of the human body, which makes it an important barrier against external aggressions. Due to its stratified epithelium formed by layers of keratinocytes and the lipophilic film on its surface, skin is impermeable to most molecules and microorganisms. However, to date, there are some pieces of evidence that describe the adverse effects of pollutants on keratinocyte physiology and metabolism. These pollutants and particularly fine particles associated with UV Irradiation are known to disrupt skin homeostasis. Indeed, in addition to oxidative stress and the ensuing inflammation, we have brought to light numerous structural modifications such as alteration of the skin barrier and metabolic activity as well as a degradation of the extra-cellular matrix.

MATERIALS AND METHODS: Different categories depending on the size of the fine particles were tested in this study: PM2.5, PM10 and Urban Dust. These particles associated or not with UVB Stress were either applied to a cell culture of normal human keratinocytes (NHK) or on a reconstructed skin model and different end-point analyses were carried out: A gene expression profiling (TLDA technology) where genes were specifically selected for their biological functions relevant to pollution, ATP quantification, inflammatory cytokines assay using the multiplex technology and imaging techniques (immunostaining and confocal microscopy) to assess the protein expression of cutaneous markers.

RESULTS: The results of the various experiments showed that pollution driven by fine particles coupled to UV irradiation is able to induce numerous skin deleterious phenomena such as a strong induction of pro-inflammatory cytokines, a decrease in cellular energy, a high oxidative stress and the degradation of extracellular matrix components. These results allow us to bring forward that chronic exposure to pollutants, associated with solar irradiation, enhances premature skin aging.

B585/P2257

Cell size and growth rate affect the proteome and modulate cell senescence

E. Zatulovskiy[1], M. Lanz[1,2], S. Zhang[1], J. Elias[2], J. Skotheim[1]; [1]Department of Biology, Stanford University, Stanford, CA, [2]Chan Zuckerberg Biohub, Stanford, CA.

Cell size is tightly controlled in healthy tissues, but it is unclear how deviations in cell size affect cell physiology. To address this, we measured how cell proteome changes with cell size. We found that size-dependent protein concentration changes are widespread and predicted by subcellular localization, size-dependent mRNA concentrations, and protein turnover. As proliferating cells grow larger, concentration changes typically associated with cellular senescence are increasingly pronounced, suggesting that large size may be a cause rather than just a consequence of cell senescence. Consistent with this hypothesis, larger cells are prone to replicative, DNA damage-, and CDK4/6i-induced senescence. Moreover, we found that size-dependent changes to the proteome, including those associated with senescence, are not observed when an increase in cell size is accompanied by an increase in ploidy. In addition to the proteomic changes, large cells also have lower specific growth rates. That both the cell's proteome and growth rate change with cell size suggests they may be interdependent. To test the role of size-dependent growth rate decrease in proteome remodeling, we used quantitative mass spectrometry to measure how the cell proteome changes in response to the mTOR inhibitor rapamycin, which decreases cellular growth rate and has only minimal effect on cell size. We found that large cell size and mTOR inhibition, both of which lower the growth rate of a cell, remodel the proteome in similar ways. This suggests that many of the effects of cell size are mediated by the size-dependent slowdown of the cellular growth rate. Importantly, size-dependent changes to the cell's growth rate and proteome composition are still apparent in cells continually exposed to a saturating dose of rapamycin, indicating that cell size can affect the proteome independently of mTORC1 signaling. Taken together, our results clarify the dependencies between cell size, growth, mTOR activity, and the proteome remodeling that ultimately controls many aspects of cell physiology.

Metabolic gating of misfolded protein import into mitochondria

Y. Wang[1], L. Ruan[1], J. Zhu[2], A. Chang[3], X. Zhang[1], A. Tomaszewski[1], R. Li[1,2,3]; [1]Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, [2]Mechanobiology Institute, National University of Singapore, Singapore, SINGAPORE, [3]Department of Chemical and Biomolecular Engineering, Johns Hopkins University Whiting School of Engineering, Baltimore, MD.

Metabolic imbalance and loss of proteostasis are common hallmarks of ageing. At the nexus of them are mitochondria, the key organelles that control cellular metabolism and influence proteostasis. The 'mitochondria as guardian in cytosol' (MAGIC) pathway represents an example in which mitochondria import and degrade misfolded proteins (MPs) concentrated on the cytosolic surface of mitochondria. This study investigates how mitochondria maintain a delicate balance of metabolic and proteostasis functions. By performing a genome-wide screening in yeast, we identified the yeast Snf1 protein kinase and its mammalian ortholog AMP-activated protein kinase (AMPK) as the master regulator of the permissibility for MPs to enter mitochondria. Activation of Snf1 upregulates the expression of nuclear encoded mitochondrial genes and inhibits the import of MPs in a manner dependent on downstream transcription factors. This inhibition is orchestrated through multiple mechanisms, including substrate

competition, translocon selectivity, and elevated expression of two outer membrane proteins. By limiting the mitochondrial entry of MPs under Snf1 activation and glucose restriction, cellular fitness and mitochondrial capacity are protected under stress associated with MPs. We also show that Snf1/AMPK prevents the mitochondrial accumulation of disease-related misfolding-prone proteins such as FUS, suggesting a novel link between metabolic states and proteinopathies.

B587/P2259

Regulation of age-associated insulin resistance by MT1-MMP-mediated cleavage of insulin receptor

X. Guo, Z. Bian, H. Wong; Hong Kong Baptist University, Hong Kong, Hong Kong

Insulin sensitivity progressively declines with age. Currently, the mechanism underlying age-associated insulin resistance remains unknown. Here, we identify membrane-bound matrix metalloproteinase 14 (MT1-MMP/MMP14) as a central regulator of insulin sensitivity during ageing. Ageing promotes MMP14 activation in insulin-sensitive tissues, which cleaves Insulin Receptor to suppress insulin signaling. MT1-MMP inhibition restores Insulin Receptor expression, improving insulin sensitivity in aged mice. The cleavage of Insulin Receptor by MT1-MMP also contributes to obesity-induced insulin resistance and inhibition of MT1-MMP activities normalizes metabolic dysfunctions in diabetic mouse models. Conversely, overexpression of MT1-MMP in the liver reduces the level of Insulin Receptor, impairing hepatic insulin sensitivity in young mice. The soluble Insulin Receptor and circulating MT1-MMP are positively correlated in plasma from aged human subjects and non-human primates. Our findings provide mechanistic insights into regulation of insulin sensitivity during physiological ageing and highlight MT1-MMP as a promising target for therapeutic avenue against diabetes.

Differential transcriptional and splicing profile in POLR3A-mutated Wiedemann-Rautenstrauch syndrome fibroblasts

G. Arboleda, D. Santos-Gil, P. Gaete, C. Arboleda-Bustos, H. Arboleda; Universidad Nacional De Colombia, Bogota, Colombia

Introduction: Wiedemann-Rautenstrauch syndrome (WRS) is a rare disease characterized by premature neonatal aging, caused by mutations in the RNA polymerase 3 subunit A (POLR3A) gene. POLR3A has important roles in regulating the transcription of small RNAs, including tRNAs, 5S rRNA and snRNA 7SK. However, the mechanisms of cellular senescence and accelerated aging in WRS are not fully understood. **Aim:** To determined differentially expressed genes and intron retention events, as well as key metabolic pathways underlying WRS from RNA-Seq data by using bioinformatic methods. **Methodology:** Primary fibroblasts from forearm skin biopsies of two WRS patients (WRS1 and WRS2) with distinct monoallelic heterozygous POLR3A mutations and control cells matched for age and gender were cultured. Total RNA was extracted and Paired-ended RNA-seq libraries were constructed using the TruSeq Strand mRNA LT Sample Prep Kit and sequenced using the Illumina NovaSeq 6000. Differential gene expression analysis was performed using DESeq2 to identify differentially expressed genes (DEGs) between WRS datasets and controls. Intron retention detection was analyzed using IRFinder. Enrichment analysis was performed by Gene Ontology and the Kyoto encyclopedia of genes and genomes pathways. **Results:** 592 DEGs for WRS1 and 984 DEGs for WRS2 were obtained compared to the control group. Additionally, 204 genes were found in common between the two WRS datasets, of which 136 were upregulated and 68 downregulated. The functional enrichment analysis showed that the PI3K-Akt signaling pathways,

organization of the extracellular matrix, retinol metabolism and regulation of the inflammatory response were found to be commonly enriched in the patients. In addition, 24 differentially expressed introns were detected between WRS patients and control. The percentage of genes with intron retention was 8,14% in WRS1, 6,28% in WRS2 and 7,8% in control. Transcripts with intron retention in WRS patients were involved in RNA-binding, cell cycle regulation and transcription regulation. **Conclusions:** This study identified key genes and signal pathways which might help us improve our understanding of the mechanisms involving POLR3A in the physiopathology of WRS.

Analysis of the role of the POLR3A gene in cellular senescence: Wiedemann-Rautenstrauch syndrome as a model

G. Arboleda, K. Velásquez-Méndez, H. Arboleda; Universidad Nacional De Colombia, Bogotá, Colombia

Analysis of the role of the POLR3A gene in cellular senescence: Wiedemann-Rautenstrauch syndrome as a modelK.L. Velásquez-Méndez[1], H. Arboleda[1,2], G. Arboleda[1,3,*1]Grupos de Neurociencias y Muerte Celular, Instituto de Genética y Facultad de Medicina; [2]Departamento de Pediatría; [3]Departamento de Patología, Universidad Nacional de Colombia, Bogotá, Colombia.
*gharboledab@unal.edu.co**Introduction:** Wiedemann-Rautenstrauch syndrome (WRS), also called neonatal progeria, is an extremely rare disease characterized by premature aging at birth, pseudo-hydrocephalus, triangular face with prominent forehead and veins, intrauterine and postnatal growth retardation, as well as absence of subcutaneous fat, osteopenia, presence of neonatal front teeth and scoliosis. In the scientific literature, at least 35 cases have been described, of which 60% are Colombian cases. Previous studies have associated WRS with biallelic mutations in the *POLR3A* gene as responsible for the senescent phenotype. **Aim:** Here we report the results of gene expression level analysis of the RPC1 protein encoded by the *POLR3A* gene for two WRS patients whose mutations were previously reported in the literature, as well as the effect of these mutations on the expression of the senescence-associated protein p53. **Methodology:** Through the expression levels of the RNA polymerase III reporter genes (5SrRNA, tRNA-Leu-CAA and 7SK RNA), the effect of WRS mutations in the transcription of the RNA polymerase III complex was analyzed, as well as the effect on the expression of 18S and 28S ribosomal subunits to assess ribosomal biogenesis. Measurements of the mitochondrial membrane potential were also performed. Finally, using the fibrillarin nucleolar protein, the size of the nuclei and nucleoli and their relationship with premature aging were also analyzed. **Results:** It was found that the *POLR3A* gene mutations c.3772_3773delCT (p. Leu1258Gly*) and c.3G>T (p. Met1?) cause destabilization of the RNA polymerase III complex, causing deregulation of the transcription of its target genes which affects vital processes for the cell, such as ribosomal biogenesis and mitochondrial function. Furthermore, fibroblasts from WRS patients show nucleolar disruption, deregulation of ribosomal biogenesis affecting global protein synthesis as well as mitochondrial dysfunction. In addition, mutations in the *POLR3A* gene induce activation of p53 in the nucleus, as well as activation of pH2AX in response to DNA damage, which is associated with normal human aging. **Conclusions:** These results open new alternatives to study cell senesce and human aging.**Acknowledgements:** Funded by DIB-Universidad Nacional de Colombia and MINCIENCIAS (#844-2019).

Lovastatin enhances follicular development in mice ovaries

Y. Kim[1], Y. Cho[2], J. Jang[3], Y. Koo[3], S. Park[1], J. Lee[1,3]; [1]CHA Fertility Center Seoul Station, Seoul, Korea, Republic of, [2]Wonju Severance Christian Hospital, Wonju-si, Korea, Republic of, [3]CHA University, Pocheon, Korea, Republic of

Ovarian aging is not reversible through the pathophysiological mechanism underlying the poor follicular development. Steroidogenesis in the oogenesis and follicular development for ovulation is highly complicated processing and several factors are involved depending on the follicle stage. The starting point of steroidogenesis is an influx of cholesterol from extracellular fluid using LDLR signaling. The up-regulation of low-density lipoprotein receptor (LDLR) correlates with clinical pregnancy during in vitro fertilization for humans. Therefore, we investigated that Lovastatin is a LDLR enhancer for hyper-ovulated stimulation for promoted ovulation and steroidogenic activity of the ovary. We injected the lovastatin to hyper-stimulated mouse ovaries and analyzed its follicular development. We confirmed the follicular development and the number of oocytes through the histological analysis and counting of ovulated oocytes. And the mRNA and protein isolated from the ovary were compared and analyzed gene expression through real time-PCR and western blot regarding follicular development and steroidogenesis genes. Body weight increased less in the lovastatin treated group than control. LDLR was expressed in ovaries and was 40% higher in lovastatin-treated ovaries than control ovaries. The number of oocytes increased 20% for lovastatin-treated ovaries than control. And maturation ratios of lovastatin-treated GV oocytes significantly increased compared to the control group. The hyper-ovulated mouse ovaries treated with lovastatin increased the expression of LDLR and StAR (Steroidogenic acute regulatory protein) which are components of the steroidogenesis pathway. In conclusion, we found that the role of lovastatin promotes follicular development by increasing the LDLR genes in the ovary of mice. Previous data shows that activation of LDLR and StAR was associated with follicular development in infertile women. Therefore, further investigation is needed to test the effect of lovastatin on human ovary. Our data suggests that lovastatin has stimulated LDLR expression to enhance ratio of follicular development in the ovaries.

Characterization of intra and sub-cellular deposits in mono and polygenic retinal degenerations using iPSC-derived retinal pigment epithelium

R. Sharma, M. Farnoodian, D. Bose, D. Ortolan, K. Miyagishima, K. Bharti; NEI/NIH, Bethesda, MD

Retinal pigment epithelium (RPE) is a monolayer of hexagonal cells located at the back of the eye; it provides nourishment and support to photoreceptors (PR) and choroidal capillaries (CC), phagocytosis of photoreceptor outer segments (OS) and polarized cytokine secretion for maintaining outer retina homeostasis and normal vision. Dysfunctional RPE, which is likely caused by aging and environmental factors, results in the degeneration of other retinal layers and causes vision loss. The hallmark phenotypic features of degenerating RPE includes intra and sub-cellular deposits. These are the common phenotypes across different retinal degenerative disorders. The underlying factors and pathways involved the biogenesis of lipid and protein-rich intra and sub-cellular deposits are still not entirely well understood. We have established induced pluripotent stem cell (iPSC) derived RPE model for monogenic (Stargardt, L-ORD) and polygenic (AMD) retinal degenerations to study lipids and protein deposits. In addition, we exploited LC-MS and MALDI-TOF imaging to understand the composition of these deposits

in different retinal degenerative diseases. iPSC-RPE are seeded on a porous plastic membrane and cultured for five weeks. Mature RPE cells from Stargardt and L-ORD patients were fed with OS for seven days and tested for the accumulation of sub-RPE deposits. The AMD model was developed by using an activated alternate complement stressor. SubRPE deposits can be labeled for APOE and lipid deposits by Nile red and BODIPY dyes. In the case of LC-MS, cells were collected and analyzed for lipidomics, while MALDI-TOF imaging was carried out on a porous decellularized membrane. Our data revealed that RPE cells from Stargardt and L-ORD patients recapitulated the intra and sub-cellular lipid deposits. With LC-MS on Stargardt patient-derived iPSC-RPE, we discovered higher amounts of sub-species of ceramide. While MALDI-TOF revealed differences in subRPE deposit composition between different diseases. In conclusion, we created RPE models to study the RPE-deposit biogenesis and their composition in different retinal degenerative diseases.

The functional landscape of an Alzheimer's disease risk factor
Z. March, P. Narayan; NIH/NIDDK, Bethesda, MD

APOE alleles are the strongest genetic modifiers of late-onset AD risk. *APOE* exists in three common alleles (*E2, E3,* and *E4*) that encode three apolipoprotein E (APOE) variants, which differ from one another at only two amino acid sites (112 and 158). Whereas the most common allele, *APOE3*, is neutral with respect to AD risk, *APOE4* is the most highly-validated risk factor for sporadic late-onset AD. In contrast, *APOE2* is considered protective due to its decreased association with AD. Moreover, rare variants have recently been uncovered that appear extraordinarily protective even against familial AD. Here, I present our progress to define the functional landscape of APOE. We have identified multiple rare coding variants as determinants of APOE conformation and have begun to delineate how specific variants affect neurodegenerative disease-associated phenotypes in human iPSC-derived neural subtypes. These studies begin to comprehensively address how genetic variation within *APOE* affects AD risk and resilience.

Cell Death

Associate Professor
Y. Wan[1], J. M. Salinas[2], X. Li[3], T. Li[3], Y. Zhang[3], E. Slevin[2], **F. Meng**[2]; [1]Dept. of Pathophysiology, Southwest Medical University, Luzhou, CHINA, [2]Indiana University School of Medicine, Indianapolis, IN, [3]Southwest Medical University, Luzhou, CHINA.

Transcribed ultraconserved regions (T-UCRs) are long non-coding RNAs (lncRNAs) that are transcribed from ultraconserved regions (UCRs) in the human genome. Accumulation of senescent hepatocytes may contribute to loss of functional hepatic mass and lead to alcoholic liver decompensation and fibrosis. The current study aimed to characterize the functional role of T-UCR regulated cellular senescence during alcoholic-associated liver diseases (ALDs). Senescence related T-UCR and gene expression was assessed using microArray, the cellular senescence PCR Array/Assays in ethanol- and LPS-treated normal human hepatocytes (N- Heps), as well as in liver specimens from a mouse model of chronic and binge ethanol feeding (the NIAAA model) relative to control liver tissue. Cellular senescence was measured by SA-β-gal Activity assay. We identified that chronic and binge ethanol feeding significantly increased the

expression of uc.189, total liver histopathology score and hepatocellular senescence by PCR array and SA-β-gal assay, along with the reduced expression of let-7a microRNA. Overexpressing of let-7a has significantly reduced uc.189 expression and blocked enhanced cellular senescence in ethanol and LPS treated N-Heps. Silencing of uc.189 has also decreased ethanol and LPS-induced senescence and increased viability in N-Hep cells. TLR4 knockout mice and lin28 knockout mice with reduced uc.189 /enhanced let-7a expression displayed less sensitivity to alcoholic injury, along with enhanced SA-β-gal activity and reduced expressions of α-SMA, Col1A1 and TIMP-1. Silencing uc.189 by TLR4/lin28 depletion also significantly reduced hepatic p53, PAI-1 and EGR1 expressions in chronic and binge ethanol feeding mice, suggests a critical role of specific T-UCR regulated cellular senescence during ALD. Our findings provide new insight into the function of long non-coding RNA regulated cellular senescence and testing novel therapeutic approaches for human alcoholic liver diseases. Mitochondrial localized novel protein Cux1 (p75) regulates mitophagy & ER stress induced cell death

A. Paripati, A. Pal, N. Sepuri; University of Hyderabad, Hyderabad, INDIA.

Mitochondria, apart from its most prominent function in ATP generation, are also involved in key cellular events like calcium signaling, lipid and amino acid metabolism, ROS signaling, regulation of cell death. Given the importance of mitochondria in cellular homeostasis, it is required to maintain mitochondria in healthy state. Mitochondria communicates with other organelles for its functions and quality control. Mitochondria and ER are known to form closely associated networks that are structurally and functionally essential to maintain cellular homeostasis and the fate of cell under various pathological conditions depends on this network. In this study we report that one of the isoforms of homeodomain transcription factor Cux1(p75) localizes to outer membrane of mitochondria. Functional studies in knock-down and overexpression of Cux1 show that it regulates the mitophagy by stabilizing the PINK1 upon mitochondrial depolarization. Additionally, it is also involved in ER-Mitochondrial interaction and ER-stress mediated cell death by specifically interacting with Mfn2. This study uncovers the possible new mechanism of ER-Mitochondrial interaction and mitophagy.

Cell survival following direct executioner caspase activation

M. Nano[1], J. A. Mondo[1], V. Balasanyan[2], G. Sun[3], D. J. Montell[1]; [1]UCSB, Santa Barbara, CA, [2]UCLA, Los Angeles, CA, [3]Shandong University, Jinan, CHINA.

Executioner caspase activation has long been considered a point-of-no-return in apoptotic cells. However, some studies report that cells can recover from caspase activation after treatment with drugs or radiation. An open question is whether cells can recover from direct caspase activation without drug-induced pro-survival stress responses. To address this question, we engineered a HeLa cell line to

express an inducible caspase-3 instead of the endogenous enzyme together with a quantitative caspase activity reporter. We measured the level and rate of caspase activity in individual cells over time and demonstrate that cells can survive direct effector caspase activation. Furthermore, we show that the dynamics and amount of caspase activity is insufficient to predict cell death vs. survival. These results indicate that pre-existing differences in cellular state modify the threshold of caspase activity required to irreversibly commit cells to die. Such differences may underlie incomplete tumor cell killing in response to apoptosis-inducing cancer treatments such as radiation and chemotherapy.

Silencing BAX Inhibitor 1 (BI-1) sensitizes senescent pulmonary fibroblasts to ER stress mediated apoptosis

D. W. Moore[1], J. G. Fernandez-Davila[1], S. Bui[1], S. D. Nathan[2], L. R. Rodriguez[1], G. M. Grant[1]; [1]Department of Biology, George Mason Univeristy, Manassas, VA, [2]Advanced Lung Disease and Transplant Program, Inova Fairfax Hospital, Falls Curch, VA.

Idiopathic pulmonary fibrosis is characterized by an abundance of highly secretory apoptotic resistant fibroblasts. We have previously demonstrated that IPF fibroblasts (IPF-F) are also resistant to oxidative stress and ER stress. The IRE1α; arm of the unfolded protein response (UPR) is critical to the fate of highly secretory cells under ER stress. UPR activation promotes IRE1α; dimerization, leading to the degradation of mRNA transcripts and splicing of the XBP-1 transcription factor. Multiple IRE1α; modulating proteins including BAX Inhibitor 1 (BI-1) are upregulated in IPF-F. As an inhibitor of IRE1α; BI-1 is a potential mediator for apoptosis resistance in IPF-F under ER stress. We hypothesis that inhibition of this pathway may alter apoptosis resistance.Senescence in primary fibroblasts was measured by β-Galactosidase staining and telomere length analysis via QPCR. Immunohistochemistry was performed to measure expression of BI-1 in donor lung tissue. IPF-F and normal human lung fibroblasts (NHLF) were transfected with siRNAs targeting BI-1, IRE1α;, and BAX. IRE1α; signaling was assayed via QPCR of: *XBP*, *HO1*, *SEC61A*, *ERO1A*, and *ERDJ4*. Cell proliferation markers *p21, Bcl-xL,* and *Cyclin D* were measured by qPCR and western blot. Cell viability was measured via Cell Titer Glo viability assay.IPF-F as compared to NHLF showed increased senescence, decreased expression of proliferation associated genes, increased expression of cell cycle arrest genes. Increased BI-1 expression was observed in primary IPF lung tissue and fibroblasts. Silencing BI-1 under conditions of ER stress reduced the percentage of senescent cells. BI-1 deficient IPF-F and NHLF demonstrated an increase in percent XBP-1 splicing. Measurement of RNA expression in BI-1 silenced fibroblasts showed an upregulation in *HO1* and *ERDJ4* and no change in *SEC61A* and *ERO1A*. Silencing of BAX and IRE1α; under conditions of ER stress induced by tunicamycin challenge resulted in decreased cell viability of both IPF-F and NHLF.The silencing of BI-1 under conditions of ER stress promoted the preferential clearance of senescent IPF-F. A potential mechanism for this may be the increased IRE1α; signaling activity under silencing conditions. In comparison, NHLF showed only a mild increase in IRE1α; activity under the same conditions. These data reinforce that BI-1 acts as a survival mechanism against ER stress in IPF-F and the differential response to BI-1 silencing suggests that this could serve as a potential target for future therapeutics.

Identification of genes that alter cancer cell sensitivity to DNA damage/OXPHOS inhibition using CRISPR screening

X. Kong, A. Bayrakci, C. Umemura, K. Yokomori; UC Irvine, Irvine, CA.

A major characteristic of cancer cells is their increasedreliance on glycolysis to maintain cellular homeostasis (Warburg effect).Recent evidence indicates, however, that the oxidative phosphorylation (OXPHOS)pathway remains critical for cancer cell survival. Our recent study indicatesthat cancer cells increase their metabolic reliance on OXPHOS in order tosurvive in the presence of DNA damage when poly(ADP-ribose) polymerase 1 (PARP1)is activated. To understand the molecular pathways underlying the metabolic switchthat promotes cell survival in response to DNA damage, we performed CRISPR libraryscreening in cells with DNA damage (MMS) with and without OXPHOS inhibitor rotenone(R). We found several PARP1 sgRNAs as the top hits for enrichment for MMS+R treatedcells, which is consistent with our previous study, confirming that OXPHOSsuppresses parthanatos (PARP-dependent cell death). We also found sgRNAsagainst MIR378G in the drop-out screen in MMS-treated cells whose mutation isknown to increase DNA damage sensitivity. These results provide strong supportfor the authenticity of the screening. Interestingly, we found that multiplesgRNAs specific for hexokinase 2 (HK2) and Phosphofructokinase, platelet (PFKP),two critical enzymes in the glycolysis pathway, were among the top hits on theenrichment list for MMS treatment (but not for MMS+R), suggesting thatsuppression of the glycolysis pathway promotes damaged cell survival. PARP1 wasshown to inhibit HK in response to stress/damage, which was simply thought to causedeleterious energy deprivation and cell death. Our results strongly suggestthat glycolysis inhibition actually has pro-survival effect, possibly byenforcing the metabolic switch to OXPHOS. For MMS+R, we found enrichment ofmultiple sgRNAs against subunits of two distinct ubiquitin (Ub) E3 ligasecomplexes that both mediate histone ubiquitination. We also found threesubunits of an Ub-dependent histone methyltransferase (HMTase) complex. Theresults were further confirmed using individual sgRNAs against candidate genesin HeLa cells expressing Cas9. Ourfindings raise the possibility that coordinated functions of these histonemodification enzyme complexes may be a major driver of parthanatos, which isnormally suppressed by OXPHOS. Ourresults reveal a link between metabolic and epigenetic regulations in responsesto DNA damage critical for cell survival.

B598/P2270

Analysis of a role for Mitochondria Associated ER Membranes in Compartmentalized Cell Elimination

A. Elkhalil, R. Sharmin, K. Juanez, Y. Mohamed, G. Clark, P. Ghose; University of Texas At Arlington - Arlington, TX, Arlington, TX.

Programmed cell death is a vital cell fate for normal development and homeostasis. Morphologically complex cells are known to have elaborate processes, such as axons and dendrites in neurons. While complex cells are commonplace, how their programmed elimination takes place is not well understood. Also elusive is how their elimination under pathological conditions or following injury occurs. We introduce a 'tripartite' killing program called Compartmentalized Cell Elimination (CCE) that eliminates two cells of the nematode *C. elegans* during its embryonic development-the morphologically complex tail-spike cell (TSC) and the sex-specific CEM neurons. CCE is characterized by three cell compartments dying in three different ways. Strikingly, the single process/dendrite of these cells demonstrates two completely different elimination modalities in its two segments, each reminiscent of different types of

developmental pruning. The proximal segment fragments in a manner similar to injury-induced Wallerian degeneration of axons, while the distal segment withdraws/retracts into itself. We find that soma-directed transport and confinement of mitochondria are necessary for CCE initiation. We have also found that genes promoting endoplasmic reticulum (ER) network stability promote process degeneration during CCE.Mitochondria-Associated ER Membranes (MAMs) are regions of the ER tethered to mitochondria that mediate communication between ER and mitochondria. MAMs are known to be involved in calcium homeostasis, lipid synthesis and cell death signaling. Recent studies also show the connection of MAMs to neurodegenerative diseases. We seek to look at the roles of MAMs in CCE. Our preliminary results show exaggerated mitochondria when ER network stability is compromised. Using tri-color imaging of the ER, mitochondria, and TSC, we plan to further look at the nature of mitochondria in these ER stability mutants and look at the involvement of the mitochondrial fusion machinery in mitochondrial elaboration. Conversely, we also plan to study the nature of the ER in mitochondria trafficking and dynamics mutants. Together we aim to understand novel roles of MAMs in CCE and by extension developmental pruning and neurodegeneration.

Mitochondria-targeted anti-oxidant mitoquinone suppresses benign prostatic hyperplasia via regulation of AR-NLRP3 pathway

B. Jin[1], H. Kim[2], T. Gil[1], H. An[1]; [1]Kyung Hee University, Seoul, KOREA, REPUBLIC OF, [2]Sangji University, Wonjusi, KOREA, REPUBLIC OF.

Mitoquinone (MitoQ), a mitochondria-targeted anti-oxidant agent, has been estimated in several diseases. Previous studies have demonstrated its anti-inflammatory and anti-proliferative potential. Nevertheless, the effect of MitoQ on the development and progression of BPH remains unclear. The present study aimed to investigate the therapeutic effects of MitoQ on BPH models and molecular mechanism(s) underlying its effects on BPH. Anti-proliferative and anti-oxidant functions of MitoQ were evaluated in dihydrotestosterone (DHT)-stimulated prostatic cells. The binding between MitoQ and NLRP3 was estimated using docking assay. The effects of MitoQ were estimated in testosterone-induced BPH animal model. The levels of AR and NLRP3 were analyzed using immunoblotting, qRT-PCR and IF assay. MitoQ inhibited AR/NLRP3 signaling and mitochondrial ROS induced by DHT in prostatic epithelial cells. Molecular modeling revealed the interaction between NLRP3 NACHT and MitoQ. Prostatic cell proliferation induced by testosterone was suppressed by oral administration of MitoQ in BPH rats model. In addition, MitoQ exerted pro-apoptotic activity and anti-oxidant effects via inhibition of AR and NLRP3 signaling pathway. Our results present anti-proliferative, anti-oxidant and pro-apoptotic effects of MitoQ in androgen-induced BPH models, suggesting MitoQ as a direct inhibitor of NLPR3 and therapeutic agent for treatment of BPH. ▣ This research was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (Grant No. NRF-2022R1A4A3019157 and NRF-2021R1A6A3A01086659).

B600/P2272

Pituitary tumor-transforming gene 1 (PTTG1) modulates the growth of oral squamous cell carcinoma by regulating double-strand DNA break

S. Park[1], J. Jung[2], S. Lee[1], J. Choi[1]; [1]Oral Pathology, Gangneung-Wonju National Universityniversity, Gangneung-si, KOREA, REPUBLIC OF, [2]Gangneung-Wonju National Universityniversity, Gangneung-si, KOREA, REPUBLIC OF.

Human PTTG1 is known as onco-protein and involved with sister chromatid separation in normal cells. PTTG1 was subsequently revealed to be highly expressed in diverse type of malignant tumors, which regulates the growth and metastatic properties of tumor. Oral squamous cell carcinoma (OSCC) is a one of the malignant tumor including oropharynx, larynx and oral cavity. Although improved detection and treatment methods of OSCC have been discovered in recent years, however, 5-year survival of patients with OSCC steadily be closed to 50%. However, the diagnostic biomarkers to detection of OSCC and molecular mechanisms underlying the regulation of PTTG1 in OSCC largely unknown. In the present study, we first investigated the role of PTTG1 in growth of OSCC. Then we explored the regulation of double-strand DNA break (DSB) depend on PTTG1 expression in OSCC growth. To investigate the function of PTTG1 in OSCC growth, we analyzed the cell viability and cellular senescence by EdU assay and SA-β-gal assay, respectively. To explain the DNA damage-induced senescence of PTTG1, we analyzed the chromosomal damage in OSCC cell lines *in vitro*. Finally, we confirmed the effect of PTTG1 on tumor growth and gene expression related to cell viability and DNA damaged-induced senescence in mice xenograft model. The expression of PTTG1 in OSCC tissues was remarkably higher than adjacent normal tissues. In addition, PTTG1 knockdown suppressed the cell viability and promoted the DNA damage-induced senescence in OSCC cell lines by accumulating chromosomal damage. In vivo mice model, tumor growth was significantly decreased in PTTG1 knockdown group compared with Mock control group via DSB. Taken together, our results suggest that PTTG1 expression modulates OSCC growth via DSB. Those finding may provide new strategies to develop more reliable diagnostic markers for patients with OSCC.

The DNA Damage Response regulates epithelial cell dynamics in the infected gut

P. Nagy, B. Hixson, N. Buchon; Department of Entomology, Cornell University, Ithaca, NY.

Intestinal microbes are central to host health but can also constitute an important etiological factor for the initiation and progression of diseases. However, the mechanisms by which pathogenic microbes influence intestinal tissue health remain largely unknown. Our overarching goal is to understand how pathogenic microbes inflict stress on the intestinal epithelium in *Drosophila melanogaster* and to characterize the impact of the molecular dialogue on cell dynamics. This is particularly important in the gut tissue where intestinal barrier, immune and digestive functions need to be coordinated with cell turnover. We and others have demonstrated that microbes stimulate epithelial turnover and initiate a feedback loop in which the elimination of enterocytes (ECs) activates intestinal stem cell proliferation in order to replace stressed/dying cells, balancing cell loss with tissue renewal. However, the molecular mechanisms that lead to EC loss in response to infection or innate immune activation are still not understood. We have found that infection induces an immediate host response in a subpopulation of midgut ECs which accumulate the DNA damage histone mark, γH2av (the phosphorylated form of H2av). Importantly, we have shown that pathogens, but not the commensal microbiota, activate the DNA damage repair (DDR) pathway which modulates epithelial cell elimination, cytokine production and stem

cell proliferation. Functional/bacterial genetics and microscopy imaging techniques allowed us to determine the microbial characteristics and epithelial cell state that influence DDR pathway activation. Gut transcriptome analyses and cell lineage-tracing methods previously developed in our lab enable us to identify how DDR pathway activation influences both cell elimination and pro-survival pathways. This work expands our understanding of how extrinsic factors and intrinsic cellular processes predispose cells to stress inflicted by infection-induced damage. Our study demonstrates that DDR pathway activation is a novel signaling route modulating cell loss and cytokine production, which is critical for health and homeostasis in a high-turnover tissue such as the intestine.

B602/P2274

Ferroptosis in myocardial infarction

M. Mohr, S. Li, A. Trouten, R. Stairley, G. Tao; Medical University of South Carolina, Charleston, SC

Every 40 seconds, a person in the United States experiences a myocardial infarction (MI), or heart attack. Following MI, mature mammalian cardiomyocytes (CMs) are unable to repopulate the injured myocardium due to a low turnover rate. After MI, fibrosis occurs to prevent rupture leaving the heart with decreased contractility and function, potentially leading to heart failure. However, the neonatal heart retains a regenerative capacity during the first week of life. We attempted to determine the main source of CM loss after MI to gain insights into potential mechanisms to preserve pre-existing CMs after injury. Regenerative postnatal day 1 (P1) and non-regenerative postnatal day 7 (P7) mice were subjected to permanent left anterior descending artery occlusion surgery (LAD-O) and hearts were collected at multiple timepoints to profile scar progression and cell death. We examined three types of cell death using confocal microscopy including previously reported apoptosis and necroptosis, as well as ferroptosis. We identified ferroptosis as the main contributor to CM death in both P1 and P7 mouse hearts with non-regenerative hearts experiencing more ferroptosis. Ferroptosis is an iron-dependent form of cell death that occurs after the peroxidation of lipid radicals leading to increased reactive oxygen species (ROS) and thus cellular damage and death. Interestingly, developmental gene paired-like homeodomain 2 (*Pitx2*) is required for regeneration after cardiac injury and activates antioxidant genes including glutathione peroxidase 4 (*Gpx4*), a key regulator of ferroptosis. We hypothesized that *Pitx2* negatively regulates ferroptosis through upregulation of *Gpx4* and other ferroptotic genes. Using confocal microscopy, we analyzed markers of ferroptosis in *Pitx2* conditional knockout hearts (cKO) and *Pitx2* overexpression hearts (OE). OE hearts showed decreased lipid peroxidation compared to controls and cKO hearts. Additionally, we performed RNA sequencing on cardiomyocytes derived from human induced pluripotent stem cells (iCMs) with siRNA of *Pitx2* and found decreased expression of genes involved in ferroptosis resistance. In conclusion, we found that ferroptosis is the main form of CM death after MI in both regenerative and non-regenerative hearts. As well, *Pitx2* can regulate ferroptosis and may be important in regeneration after MI.

Physical Approaches to Cell Biology 2

Condensates of Disordered Proteins Have Small-World Network Structures and Interfaces Defined by Expanded Conformations

M. Farag[1], S. R. Cohen[1], W. M. Borcherds[2], A. Bremer[2], T. Mittag[2], R. V. Pappu[1]; [1]Biomedical Engineering, Washington University in St. Louis, Saint Louis, MO, [2]Structural Biology, St Jude Children's Research Hospital, Memphis, TN.

Biomolecular condensates are thought to form via phase separation coupled to percolation (PSCP) driven by multivalent protein and RNA molecules. PSCP combines phase separation, a density transition, and percolation, a networking transition. What kind of mesoscale and molecular scale structures arise from PSCP based processes and do the interfaces formed via PSCP of flexible, intrinsically disordered proteins have special features? Here, we answer these questions by modeling PSCP using a coarse-grained *stickers*-and-*spacers* model implemented in LaSSI, a lattice-based simulation engine. Specifically, we model the low complexity domain of hnRNPA1 and designed variants thereof. The LaSSI model at single bead per residue resolution was parameterized using experimental data for chain conformations in dilute solutions. We show that the model generates phase diagrams that agree with experimental measurements. We find that individual chains are more expanded inside condensates when compared to the coexisting dilute phases. This arises from the preference for intermolecular physical crosslinks within condensates vs. the preference for intramolecular physical crosslinks in dilute phases. The network structures of molecules within condensates have small world topologies, implying a hub-and-spoke-like organization and significant spatial inhomogeneities that explain why condensates are viscoelastic network fluids. Our results also show that the interfaces of condensates have distinct molecular and mesoscale features. The interfacial width scales with the polymer length at low temperatures and increases exponentially with increasing temperatures, regardless of polymer length. Strikingly, we find that chains at the condensate interface have uncharacteristically high radii of gyration - larger than those of chains in the dense or dilute phases. Further, chains at the interface are oriented perpendicular to the surface of the condensate. Our results regarding the structures of interfaces have a direct bearing on recent discoveries demonstrating the importance of interfaces in mediating condensate mechanics and surface interactions, including polymerization and fibrillation reactions.

RNA Structure Controls RNA Multimerization, Phase Separation with Protein, and Time-Dependent Condensate Viscoelasticity

I. Seim[1], A. Graham[2], A. Mathijssen[3], A. Gladfelter[1]; [1]University of North Carolina At Chapel Hill, Chapel Hill, NC, [2]University of California, San Francisco, San Francisco, CA, [3]University of Pennsylvania, Philadelphia, PA.

Biomolecular condensates can form by phase separation and likely serve myriad functions across cell biology. Many studies have characterized protein condensates, sometimes including model RNAs that are usually nonspecific, short, and/or homopolymeric. However, the majority of biomolecular condensates in cells likely comprise mixtures of proteins and complex RNAs including mRNAs. Thus, characterization of the role of RNA sequence and structure with respect to protein phase behavior is paramount to understanding biologically relevant condensates. We leveraged our understanding of the

Whi3 protein and its condensation with the G1 cyclin-encoding *CLN3* mRNA to characterize the contributions of mRNA structure to phase separation. Whi3-*CLN3* condensates influence nuclear division in syncytial cells and Whi3 preferentially phase separates with this target RNA. We first created a directed evolution algorithm that designs shuffled *CLN3* RNA sequences which either maximize or minimize predicted free energies of folding while preserving mass, known Whi3 binding sites, and overall nucleotide composition. RNAs with minimized free energies of folding contain many stable duplexes, while RNAs with maximized energies have unstable structures with long single-stranded regions. Using mass photometry, we show that RNAs with stable structures are mostly monomeric, while RNAs with unstable structures multimerize more favorably. When mixed with protein, all RNAs undergo phase separation, but condensate compositions are altered. Unstable RNAs that multimerize more favorably form condensates with high RNA concentrations and low protein concentrations, while RNAs with stable structures and a low tendency to multimerize form condensates with low RNA concentrations and high protein concentrations. Finally, we used passive microbead rheology to characterize the time-dependent viscoelasticity of condensates formed by the different RNAs. Unstable RNAs form condensates that undergo significant aging with long viscoelastic relaxation times indicating solid-like properties at many timescales. However, stable RNAs form more liquid-like condensates that undergo less aging and have shorter viscoelastic relaxation times. Thus, RNA structure can have multi-scale consequences for biomolecular condensates, with impacts on RNA multimerization and condensate composition and material properties.

Effects of delamination treatment time and fluid shear force on the maintenance of pluripotency in mouse ES cells during the passage process

K. ABE[1], K. Ueno[2], S. Miyata[3]; [1]Center for Environmental Engineering, Medical Environment Engineering Group, Shimizu Corporation, Institute of technology, Tokyo, JAPAN, [2]Graduate School of Science and Technology, Keio University, Tokyo, JAPAN, [3]Faculty of Science and Technology, Keio University, Yokohama, JAPAN.

Since iPS cells, ES cells, have the ability to differentiate into various cells and are available for various treatments and studies, they have received great attention as cell products. How efficient and large-scale production of cells, a commodity, reduces treatment costs and leads to popularization, but many of the cultures are performed by humans. Automated culture equipments have also been developed, but in the maintenance culture of pluripotent stem cells, in order to proliferate cells efficiently while preserving their differentiation potential, cultured experts often use empirically constructed operations as a reference standard, and few cases have been comprehensively investigated. It is crucial for the development of the culture equipment to engineer the manual cell culture manipulation until now, and to clarify the impact of various conditions in the operation on the cell. Therefore, this study focused on the cell detachment process of the passage work in the culture of pluripotent stem cells, and clarified the impacts of cell detachment treatment time and enzyme treatment time on the differentiation potential of cultured pluripotent stem cells.

Biophysical Characterization of Cytotoxic T cell Heterogeneity in Cancer Progression

Y. Zhang[1], J. Yu[1], T. Dinter[1,2], R. Wu[1,3], S. Duquette[1,3], T. Miettinen[1], A. Miller[1,4], S. Spranger[1,2,5], S. R. Manalis[1,3,6]; [1]Koch Institute for Integrative Cancer Research, Massachusetts Institute of Technology, Cambridge, MA, [2]Department of Biology, Massachusetts Institute of Technology, Cambridge, MA, [3]Department of Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA, [4]Department of Health Sciences and Technology, Harvard University - Massachusetts Institute of Technology, Cambridge, MA, [5]Ragon Institute of MGH, MIT and Harvard, Cambridge, MA, [6]Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA.

Cytotoxic T cells are key modulators of immune response and exhibit significant heterogeneity in terms of phenotype and function. Although previous studies have shown that T cell biophysical properties vary during cell activation and become altered by inflammatory conditions, the extent to which differential T cell function is associated with distinct biophysical properties is unknown. To address this, we are using a microfluidic device called suspended microchannel resonator (SMR) that measures the buoyant mass (BM) of individual cells with a precision near 0.1%. BM is defined as the product between a cell's volume and its density difference relative to the surrounding solution. Upon measuring BM of resting T cells from PBMCs of healthy donors, we consistently observed a bimodal distribution consisting of heavy (10-20 pg) and light (<10 pg) cells. We verified through scRNA-Seq and flow-based assays that both populations consisted of viable cells. We observed similar bimodal distribution from CD3+CD8+ T cells isolated from spleen of healthy mice. Interestingly, both the volume and density distributions of these T cells showed only one population, indicating that neither of these parameters alone was responsible for the bimodality of T cell BM. Thus, although these two T cell populations cannot be distinguished by conventional methods such as light scattering and density gradient centrifugation, high precision BM measurements uniquely enabled by the SMR can clearly distinguish these two populations. To investigate how the light and heavy populations relate to T cell state, we inoculated C57BL/6 mice with KP-SIY cells and separated exhausted tumor-reactive T cells (PD1+/Tim3+) from tumor followed by BM measurements. We found that exhausted T cells contained mixed populations of light and heavy cells while both effector and central memory T cells consisted primarily of heavy cells. To further compare the functional differences between heavy and light populations, we developed a non-invasive cell sorting platform for SMR based on BM gating and sorted exhausted T cells into light and heavy bins followed by bulk RNA sequencing. We found that genes associated with chemotaxis (Ccl3, Ccl4), activation (Ifng) and terminal differentiation (Rps8) are downregulated in light cells, while Nap1l3, which is predominantly expressed in hematopoietic stem cells, is upregulated. These results suggest that heavy cells may represent a population that tends to be long-lived and retain proliferative capacity, while the light cells could be T cells within a dormant state that can be further differentiated. Ultimately we envision that single-cell biophysical measurements with high precision may provide informative biomarkers for distinguishing between functional and dysfunctional T cells.

Fibrotic wound healing as a function of fluid viscosity

Y. Chen[1], M. Pittman[2], D. Yan[2], H. Qureshi[2]; [1]Johns Hopkins University, Baltimore, MD, [2]Mechanical Engineering, Johns Hopkins University, Baltimore, MD.

Cells are surrounded by and move through fluids that span orders of magnitudes of viscosity *in vivo*, including mucus, saliva, blood, and synovial fluid, among others. We observed that some adherent cells migrate at higher speeds in highly viscous fluids, with the consistency similar to honey. We found that an actively ruffling lamellipodium when immersed in low- viscosity fluids is required for this counter-intuitive response. Upon viscosity increase, viscous drag immediately redistributes the membrane originally stored in the ruffles, resulting in larger spread area, faster focal adhesions formation, greater traction forces, and faster cell migration. Fibroblasts, neutrophils and macrophages exhibit ruffling lamellipodia thus visco-sensitive; whereas minimal ruffles are observed in inter-connected epithelial cells within an epithelium. Consequently, at high viscosity fibroblasts, neutrophils and macrophages move faster than at low viscosity, while inter-connected epithelial cells do not increase the migration speed. In the context of wound healing, faster moving fibroblasts, neutrophils and macrophages disproportionately occupy the wound site before epithelial cells arrive, depositing excessive ECM, exaggerating inflammatory responses and disrupting reepithelization. Furthermore, YAP translocates to the nucleus as viscosity increases. YAP promotes expression of the genes associated with proliferation, inflammation and tissue infiltration in both macrophages and neutrophils; YAP also upregulates genes in fibroblasts promoting myofibroblast phenotypes, leading to increase in contractility, ECM deposition, and pro-inflammatory cytokine secretion. In summary, increased viscosity in body fluids (mucus, exudate) are likely to promote fibrosis during wound healing. Reducing viscosity might suppress the fibrotic process which is an important part of disease progression in chronic lung diseases and cancer.

B609/P2280

Intracellular diffusion scales with cell size

C. Tan, F. Chang; University of California, San Francisco, San Francisco, CA.

Cells exist in a wide variety of sizes yet cells within acertain cell type exhibit a narrow range of size - does this suggest an optimalcell size? What happens when cells are the “wrong” size? How do cellularproperties change in different cells sizes? For instance, previous studiessuggest that in abnormally large or quiescent cells, the cytoplasm appears moredilute than in normal-sized cells. Here, we use genetically-encoded fluorescent40-nm nanoparticles (GEMs) (Delarue et al. 2018) to measure intracellulardiffusion in various-sized cells in the fission yeast *Schizosaccharomycespombe*. Using genetic mutants to alter cell size (e.g. *cdc25* and *wee1*mutants), we found that the GEMs diffusion coefficient increased in larger cellsand decreased in smaller cells. These size-dependent effects were present bothin the cytoplasm and nucleoplasm. We are currently testing the effects of theDNA-to-cytoplasm ratio on diffusion. Future studies will focus on probing therelationships between these size-dependent changes in diffusion with cellularcomposition and functions.

B610/P2281

A multiscale whole-cell theory for mechano-sensitive migration on viscoelastic substrates

N. Kaplan, W. Shu; Virginia Tech, Blacksburg, VA.

Increasing experimental evidence validates that both the elastic stiffness and viscosity of the extracellular matrix regulate mesenchymal cell behavior, such as the rational switch between durotaxis (cell migration to stiffer regions), anti-durotaxis (migration to softer regions), and adurotaxis (stiffness-insensitive migration). To reveal the mechanisms underlying the crossover between these motility regimes, we have developed a multiscale chemo-mechanical whole-cell theory for mesenchymal migration. Our framework couples the sub-cellular focal adhesion dynamics at the cell-substrate interface with the cellular cytoskeletal mechanics and the chemical signaling pathways involving Rho GTPase proteins. Upon polarization by the Rho GTPase gradients, our simulated cell migrates by concerted peripheral protrusions and contractions, a hallmark of the mesenchymal mode. The resulting cell dynamics quantitatively reproduces the experimental migration speed as a function of the uniform substrate stiffness and explains the influence of viscosity on the migration efficiency. In the presence of stiffness gradients and absence of chemical polarization, our simulated cell can exhibit durotaxis, anti-durotaxis, and adurotaxis respectively with increasing substrate stiffness or viscosity. The cell moves toward an optimally stiff region from softer regions during durotaxis and from stiffer regions during anti-durotaxis. We show that cell polarization through steep Rho GTPase gradients can reverse the migration direction dictated by the mechanical cues. Overall, our theory demonstrates that opposing durotactic behaviors emerge via the interplay between intracellular signaling and cell-medium mechanical interactions in agreement with experiments, thereby elucidating complex mechano-sensing at the single-cell level.

B611/P2282

Configurational entropy as a driver of structural heterogeneity in tissues

V. Srivastava[1], J. L. Hu[1], S. F. Shalabi[2], J. C. Garbe[1], M. R. Stampfer[3], M. A. LaBarge[2], Z. J. Gartner[1]; [1]Pharmaceutical Chemistry, University of California San Francisco, San Francisco, CA, [2]Beckman Research Institute, City of Hope, Duarte, CA, [3]Life Science Division, Lawrence Berkeley National Laboratory, Berkeley, CA.

Tissues are comprised of multiple cell types, embedded in a complex and heterogeneous microenvironment. A hallmark of tissues is the ability of their cells to maintain complex structures in vivo that are central to their function. Tissue structure emerges and is maintained by programs of self-organization that derive from cell mechanics and cell-cell signaling. Most existing models predict that these driving forces promote a single correct tissue structure. However, the structure of many tissues, while possessing a well-defined average structure, remain spatially heterogeneous where the local arrangement of cells can deviate significantly from the population average. This observation is difficult to reconcile with models of tissue self-organization based on mechanics or cell-cell signaling alone. Using the human mammary gland as a model, we quantified the structural heterogeneity in the relative position of the primary cell lineages (luminal and myoepithelial cells) with respect to the basement membrane. We observed significant local structural heterogeneity even after correcting for differences in tissue composition. We investigated the fundamental sources of structural heterogeneity using reconstituted human mammary organoids after carefully controlling for their composition, geometry and microenvironment. These organoids self-organized to largely exclude luminal cells from the tissue

edge, but maintained a highly heterogeneous ensemble structure centered around a reproducible mean. We show that the observed structural distribution follows Boltzmann statistics, corresponding to a maximum entropy distribution given the energetic constraints from lineage-specific interfacial mechanics. We experimentally validated the relative entropy of different tissue configurations using spheroids containing a single cell type, in the absence of a mechanical potential. We used this statistical mechanical framework to systematically engineer the structure of organoid ensembles by either varying their mechanical energy (cell-ECM and cell-cell adhesions) or entropy (composition and geometry). Together, these experiments reveal that the configurational entropy of cell arrangements imposes a theoretical maximum limit to structural order at the tissue level.

Multi-gene Co-Transfection is Dependent on Transfection Method

U. Baliga, D. Dean; University of Rochester, Rochester, NY.

Many research approaches require the delivery of multiple different genes to a single cell. These approaches include iPSC generation, viral reverse genetics, and molecular pathway analyses. However, as increasing numbers of distinct genes are delivered, the efficiency of every distinct gene being delivered to a given cell is reduced. This creates an expensive and frustrating bottleneck in multigene studies and may complicate analysis when some cells only receive part of the total desired genetic cargo. Various non-viral transfection methods are used to deliver multiple genetic cargoes, commonly lipofection and electroporation. We analyzed co-transfection of both methods through their ability to deliver plasmids expressing different fluorescent proteins. We further tested increasing the amount of plasmid used in the transfection and observed how co-transfection and cytotoxicity were affected by increasing the amount of transfected plasmids. Co-transfection was analyzed using spectral flow cytometry and fluorescence microscopy, and cytotoxicity was analyzed using an LDH assay. We found that increasing numbers of plasmids resulted in fewer co-transfected cells, regardless of method, in both HEK293T and A549 cells. Lipofection resulted in greater co-transfection of HEK293Ts, however electroporation resulted in greater co-transfection of A549 cells. Using lipofection in either HEK293T or A549, increasing the number or quantity of plasmids delivered resulted in minor increases of cytotoxicity, paralleled by a similar increase in co-transfection. Electroporation did not show this increased cytotoxicity with increased plasmid number or quantity, despite a higher baseline cytotoxicity. Increased amount of plasmid in electroporation resulted in greater improvement of co-transfection. These data indicate that (1) the choice of transfection agent affects co-transfection between different cell lines, and (2) increasing plasmid quantity in electroporation improves co-transfection more than lipofection does, without an increase in cytotoxicity. In the future, these co-transfection data will be tested functionally for treatment of acute respiratory distress syndrome, co-transfection an MRCKa plasmid to improve lung barrier function, and a plasmid expressing a STING shRNA to reduce inflammation.

How Cells Program Mineral Shape in Sea Cucumbers - Part 2

C. Brannon[1], P. Vyas[2], L. Formery[3], C. Lowe[1], M. Prakash[1]; [1]Biology, Stanford University, Stanford, CA, [2]Bioengineering, Stanford University, Stanford, CA, [3]Biology, Stanford, Stanford, CA.

Biomineralization is a widespread phenomenon in the tree of life yet remains poorly understood. While the chemical processes underlying biomineralization have been studied in a range of organisms, the fundamentals of biomineral morphological programming remain unknown. We utilize holothurians as an exciting new model system for studying the biology of biomineral morphological programming. Holothurian biominerals exhibit striking morphological diversity both within and across species. Further, this morphology differs substantially from its abiotic counterpart. This leads us to wonder, how are holothurian skeletogenic cells controlling biomineral construction? We hypothesize that proteins secreted by associated skeletogenic cells into the biomineral growth compartment may play a role in shaping biomineral morphology. We explore this hypothesis through Liquid Chromatography-Tandem Mass Spectrometry (LC-MS-MS) on protein extracted from biomineral. We identify known biomineralization proteins embedded in holothurian biomineral and explore the spatial distribution of embedded protein using Nanoscale secondary ion mass spectrometry (NanoSIMS). In parallel to establishing the spatial patterning of protein deposition in the biomineral itself, we are developing approaches for single-cell RNA-sequencing on holothurian skeletogenic cells, and searching for transcriptomic diversity which may correspond to biomineral morphological diversity. By applying modern techniques in cell and molecular biology to the holothurian system, we aim to both answer this biological question and reveal novel mechanisms for programming shape into mineral structures.

B614/P2285

What's the move? Novel counter-rotational flow in Xenopus embryonic epithelia creates heterogeneous strain fields and long range alignment of fibronectin.

G. Masak, L. Davidson; Integrative Systems Biology, Bioengineering, Developmental Biology, University of Pittsburgh, Pittsburgh, PA.

We report a novel form of counter-rotational, or 'Polonaise' flow in the late-neurula early-tailbud stage in *Xenopus laevis* embryos. Rotational or counter-rotational flows occur when collective migration or directed rearrangement is confined by physical barriers, either in embryonic or engineered contexts. Such flows are typified by vortices or swirls in cell trajectories. First described near the anterior end of the primitive streak in avians, counter-rotational movements have also been described in hair follicle morphogenesis in mammals. These flow patterns are thought to play an important role in patterning cell identities and setting up subsequent stages of morphogenesis and organogenesis. Live stereoscope timelapse sequences of the posterior end of embryos revealed unique tissue movements around the blastopore beginning in late neurula stages, similar to those described during chick gastrulation. We expressed a fluorescent nuclear reporter (H2B-mScarlet) to facilitate cell tracking through high-resolution confocal microscopy, enabling us to more accurately define patterns of individual cell movements. Image analysis of stereoscope and confocal timelapse sequences with our custom 'StrainMapper' macros reveal similar patterns of displacement, deformation, and strain. This analysis reports highly heterogeneous patterns of anisotropic strain, compression, and dilation in the dorsal and ventral tissues surrounding the blastopore. These counter-rotational flows occur in the cell and mechanical context of the blastopore during late neural to early tailbud stages. Dorsal axial tissues

continue to undergo convergent extension as fusion of neural folds is completed. By contrast, ventral tissues are more static and only initiate convergent extension during mid tailbud stages. To explore the origins of the heterogeneous strains, we carried out immunostaining of fibronectin, collagen and fibrillin extracellular matrix together with cytoskeletal factors actomyosin and cytokeratin within posterior tissues. Fibronectin fibril orientation between surface and deep cell layers suggests highly coordinated development of long range tension within the ventral tissues while apical surface cytoskeleton and cell shapes in surface cells suggest compression. We do not observe structures that might 'confine' epithelial in the plane but instead propose that counter-rotational flow is the result of more rigid confinement between layers as ventral tissues accommodate dorsal extensional movements. The polonaise movements at the posterior of the Xenopus embryo provide a third model system to investigate principles that leads to formation of the movement and to explore its role in establishing posterior neural and mesodermal cell fates in posterior stem cells.

B615/P2286

Contractile Actomyosin Cables and Pulling Forces from Adjacent Tissue Cooperate to Drive *Drosophila* Germ-band Extension

T. Zhu, H. Zhu, B. O'Shaughnessy; Chemical Engineering, Columbia University, New York, NY.

Germ-band extension in *Drosophila* is a major event during embryogenesis, when convergent-extension dramatically reshapes the germ-band. Fluid-like cell motions narrow the germ-band in one direction (dorsal-ventral axis, DV) and elongate it in the other (anterior-posterior axis, AP).
What forces drive germ-band extension? This is controversial. (1) One driving force is from planar polarized myosin at cell-cell junctions parallel to the DV axis. Blocking of myosin activation with optogenetic RhoGAP (optoGAP) activation reduced germ-band elongation ~1/3 and suppressed cell intercalation (Herrera-Perez et al., 2021). (2) Another contribution is the pulling force from the invaginating posterior midgut, adjacent to the posterior end of the germ-band. Blocking invagination with the *torso* mutation reduced germ-band elongation ~1/3 (Collinet et al., 2015). Further, the degree of DV elongation of germ-band cells is reduced with the *torso-like* mutation that blocks pulling forces (Lye et al., 2015), but is little affected by optoGAP-mediated blocking of myosin activation (Herrera-Perez et al., 2021).
Thus, experiment implicates both myosin cables and pulling forces from adjacent tissue, but their respective contributions and the underlying mechanisms are poorly understood. Thus, we developed a biophysical model of *Drosophila* germ-band extension, with junctional actomyosin contractility, elastic restoring forces, internal viscous forces, extracellular drag, forces from adjacent tissues and cell intercalation either by T1 transitions, when DV cell edges shrink to zero and merge two vertices, or by many-cell rosette formation (Herrera-Perez et al., 2022).
Our results quantitatively reveal that planar polarized myosin and posterior midgut pulling are major driving forces for convergent extension in the DV and AP directions, respectively. Actomyosin cables shrink junctions and intercalate cells, but cannot elongate tissue at wild-type rates, consistent with the phenotype of *torso* mutants (Collinet et al., 2015). Normal tissue elongation required both myosin cables and posterior midgut pulling, and in simulations with both, the profile of cell lengths reproduced the experimental monotonic increase in the AP direction (Lye et al., 2015). These results suggest convergent extension is cooperatively driven by myosin contractility and active pulling from adjacent tissue.

B616/P2287

Nanomechanical surface characterization of T lymphocyte viscoelasticity during formation of the immune synapse

K. Do, C. H. Parvini, A. X. Cartagena-Rivera; National Institutes of Health, Bethesda, MD

The cell-cell interface that forms between a T cell and an antigen-presenting cell (APC) is widely known as the immunological synapse (IS), where engagement of the T-cell receptor with its specific peptide antigen drives T cell activation. A growing body of work has shown that the mechanical properties of T cells during activation significantly influence essential cellular functions including proliferation, migration, APC detection, and killing. The formation and maintenance of the IS itself have been shown to be facilitated by force generation through actomyosin and microtubule cytoskeletal dynamics. However, the mechanism by which this force generation affects a T cell's mechanical properties is not well understood. Here, we demonstrate the use of a recently published discrete integral transform technique on force-distance datasets collected from T cells during IS formation using high-resolution atomic force microscopy. This approach enables quantitative, multi-timescale observation of the local viscoelastic response via common mechanical parameters, namely the storage modulus, loss modulus, and loss angle at the nanometer length scale. Our viscoelastic measurements reveal that T cells at the nanoscale level exhibit structurally heterogeneous nanoscale viscoelastic properties in response to forming an IS induced by CD3/CD28 stimulation, as indicated by stiff and viscous edge and central regions, with a simultaneously softer and more fluid peripheral transition region. These observations correlate well with actomyosin cytoskeletal changes within those regions and with the understanding that the peripheral transition region is known to cluster LFA-1 ligands. This study reveals the complex dorsal viscoelastic behavior of T cells during IS formation, which could be leveraged to better understand T cell activation.

The study of preimplantation embryo development with 3D-bioprinted gelatin methacrylate as oviduct environment mimics systems

J. JANG[1], D. Kim[2], M.-H. Kang[3], M. Cho[3], Y. Kim[3], Y. Koo[1], S. Yeo[4], S. Park[4], J. Lee[1,3]; [1]CHA University, Pocheon, Korea, Republic of, [2]Seoul National University, Seoul, Korea, Republic of, [3]CHA Fertility Center, Seoul, Korea, Republic of, [4]Korea Institute of Machinery and Materials (KIMM), Daejeon, Korea, Republic of

In vivo condition is not a plastic dish but a soft tissue. Therefore, optimal soft tissue like oviduct physical condition develops for the optimal culture of mouse oocyte and embryo. Mechanical properties are fundamental properties of the cells and tissues of living organisms. The mechanical properties of a single cell as a biocomponent are determined by the interdependent combination of cellular components' mechanical properties. In this study, we investigate that the development of the oviduct's environment mimics the optimal culture dish for optimal reproductive cell culture. We developed an oviduct tube mimic culture system using gelatin methacrylate (GelMa) solution by 3D-bioprinting a set-up mechanical property from 2kPa, 4kPa and 10kPa. Quantitative estimate of the mechanical properties of hydrogel depends on the state, method of measurement, and the theoretical model that has been used. Then we used the B6D2F1 female for embryo collection through superovulation. Then we culture in a time lapse system incubator with 5% CO2, 37℃ condition in the SAGE in vitro blastocyst media with different hydrogel culture dish. We acquired images every 5 minutes for each culture dish. And we evaluated the

embryo development during each examination and recorded it through images. We checked up development ratios and cleavage time for the point of embryo during time lapse culture. Then we classified the quality of the embryo depending on the cleavage speed and blastocyst ratios. 10kPa culture dish shows fast development and high ratios of blastocyst formation compared to the control dish. Also hatched out ratios of blastocyst significantly increases on the 10kPa culture dish compared to the control dish. Then the blastocyst on the hydrogel culture dish reveals significantly higher Oct4, Sox, Nanog as fetal formation related gene expression ratios then control group. Hydrogel culture system induced inner cell mass in the embryo compared to the control group. In conclusion, Hydrogel promoted the speed of blastocyst development and hatched out ratios. It also significantly increased inner cell mass size and ratios compared to the control group. Therefore, optimal extracellular mechanical stimulation enhanced blastocyst developmental ratios. And optimal cell hydrogel base mechanical culture system could apply to improved clinical outcome of in vitro fertilization patient to high pregnancy and healthy live birth.

B618/P2289

Ionic and Cytoskeletal Control of Cell Protein Density

G. J. Fu[1,1], Q. Ni[1,1], Z. Ge[1,1], S. X. Sun[1,1,2]; [1]Johns Hopkins University, Baltimore, MD, [2]Johns Hopkins School of Medicine, Baltimore, MD

Cellular processes depend on the concentration of intracellular proteins in the cytoplasm. In adherent mammalian cells, protein concentration or protein density (protein mass / cell volume) is tightly regulated during the cell cycle and is critical for proper cell metabolism and physiological activities. Cells actively monitor and maintain cell volume via ion channels and cytoskeleton. Changing extracellular ionic content will disrupt the transmembrane osmotic gradient and change cell volume. On the other hand, ions can influence protein synthesis and protein function both physically and epigenetically. However, a quantitative study of ionic and cytoskeletal control of cell protein density is still lacking. In this work, we combined quantitative phase microscopy and the Fluorescence Exclusion method to investigate how different ions and cytoskeletal components regulate cell protein density. We find that depletion of extracellular sodium and chloride can alter cytoplasmic protein density, however, the alterations are variable, depending on the timescale. At the timescale of hours, depleting either sodium or chloride (without changing osmolarity) leads to protein density increase by decreasing cell volume. At the time scale of a cell cycle, chloride depletion increases cell volume while leaving protein mass intact, resulting in a cell protein density decrease. Sodium depletion also reduces protein density, but both cell volume and protein mass are increased. Extracellular calcium, potassium, and the actin cytoskeleton also impact cell volume and protein mass but do not alter the protein density. Our work reveals the central role of ions in controlling cell protein density, providing fundamental understandings of cell size and cell cycle regulation.

B619/P2290

A mechanical cusp catastrophe imposes a universal constraint on the shapes of tip growing cells

M. E. Ohairwe, E. R. Rojas; New York University, New York, NY

Understanding the mechanistic and evolutionary bases for cellular morphology are central problems in biology. Evolution has converged on tip growth many times, yielding filamentous cells, yet tip-growing cells display a range of apical morphologies. To understand this range, we measured the spatial

gradients of the principal tensions and expansion rates in the cell walls of tip-growing cells from three kingdoms and found that, in each case, cell growth and apical morphology are consequences of mechanical stretching of the cell wall by turgor pressure. As a result, we could use continuum-mechanics theory to describe the entire space of possible apical morphologies that could be generated using this mechanical mechanism. Surprisingly, we discovered that the experimentally measured morphologies of a wide range of tip-growing species populate only a small region of this theoretical "morphospace.'' Through further analysis, we discovered that natural morphologies are constrained by a "cusp bifurcation'' in the morphospace. Specifically, the bistable region of the morphospace associated with the bifurcation imposes a boundary that separates fast-growing naturally occurring morphologies from unobserved morphologies that are predicted to grow more slowly. We tested this prediction by pharmacologically perturbing the tip growth of species with apical morphologies close to the boundary, which indeed resulted in both slow growth and the non-natural apical morphologies associated with the other side of the boundary. Collectively, our results reveal how the interplay between natural selection for fast cell-growth and the convergent evolution of turgor-driven growth has resulted in a universal developmental constraint on the shapes of a broad class of cells.

B620/P2291

Cancer-associated mucins provide sustained physical protection against Natural Killer cell attack

J. H. Paek, S. Park, M. J. Paszek[1,1]; Cornell University, Ithaca, NY

Cancer is often associated with aberrant expression of cell surface mucins, resulting in a thick cellular glycocalyx that coats the cancer cell membrane and governs its interactions with immune cells. Several biochemical studies have uncovered an immunosuppressive role of the O-glycans that decorate cancer-associated mucins. However, densely packed mucin biopolymers on the cell surface may also physically protect cells from immune recognition and attack. Here, we investigate how the physical properties of a mucin-rich glycocalyx impact effector-target interactions. Using CRISPR-Cas9 gene editing to manipulate the physical structure of the glycocalyx, we show that the cancer-specific glycocalyx can act as a nanometer-scale shield that provides resistance to Natural Killer (NK) cell-mediated cytotoxicity. We also develop a 3D co-culture platform coupled with live-cell imaging to investigate the dynamics and mechanisms of immune cell engagement and killing of target cells. We show that NK cells are highly motile and exhibit classical amoeboid migration through complex collagen matrices as they search for their target cells. We find that target cells with a thin mucin barrier can be killed within minutes of contact with an NK cell. Meanwhile, cells with high mucin surface density have a remarkable ability to resist NK cell attack for several hours of continuous engagement. Lastly, we show how equipping NK cells with mucin-digesting enzymes endows them with the ability to overcome this barrier and enhances their cytolytic activity against target cells that exhibit a mucin-rich glycocalyx. These results suggest that NK cells can be engineered to utilize mucinases to boost their activity against target cells, leading to a novel strategy for cancer immunotherapy.

Nucleus uptake of water soluble C_{60} derivatives: a molecular platform for targeting cargo to diseased cells

R. Biswas, S. Yang, Z. Shi, J. Zhang; Chemistry and Chemical Biology, Rutgers University, New Brunswick, NJ.

Entry of cargo into the nucleus is challenging because of the size and molecular weight cutoff of the nuclear membrane, yet the nucleus is a significant target for therapeutics as alterations to the native genetic material can lead to pathological conditions such as cancer among others. Here we investigated the ability of water-soluble C_{60} β-cyclodextrin derivatives carrying doxorubicin to enter the nucleus of HeLa cells. By selectively labelling the nuclei and lysosomes of HeLa cells and using fluorescence microscopy, we established that one of the molecules with a hydroxylated C_{60} cage was able to efficiently target the drug into the nucleus whereas the one with an intact hydrophobic cage remained trapped in the lysosome. Additionally, by using transmission electron microscopy, we showed that the C_{60} derivatives were able to penetrate the nucleus. We tested through cell viability assays that the C_{60} derivatives themselves did not reduce cell viability, however the doxorubicin loaded versions significantly reduced cell viability under optimal doxorubicin loading. The above observations led us to investigate the effect of these molecules on stress granules as they are implicated in neurodegenerative diseases such as amyotrophic lateral sclerosis and Alzheimer's, which is currently under investigation. As discussed above, the ability of C_{60} derivatives to cross different layers of the cell could be attributed to the unique structure of C_{60} which belongs to a broad family of carbon materials called fullerenes. The hydrophobic carbon cage helps C_{60} or its derivatives to effectively partition into the lipid bilayer of the cell membrane. Currently, we are developing a bi-functional C_{60} derivative with orthogonal functional groups which will have the potential to be functionalized with fluorescent tags and other bioactive molecules such as peptides, sugars or nucleic acids. It is worthwhile to point out that the C_{60} cage has functional purposes beyond its use as a structural scaffold. Depending on the functional groups and the nature of conjugation of the fullerene cage, C_{60} derivatives are known to quench reactive oxygen species (ROS) which we are currently investigating. This is important from a therapeutic standpoint to treat ROS induced inflammation which is prevalent in many diseases such as intervertebral disc disease. To conclude, the primary focus of this presentation will be on the cellular uptake behavior of C_{60} derivatives into HeLa cells and their specific targeting to the nucleus and its implications. In addition to this, current efforts to develop bi-functional C_{60} derivatives which can be potentially used for imaging and delivering essential bioactive molecules such as chemotherapeutics or anti-inflammatory compounds to diseased cells will be discussed.

Bioorthogonal ligation-activated fluorogenic FRET dyads

E. Albitz, D. Kern, A. Kormos, M. Bojtár, G. Török, A. Biró, Á. Szatmári, K. Németh, P. Kele; Research Centre for Natural Sciences, Budapest, HUNGARY.

We explored a concept that enables the transformation of the excellent tetrazine-ligation dependent fluorogenicity of blue-excitable cores to biologically more preferable red emission. The synthesized energy transfer (FRET) dyads were studied under different conditions. Intracellular protein labelling

studies of live cells with subsequent confocal fluorescence microscopy imaging served evidence for the applicability of these fluorogenic dyads. Results have shown that the relay of bioorthogonally activatable blue fluorogenicity indeed results in improved yellow/red fluorogenicities. Furthermore, the large apparent Stokes-shifts of the dyads in combination with a spectrally matching fluorogenic coumarin enabled multicolor imaging of distinct intracellular structures using a single excitation wavelength with distinct emission ranges. Moreover, due to the improved photostability of the dyads their use in STED imaging experiments was also demonstrated.
The modularity of the design allows a generalizable approach that can be applied to various fluorogenic scaffolds in combination with suitable acceptors. Thus, we believe that such energy transfer-based relay of bioorthogonal reaction aided fluorogenicity may address the wavelength limitation of tetrazine modulated fluorogenic probes.

Analyzing Site-specific and Direct Interactions of AAA Proteins with Cofactors and Substrates in Living Cells

L. E. Vostal[1,2], W. Zhang[3], B. T. Chait[3], T. M. Kapoor[1]; [1]Laboratory of Chemistry and Cell Biology, The Rockefeller University, New York, NY, [2]Tri-Institutional PhD Program in Chemical Biology, The Rockefeller University, New York, NY, [3]Laboratory of Mass Spectrometry and Gaseous Ion Chemistry, The Rockefeller University, New York, NY.

Members of the ATPases associated with diverse cellular activities (AAA) protein family are macromolecular machines that require interaction with cofactors or adaptors to remodel target substrates across a variety of cellular processes, including cytoskeleton regulation, membrane biogenesis, and proteostasis. In particular, valosin-containing protein (VCP/p97) is a hexameric AAA protein that interacts with ~30 cofactors that recruit poly-ubiquitinated and non-ubiquitinated substrates. These substrates are likely unfolded by threading them through the central pore of the VCP hexamer for subsequent recycling or degradation. Previous studies have used proteomic and structural approaches to characterize VCP-cofactor and VCP-substrate interactions *in vitro*. However, the binding modes of known VCP interactors to the AAA protein hexamer have not been analyzed in living cells. Here, we adapt iCLASPI, an approach relying on amber suppression, photo-crosslinking, and quantitative proteomics, to probe site-specific and direct VCP protein-protein interactions in living cells. We have focused on examining VCP-cofactor interactions, which structural studies map to a hydrophobic groove in the VCP N-terminal domain or above the entrance into the VCP central pore. We find that a known cofactor, Npl4, crosslinks directly to VCP L278 positioned at the entrance to the central pore, but not within the central pore near residues E314 and D592 in living cells. Additional cofactors, p47 and p37, crosslink to the same region of VCP as Npl4, consistent with a model in which mutually exclusive regulation of the AAA protein can be achieved in cells. Our modified iCLASPI approach will be used to map the native binding sites of VCP interactors and to examine the temporal dynamics of these interactions during cell division. In ongoing work we are applying our approach to VPS4, a AAA protein involved in membrane remodeling. Together, our findings introduce a robust method for probing site-specific and direct AAA protein-protein interactions in living cells, where these interactions are essential for several cellular processes.

Should I Stay of Should I Go?: Investigating Repellent Chemoanemotactic Responses in Crickets

R. O. Alzyoud, **V. D. C. Shields**; Biological Sciences, Towson University, Towson, MD.

Insects, like most organisms, use their olfactory (smell) system to detect and analyze environmental cues. Their antennae bear olfactory sensory organs (sensilla) containing neurons that encode and process olfactory stimuli. Such stimuli can trigger behaviors, such as orientation toward food, mating partners, and avoidance of predators. House crickets make excellent model systems in neuroscience as they, like other insects, have moderately complex nervous systems and bear a rich behavioral repertoire. House crickets are generally considered to be pests. Due to their omnivorous feeding preference, they can potentially contaminate food sources with their fecal matter. Additionally, their audible chirping noises are very annoying. The aim of this study was to determine the behavior elicited by several essential oils known to elicit repellency or movement away from the odorant source (i.e., negative anemotaxis) in some insects. More specifically, we tested the essential oils of peppermint, citronellal, eucalyptus, lavender, lemon eucalyptus, wintergreen, and orange. We hypothesized that some of these essential oils would act as repellents. We found that peppermint oil and lemon eucalyptus oil were similarly strongly repellent. Eucalyptus oil and citronellal oil were only moderately repellent individually, but when combined (lemon eucalyptus oil), were strongly repellent. Lavender oil was strongly repellent but not as potent as lemon eucalyptus and peppermint. Wintergreen oil and orange oil appeared to be similarly moderately repellent. Some of the repellent compounds may be useful for applied researchers to develop olfactory repellent traps to deter crickets from entering homes and contaminating food sources. This research was funded by NIH grant 5-R25-GMO5826416 and NSF MRI grant 1626326 to V.D.C.S.

Bioorthogonal diagnostic fluorophores for imaging oxidative stress-induced carbonylation in live cells

J. Argueta[1], A. Franklyn[1], T. Shirley[1], B. Jones[2], E. Krawczyk[2], S. Ranjit[2], M. Levi[2], **O. Dilek**[1]; [1]University of the District of Columbia, Washington, DC, [2]Georgetown University, Washington, DC.

Oxidative stress is reported to associated with the development of cellular damage, cancer, aging and several age-related disorders. Oxidative stress often induces carbonylation of biomolecules in cellular systems. Detection of carbonyl-containing biomolecules in live cells with novel bioorthogonal fluorophores provides a fast, selective, and stable approach for imaging. To introduce fluorophores into the cellular systems, these fluorophores should have distinct chemical and photophysical characteristics to achieve successful imaging: high stability, less toxicity, fast kinetics, good spectral properties (*e.g.,* large Stokes shifts, reasonable quantum yields, drastic changes on absorption and emission spectra). In this work, we developed small molecule-based fluorophores that have a reactive hydrazine functional group, which rapidly formed a fluorescent turn-on hydrazone product upon reacting with the carbonyl groups in biological system—is called bioorthogonal fluorescent labeling so that we were able to visualize carbonylation process in various cancer cell lines. Our spectroscopic and confocal microscopy results showed that newly synthesized fluorophores can be labeled successfully in human dermal fibroblasts along with renal cell carcinoma (RRC) cell lines and prostate cancer (PC) cells. In addition, synthesized fluorophores can selectively detect carbonylation level that differs in response to exogenous and endogenous stress in healthy and cancer cells. Use of click chemistry method to monitor carbonylation with a bioorthogonal fluorophore has proven itself to be superior in satisfying many

criteria (e.g., biocompatibility, selectivity, yield, stability, and so forth); our results will therefore provide a powerful probe technology that can label carbonyl moieties in live cells. We anticipate that development of new library of fluorophores will not only advance the discovery of future drug therapeutics targeting carbonylation process, but also enable the development of better imaging agent technologies that have potential to diagnose early stages of selective diseases.

Saccharomyces cerevisiae* Proteins Exhibit Benzil Reductase Activity *in vitro

B. Garcia, **K. Riley**; Chemistry, Rollins College, Winter Park, FL.

IRC24 and NRE1 encode putative oxidoreductases separated by 284 bp on chromosome IX of *Saccharomyces cerevisiae*. Little is known about either enzyme, though an unpublished structure for NRE1 was deposited into the Protein Data Bank as part of a high throughput study. The IRC24 and NRE1 proteins are relatively small (263 and 254 amino acids, respectively), cytoplasmic, and are 52% identical/70% similar in sequence. Bioinformatic predictions identified likely NAD(P)-binding Rossmann folds in both proteins, implicating NAD or NADP as a likely cofactor. Comparisons of the NRE1 protein structure to homologous protein structures KRED1-Pglu from the yeast *Ogataea glucozyma* and carbonyl reductase variant 4 from the bacterium *Serratia marcescens*, further confirmed a conserved the Rossmann fold and illuminated a conserved active site motif thought to bind to diketone compounds such as benzil. His-tagged IRC24 and NRE1 purified from *E. coli* were compared in terms of their substrate/cofactor preference and catalytic parameters. Both enzymes catalyze redox reactions in vitro with measurable kinetics and substrate/cofactor preferences. These *in vitro* studies will hopefully inform our understanding of the role of these probable paralogs *in vivo.*

Effects of Protein Binding Site Valence in RNA on Biological Condensates

S. J. Cole[1], C. Roden[2], A. Gladfelter[2]; [1]Biochemistry and Biophysics, University of North Carolina Chapel Hill, Chapel Hill, NC, [2]University of North Carolina Chapel Hill, Chapel Hill, NC.

Spatial and temporal control of biochemistry is central to cell function. One way the cell spatially controls reactions is through formation of biomolecular condensates, the mismanagement of which is tied to several disease states. Most condensates are a mixture of RNAs and RNA binding proteins (RBP), yet it is still mysterious how RNAs impact the form and function of condensates. One key question is how RNA properties, such as sequence and structure effect condensate properties. Key insights into the role of RNA sequence and structure in condensates have come from study of the Whi3 RNA-binding protein within the multinucleate filamentous fungus Ashbya gossypii. Whi3 forms three distinct condensates with the RNAs encoding WHI3 itself, BNI1, and CLN3 RNA. Despite all three condensates containing Whi3 protein, these condensates are essential for different functions and found in distinct locations in the cell. Previous work showed that reconstituted Whi3 droplets had different material properties depending on which RNA was present and we predict is important for the distinct local functions. BNI1 and CLN3 condensates display different relative concentrations of Whi3 protein in the condensate and this could be one basis for the differences in material properties. However, this is a surprising difference to observe since each of these RNAs have the same number of Whi3 binding sites. This led us to hypothesize that there are functional differences amongst the binding sites that vary somehow in their ability to interact with Whi3 protein to drive phase separation. This project examines

multiple mechanisms underlying this difference 1) spacing of the binding motifs on the RNA, 2) the local structure of the sites in the RNA or 3) other differences in the sequence between these RNAs (potentially unidentified Whi3 binding sites) that may contribute to their ability to recruit Whi3. We first hypothesized that there are specific sequence or structural elements surrounding Whi3 binding motifs that effect the binding affinity of Whi3 for the site. We tested this with CLN3 transcripts with individual binding sites removed in in vitro phase separation assays and find evidence that not all Whi3 binding sites are created equal indicating heterogeneity and potentially cooperativity in Whi3 interactions with specific sites on target RNAs. We are now testing the sites individually for affinity differences. This system is revealing how valence in RBP/Protein interactions can be fine-tuned based on subtle affinity differences that arise from RNA sequence context. This work will shed light on how the structure and sequence-encoded features surrounding protein binding sites on RNA control assembly of biomolecular condensates.

Controlling the Activity of Polo-like Kinase 1 with Light

V. von Glasenapp[1,2], D. Chang[3,4,2], N. Winssinger[3,2], M. Gotta[1,2]; [1]Department of Physiology and Metabolism, University of Geneva, Geneva, SWITZERLAND, [2]NCCR Chemical Biology, University of Geneva, Geneva, SWITZERLAND, [3]Department of Organic Chemistry, University of Geneva, Geneva, SWITZERLAND, [4]Current address: Institute of Chemical Science and Engineering, EPFL, Lausanne, SWITZERLAND.

Polo-like kinase 1 (Plk1) is a conserved mitotic kinase necessary for several processes during cell division, such as mitotic entry, bipolar spindle assembly and cytokinesis. The activity of the kinase is regulated during the course of mitosis to be active at specific time points. The small molecule inhibitor BI2536 has been widely used to study the functions of Plk1. We have developed a Plk1 inhibitor based on BI2536 that can be controlled with light to have precise temporal control. We have attached a coumarin based photoremovable protecting group to the inhibitor at a position important for interaction with the kinase. In HeLa and hTERT-RPE cells the caged inhibitor is stable and does not interfere with the cell cycle even at high concentrations. It can be rapidly uncaged and activated under the confocal microscope as well as wide field microscopes equipped with a laser or a lamp of a wavelength of 488 nm. Once uncaged, the inhibitor efficiently interferes with Plk1 activity. We have successfully used the caged inhibitor in high-content microscopy and achieved precise temporal control of Plk1 inhibition. We are now functionalizing the inhibitor to introduce spatial control. This tool will allow us to dissect the roles of Plk1 at different locations and in individual cells of developing organisms and organoids.

Assessment of side effects of chemotherapy drugs on a patient derived small intestine organoid model

J. S. Boyd, V. Chu; Cellular Assays R&D, MilliporeSigma, Temecula, CA.

Patient-derived organoids are increasing in interest for their utility as relevant pharmacological models for drug screening. In contrast to 2D cellular models, 3D organoid models more closely represent the structure and types of differentiated cells, more accurately recapitulating in vivo physiology and response to therapeutic agents. Drug-induced gastrointestinal toxicity is a common adverse effect that impairs efficacy and reduces treatment options for patients, thus making relevant assays using in vitro

cellular models highly desirable. We tested a panel of chemotherapeutics known to induce varying degrees of diarrhea incidence using a commercially-available human small intestine duodenum model via organoid viability assay. Drug toxicity values for the human patient-derived duodenum small intestine organoids closely mirrored published values for human ileum small intestine organoids. Toxicity data were correlated with effects on membrane integrity assessed via epithelial transmembrane epithelial resistance (TEER). This study reinforces the relevance of patient-derived organoid models for drug toxicity and in vitro risk assessment of drug side effects.

Chemoproteomic-guided development of SLC15A4 inhibitors with anti-inflammatory activity

T.-Y. Chiu, C. G. Parker; The Scripps Research Institute, San Diego, CA

SLC15A4 is an endolysosome-resident transporter that is intimately linked with autoinflammation and autoimmunity. Specifically, SLC15A4 is critical for Toll-like receptor (TLR) 7, 8, and 9 as well as the nucleotide-binding oligomerization domain-containing protein (NOD) 2 signaling in several immune cell subsets. Notably, SLC15A4 is essential for the development of systemic lupus erythematosus in murine models and is associated with autoimmune conditions in humans. Despite its therapeutic potential, to our knowledge no pharmacological tools have been developed that target SLC15A4. Here, we use an integrated chemical proteomics approach to develop a suite of chemical tools, including first-in-class functional inhibitors, for SLC15A4. We demonstrate SLC15A4 inhibitors suppress endosomal TLR and NOD functions in a variety of human and mouse immune cells and provide early evidence of their ability to suppress inflammation *in vivo* and in clinical settings. Our findings establish SLC15A4 as a druggable target for the treatment of autoimmune/autoinflammatory conditions.

B631/P2302

Development of MDM2-targeting PROTAC System for Hard Tissue Regeneration

S. Jeong, S. Kang, J. Kim; Seoul National University, Seoul, Korea, Republic of

MDM2 is a negative p53 regulator, and various inhibitors targeting MDM2 has been developed as anticancer drugs. Our previous study confirmed that p53 activation through inhibition of MDM2 induces osteogenic differentiation in multipotent mesenchymal stromal cells (MSCs). MDM2 inhibitor remarkably induced biomineralization in MSCs, but p53 activation was insufficient due to an MDM2-p53 autoregulatory feedback loop. To overcome this limitation of MDM2 inhibitors, we applied proteolysis targeting chimera (PROTAC), a technology that degrades a protein of interest (POI) through an intracellular ubiquitin-proteasome system. Hence, we propose a strategy to induce hard tissue regeneration by MDM2-targeting PROTAC technology. We selected POI ligand among various MDM2 inhibitors by Alizarin Red S (ARS) based screening process, and the selected ligands were applied to CRBN or VHL ligands. The MDM2-PROTAC synthesis platform was designed to include each ligand combination, and 16 compounds of MDM2-PROTAC were synthesized. We discovered multiple candidates that effectively degraded MDM2 protein by immunoblot assay. By performing the degradation test following concentration of selected compounds, the maximal degradation concentration (DC_{max}) and the half maximal degradation concentration (DC_{50}) were identified. In addition, timelapse live cell imaging was conducted to visualize the degradation dynamics and efficiency of MDM2-PROTAC in EGFP-MDM2-expressing cells. For functional validation in biological systems, we demonstrated that MDM2-PROTAC induced a robust effect on biomineralization compared to the

MDM2 inhibitor. MDM2-PROTAC significantly increased mRNA levels of osteogenic differentiation marker genes. Also, the effect of MDM2-PROTAC was validated in animal models of hard tissue defect. In this study, we demonstrated the potent protein degradation effects of newly developed MDM2-PROTAC and an intracellular MDM2 regulation strategy using PROTAC technology customized to induce biomineralization. These results are expected to lead to development of a new therapeutic modalitiy for hard tissue regeneration, expanding the application of the PROTAC system.

Pipeline development for a fast quantitative kinetic understanding of nucleotide addition catalyzed by RNA/DNA polymerases

Z. I. Carter, L. Saleh, A. F. Gardner; New England Biolabs, Ipswich, MA

The 99 kDa single subunit enzyme, T7 RNA Polymerase, is a well-studied enzyme with manuscripts dating back to the late 1950's. Despite this fact, many mechanistic questions still exist. A few include: Does T7 RNAP incorporate the four conical nucleotides with an identical kinetic mechanism? Are particular nucleotides misincorporated more readily? How does the sequence context impact the rates of misincorporation? Etc. Many traditional Polymerase assays still in use today use sequencing gels to resolve elongated DNA/RNA transcripts. Sequencing gels are both slow and low throughput. Here we have adapted a traditional T7 RNA polymerase assay for fluorescent detection. We report the development of a pipeline to measure single nucleotide incorporation kinetics, misincorporation kinetics, modified nucleotide incorporation kinetics, and multi-nucleotide incorporation kinetics. Time courses monitoring nucleotide addition were generated using transient-state kinetic techniques in combination with a high-throughput capillary electrophoresis system. This experimental methodology allowed 20+ time courses to be collected and analyzed in hours compared to days or perhaps weeks using standard denaturing sequencing gels. Rate-constants were measured describing the incorporation of the four canonical nucleotides into a nascent RNA strand. The hypermodified N1-methyl-psudouridine, which is used in the production of the COVID-19 vaccine, was also investigated. Additionally, we generated estimates for the rate-constants describing misincorporation in a variety of sequence contexts. Model-independent and model-dependent analyses were performed for each nucleotide addition revealing mechanistic insight for this critical enzyme. We expect this novel pipeline and the corresponding analysis strategies to be broadly applicable to many RNA/DNA polymerase researchers.

B633/P2304

1,4-Dioxane prevents LPS-induced macrophage inflammatory response in a NF-κB-independent manner

Z. Cabail; SUNY-Old Westbury, Old Westbury, NY

1,4 dioxane is an emerging environmental hazard that has been reported to elicit carcinogenic effects to humans. 1,4 dioxane is a Synthetic Organic Compound (SOC) found in several daily-life products, including shampoos, body washes, baby products, laundry detergents, hand and dish soaps. A wide range of evidence demonstrate that environmental toxic products are associated with the onset, development, and progression of cancer. Macrophages are cells of the innate immune system responsible for mounting an inflammatory response. Macrophages that infiltrate the tumor stroma and become tumor-associated macrophages (TAMs) polarized towards a pro-inflammatory state. It has been

reported that environmental toxicants alter the balance macrophage polarizations from inflammatory M1 toward anti-inflammatory M2 and this may be contributed to tumor growth. Recent evaluation of public water suppliers across Long Island, NY, where our college (SUNY-Old Westbury) is located, reported the highest levels in the nation of 1,4-dioxane contamination in groundwater and drinking water. This prompted our lab to investigate the molecular mechanisms of macrophage polarization in response to 1,4 dioxane. Therefore, the goal of this study is to achieve a mechanistic understanding of how 1,4 dioxane affects the inflammatory response. We used a murine macrophage cell line, RAW264.7, and a murine microglia -a specialized population of macrophages found in the central nervous system- cell line, BV-2. These cells were exposed to different concentrations of 1,4 dioxane in a time-course manner to mimic the plasma concentration of 1,4 dioxane after exposure. Immunoblotting showed that LPS-induced macrophage/microglia activation after pre-treating cells with different concentrations of 1,4 dioxane, and at different time points, resulted in the downregulation of the functional marker of M1 pro-inflammatory phenotype inducible nitric oxide synthase (iNOS). This was accompanied by decrease levels of liver Arginase, a signature protein of M2 anti-inflammatory activation. This polarization was not mediated by the key regulator of the M1 program NF-κB. Further investigation of the cellular signaling mediating the inhibition of LPS-induced inflammatory response by 1,4 dioxane is warrant.

The conserved RNA binding protein Orb2 upregulates rare codon biased transcripts during differentiation of *Drosophila* neurons.

R. K. Stewart, S. Allen, D. Fox; Duke University, Durham, NC.

Many processes drive differentiation, including changes in protein expression from RNA transcripts. One process that is understudied for its effect on protein expression during differentiation is codon bias. Codon bias occurs when certain codons are rarely used compared to their synonymous counterparts and is present throughout all forms of life. To begin to understand how codon bias impacts development and differentiation, we completed an animal wide reporter-based screen in the model organism *Drosophila.* This screen revealed cell type and tissue-specific responses to codon bias. Specifically, we found the testis and brain are unique in their ability to express protein derived from rare-codon enriched reporters. In these tissues, we find robust protein expression from reporters enriched in rarely used codons, whereas the other tissues in the fly do not express such reporters. Upon further investigation in the brain, we found differential regulation of protein expression from rare codon enriched transcripts within a single stem cell lineage. Neural stem cells are unable to express reporters or endogenous genes encoded by rare-codon enriched genes, while differentiated neurons do so robustly. Differentiation is tied to the ability to express transcripts enriched in rare codons, as experimentally blocking neuronal differentiation drastically reduces rare-codon enriched reporter protein. To uncover molecular regulators that enable neurons to specifically express rare codons, we conducted a reverse genetic screen of 54 candidate regulators. This screen identified the conserved cytoplasmic polyadenylation element binding (CPEB) protein Orb2 and its translational coregulator CG4612 as regulators of rare codon specific protein expression in neurons. Using both RNA FISH and RNA-seq we then identified endogenously expressed rare-codon enriched mRNAs regulated by Orb2. These rare-codon enriched mRNAs are linked to Orb2's function in long term memory in specific neuronal cell types. Using our *Drosophila* model, we have uncovered an Orb2-dependent mechanism that critically regulates rare

codon-dependent expression in neurons. Our findings reveal dynamic central dogma regulation within a defined stem cell lineage that drives cellular differentiation and function.

B636/P2306

The Epithelial to Mesenchymal Transition (EMT) in early differentiation: integrating and interrogating cell organization, cell behavior, and cell identity

A. Borensztejn[1], .. Allen Institute for Cell Science[1], J. A. Theriot[2], C. Hookway[1], S. M. Rafelski[1]; [1]Allen Institute for Cell Science, Seattle, WA, [2]Department of Biology and Howard Hughes Medical Institute, University of Washington, Seattle, WA.

The Allen Institute for Cell Science aims to understand the principles by which human induced pluripotent stem cells (hiPSC) establish and maintain robust dynamic localization of cellular structures and how cells transition between states during differentiation and disease. The epithelial to mesenchymal transition (EMT) is a state change that occurs in both normal and pathological contexts, including development and cancer metastasis respectively. The EMT has been described as a behavioral change from largely non-motile to migratory, a change in organization from apical-basal to front-back polarity, and a change in identity by protein/transcript expression profile. However, the dependencies and relationships between all three of these aspects of EMT are not well understood and require a large-scale, multi-modal data integration approach. We are working to develop and standardize a framework to combine live-cell imaging of dynamic cell behavior with cell identity characterization via multiplexed immunolabeling or RNA-FISH. We have found subpopulations of migratory cells for which the expression of particular markers is associated with being more or less stationary. A standardized framework will allow us to assess how widespread results like these are, and to probe relationships between additional markers and behaviors. In parallel, we have obtained a single cell RNA-seq (scRNA-seq) dataset with high temporal resolution over the duration of EMT, which has allowed pseudotime trajectory analysis. We find more variation in the pseudotime assignment of cells collected at (real-time) timepoints associated with dramatic behavioral changes. We are additionally using this data to identify novel probes to feed back into the live-cell/fixed and labeled cell framework described above. This integrative approach allows us to formally compare EMT in different contexts, including examples in perturbed cells or when EMT is induced by different methods. We believe that this multi-modal, multi-scale approach might serve as a template for studying EMT in many contexts and aid in understanding cell states and transitions more generally.

B637/P2307

Toxicant-responsive miRNAs skews human embryonic stem cell osteoblastogenesis

N. R. L. Sparks[1], D. Williams[2], N. zur Nieden[2,3]; [1]Environmental and Occupational Health, University of California Irvine, Irvine, CA, [2]Molecular, Cell & Systems Biology, University of California Riverside, Riverside, CA, [3]Stem Cell Center, University of California Riverside, Riverside, CA.

Birth defects that affect skeletal tissues are a major public health concern causing a life-long impact on the individual and their families. Insults from environmental chemicals can disrupt the dynamic genetic regulatory processes that can affect tissues of the neural crest and/or mesoderm which would manifest skeletal disorders of the skull or short/long bones, respectively. The number of chemicals that need evaluation of risk to the developing skeleton cannot be met with traditional testing methodologies. Here, we aimed to identify microRNAs (miRNAs) as biomarkers associated with impaired skeletal

development caused by toxicant exposure in an *in vitro* human embryonic stem cell (hESC) osteoblast differentiation model. Osteogenically differentiating hESCs were exposed to test chemicals known for their toxic effects on *in vivo* skeletal development. All tested chemicals inhibited hESC osteoblast differentiation. In addition, altered skeletal fate commitment determined by *RUNX2* upregulation and downregulation of *PAX7*, *SNAI2*, *TBX6*, and *CCN1*. Global miRNA profiling provided evidence of toxicant-responsive miRNA signatures. Chemicals cyclopamine, cyclophosphamide, methotrexate, methoxyacetic acid, ogremorphin, triadimenol, valproic acid, and 5-flurouracil identified 202, 425, 404, 313, 518, 394, 354, and 259 differentially expressed miRNAs, respectively, after exposure. Global profiling revealed 65 differentially expressed miRNAs shared between all chemicals. MiRNAs involved with ossification were deregulated by each chemical. Gene ontology (GO) indicated that the overlapping miRNAs are involved in skeletal system development, neural crest developmental/differentiation, and mesoderm development, and associated with key signaling pathways such as canonical WNT, BMP, and TGF-beta. To phenocopy the toxicants effects, selected miRNAs were knockdown or overexpressed during hESC-osteoblastogenesis. Candidate miRNA inhibitors and mimics representing down and up regulated miRNAs, respectively, attenuated hESC osteogenic differentiation, mimicking the toxicant's inhibitory effects. Further, hESC-osteoblast differentiation was rescued with miRNA mimics and inhibitors to restore miRNA expression levels during toxicant exposure. These results suggests that disruption of these necessary processes interferes with osteogenic development and provides new insights into using miRNA expression profiles as a toxicological molecular endpoint for osteotoxicity. These dynamic toxicant-induced changes in miRNA signatures reflect crucial roles of miRNAs during skeletal development and can serve as a biomarker for skeletal defects.

MicroRNA-124 plays a dual role to modulate neurogenesis and mesodermal development

K. Konrad[1], S. Suarez[2], J. Song[1]; [1]University of Delaware, Newark, DE, [2]Regeneron, Terryville, NY.

MicroRNA-124 (miR-124) plays a conserved role in regulating neurogenesis; however, its additional function in various developmental processes is less defined. We use the purple sea urchin as a model to reveal the function of miR-124. The sea urchin has one of the most well-documented gene regulatory networks (GRN), making it an excellent model to integrate the regulatory role of miR-124 into its GRN. We observed that inhibition of miR-124 resulted in decreased larval gut contractions and swimming velocity, indicating potential neuronal defects. Inhibition of miR-124 resulted in an increased number of cells expressing transcription factors associated with progenitor neurons and a concurrent decrease of mature and functional neurons. Results revealed that in the early blastula/gastrula stages, miR-124 regulates undefined factors during neuronal specification and differentiation. In the late gastrula/larval stages, miR-124 regulates *Notch* and *NeuroD1* during the transition between neuronal differentiation and maturation. In addition, we observed that miR-124 has a novel role in regulating the differentiation of mesodermally-derived immune cells, by targeting both Notch and Nodal signaling pathways. The sea urchin immune cells consist of blastocoelar cells (BCs) and pigment cells (PCs), which are derived from the same progenitor cells. Inhibition of miR-124 resulted in an increase of BC-specific gene expression and a concurrent decrease in differentiated PCs. Removing miR-124's suppression of *Nodal* leads to increased BCs and decreased PCs, while removing miR-124's suppression of *Notch* leads to increased BCs and PCs. In summary, we systematically examined the conserved function of miR-124 in neuronal development and identified miR-124's novel role in mesodermal differentiation.

Optogenetic manipulation of brain cell development in the early embryo

K. Fenelon, S. Abbasi, A. Chandrasekhar, P. H. Borad, T. Koromila; Biology, University of Texas Arlington, Arlington, TX.

Embryonic cells experience distinct signaling dynamics, levels, and combinations that control differentiation into the diverse cell fates needed in healthy adults. To determine how signaling is decoded during development, experimental control over signaling inputs is required. Pioneer-like factors activate a multitude of genes simultaneously to produce antecedent cells for burgeoning common lineages of distinct germ layers or tissue primordia. Neural progenitor specification and differentiation occur early in development with detectable neuroblasts arising as early as stage 8/9 early of *Drosophila* embryogenesis. The roles of transcription factors (TFs) that activate the zygotic genome such as Zelda (Zld)/POU5F1, Odd-paired (Opa)/ZIC, and Ocelliless (Oc)/OTX1/2 are largely conserved across the animal kingdom. Opa drives the transcriptional landscape to undergo a dramatic shift to prepare the syncytial nuclei for cellular sovereignty rounding out the blastula stage and transitioning the embryo into gastrulation. After this, subpopulations of cells destined for exponentially expanding fates begin to arise driven by more local TF, like Oc. Our hypothesis is that Opa and Oc are driving brain cell specification in the early embryo. Using super resolution microscopy, we find that opa and oc expression domains overlap, with both factors being simultaneously transcribed within neuron cells in the overlapping region. Further, analysis of scRNA-seq data reveals enrichment of several known neural developmental genes in cells containing both opa and oc transcripts. Interrogation of these genes against Opa, Oc and Zld ChIP-seq datasets and expression databases suggests that Oc and/or Opa regulate their expression. Also, we are developed a blue light-activated optogenetic tool to orthogonally, reversibly activate TFs in Drosophila embryos. We are further able to optogenetically control protein function through using photo-inducible nuclear export tools, providing further temporal control. In addition, we are using live RNA transcript imaging to visualize gene expression of multiple neuroblast specific genes at a single cell level. Our data demonstrate novel combinatorial, pioneering functions of Opa and Oc in the establishment of the neural cell lineage in the early *Drosophila* embryo. Additionally, Oc binds to a subgroup of both DV and AP enhancers independently and activates them in a third wave of zygotic transcription. The study of these dynamics in vivo in a multicellular animal like *Drosophila* presents an opportunity to understand the role of transcription dynamics for tissue differentiation and patterning. This work is vital to understanding the cell fate determinations which beget the coordinated cellular diversity of mature animalia. Funding: STARs UTA

The fly larval nerve cord on a budget: preparing for the future while taking care of the present needs

T. T. NGUYEN, R. Vicidomini, S. Choudhury, T. Han, T. Brody, M. Serpe; NICHD/NIH, Rockville, MD.

The insects ventral nerve cord (VNC), the equivalent of mammal the spinal cord, coordinates and integrates neural signaling from brain and periphery nervous system to produce a variety of locomotor outputs. Holometabolous insects, which undergo complete metamorphosis, need very different VNC functions, one for controlling crawling during the larval stages and another one for enabling the adult complex locomotor activities. How do insects develop and manage two different VNC? In flies, an atlas of the adult VNC has been assembled. However, the molecular characterization of the cells in third instar VNC remains to be determined.Here we use scRNA-seq to profile the transcriptome of 31,040

single cells from *Drosophila* third instar VNCs. Surprisingly, we found that almost 60% of these cells (17,920) are immature and undergoing a developmental program that will generate the adult VNC. These populations of cells include newborn secondary interneurons (INs) and motor neurons (MNs), glial precursors. The remaining cells are mature primary INs, MNs, and glia that fulfil various functions during the larval stages of development. Among the immature cells, we identified a transcription progression from neuroblasts to newborn secondary neurons. We found that all 21 hemilineages (LINs) reported in adult VNCs have correspondent clusters of secondary neurons in the larval VNC. Moreover, each larval secondary LIN has already acquired neurotransmitter identity and has its own repertoire of cell fate determinants. Almost 40% of the larval VNC cells are mature neurons and glia that control larval behavior and function. We identified over 40 subtypes of differentiated primary INs, each expressing unique combinations of transcription factors and neurotransmitters. Interestingly, primary INs are very different from secondary neurons. Finally, we identified and compared immature secondary and mature primary MNs. Adult newborn secondary MNs have low level of glycolysis related genes, low level of genes encoding synaptic proteins, and express no BMP target genes. In contrast, larval MNs are metabolically active (high level of glycolytic genes) are connected and functional (high level of synaptic genes) and are shaped by retrograde BMP signaling (express BMP target genes). Our studies uncover a surprising partition of the larval VNC which prepares the cells for the adult VNC while ensuring that larval needs are met. This larval VNC atlas provide a valuable resource for future studies of neurodevelopment and behavior.

Mechanosensation via NompC Regulates Sensory Progenitor Differentiation in Maintaining Proprioception of Adult *Drosophila*

R. Zhu, S. Younger, K. Li, P. Jin, L. Y. Jan, Y. N. Jan; Department of Physiology, UCSF/HHMI, San Francisco, CA.

The “sixth sense” proprioception is mediated by mechanosensory neurons in muscles, tendons, and ligaments. Mechanosensitive channels (MSCs) are essential components for these neurons. MSC gene variant could result in proprioception defects in human. While consequences of chronically losing the mammalian MSCs are hard to study, we turned to *Drosophila melanogaster* MSC NompC, a Transient Receptor Potential family protein. The survival flies with *nompC* knocked out (KO) by CRISPR significantly decreased compared to w1118 control after eclosion. Further, the KO adult flies exhibited wing held-up defect and uncoordinated movement after eclosion. Re-expression of the full-length NompC protein by using binary Gal4 drivers revealed that NompC is required in class I/bd dendritic arborization (da) neurons, but not in other da neurons, motor neurons or muscles to regulated wing held-up phenotype. Localization of nompC by nompC-Gal4 overexpression of fluorescent marker and endogenous knocked-in *gfp* in *nompC* , together with rescue experiments pin pointed that NompC in type I small sensillum campaniformium of dorsal radius Sc12 at wing hinge is important for normal wing posture. Re-expression of NompC mutants that lost their mechanosensitivity in Sc12 cells failed to rescue the held-up phenotype observed in the KO, suggesting mechanosensation via NompC is important for maintaining the wing posture. Lineage analysis of Sc12 cells by LacZ and Gal4 systems suggested a defect in sensory progenitor cell number at early pupal formation. Consequently, the neuron number and glial number are reduced in the Sc12 niche of NompC-depleted adults. Mutants of NompA, a putative NompC binding partner in the extracellular matrix, displayed a similar help-up/held-out proprioceptive wing posture defect, and we are currently testing whether NompA is also involved in sensory progenitor’s

development. Our studies suggest that external force sensed by NompC in sensory progenitors is important for their differentiation, which in turn is responsible for maintaining normal wing posture.

Profiling of differently reproductive-aged ovaries from marmoset monkey

S. Ku[1], Y. Kim[2]; [1]Dept of OBGYN, Seoul Natl University Hospital, Seoul, KOREA, REPUBLIC OF, [2]Biomedical Research Institute, Seoul Natl University Hospital, Seoul, KOREA, REPUBLIC OF.

Ovarian reserve decreased naturally with age or by chemotherapy. However, the exact mechanism is not known and is difficult to elucidate due to the ethical limits of the human sample. Marmoset monkey (*Callithrix jacchus)* is a rising non-human primate (NHP) model of biomedical research and an optimal model for reproductive medicine due to their close reproductive physiology and short gestation period. In this study, we profiled the mRNA expressions of 84 genes, related to female infertility, in differentially aged marmoset monkey ovaries. Ovariectomy of each aged marmoset monkey was performed and the ovaries were cut into small pieces (1x1 cm^2). Then, the pieces were enzymatically dissociated with Col. IV (1 mg/ml) and filtered through 40 μm strainers. Collected cells were replated and processed for further RNA extraction and qRT-PCR. The results were analyzed using databases. The expression profile of a total of 84 genes related to the female infertility of each aged ovary was analyzed. Among the female Infertility related genes, TGFβ, IL1 α, IL5, VEGFα, IL1β, Bcl2, ITGAV, TNF, MMP9, AKT1, MMP2, EGF, TIMP1, and ITGB, are involved in fibrosis and increased as reproductively aged. This study analyzed the female infertility-related genes in pre-pubertal, reproductive, and menopausal aged marmoset ovaries. The results indicated that the decreased ovarian reserve is strongly related to the onset of fibrosis (2020R1A2C1010293 and 2022R1A2B5B01002541).

Characterization of Calcium Binding and Coiled Coil Domain 1 (Calcoco1) in Skeletal Muscle

A. Kajdic, D. Waddell; Biology, University of North Florida, Jacksonville, FL.

Skeletal muscle atrophy results in loss of muscle mass and strength and is caused by a range of physiological conditions including aging, cancer, corticosteroid use, and denervation. To further our understanding of the molecular genetic events associated with muscle atrophy, a previous study isolated skeletal muscle from mice following 3 days and 14 days of denervation and the gene expression profile was analyzed by microarray and compared to control muscle to identify novel, atrophy-induced genes. The microarray revealed that Calcium Binding and Coiled Coil Domain 1 (Calcoco1) is expressed in skeletal muscle and induced in response to denervation. The cDNA of Calcoco1 was successfully amplified and cloned from cultured C_2C_{12} cells, demonstrating that this gene is expressed in muscle cells. Quantitative PCR was subsequently conducted using RNA isolated from proliferating and differentiating muscle cells to determine the expression profile of Calcoco1 at the transcriptional level. We observed moderate activation of Calcoco1 through myoblast proliferation and early differentiation, followed by a robust increase in expression at later stages of myotube differentiation. These results were mirrored at the protein level where it was observed that Calcoco1 is expressed in early proliferation and increases as differentiation progresses. To elucidate the function of Calcoco1 in muscle, we transfected cultured muscle cells with a Calcoco1 expression plasmid and then harvested the cells at timepoints ranging from proliferation through late differentiation. The cell lysates were probed by Western blot for markers of muscle cell differentiation, including Myosin Heavy Chain (MyHC) and myogenin, which both show

significant repression in response to Calcoco1 overexpression. The Calcoco1 protein is predicted to contain both a calcium binding domain and a coiled-coiled domain, suggesting that it may play a role in protein-protein interactions or as a putative transcription factor. To begin to investigate these possibilities, we sought to determine the sub-cellular localization of Calcoco1 in muscle cells by fusing Calcoco1 cDNA to Green Fluorescent Protein (GFP) and expressing it in muscle cells. Visualization by confocal microscopy revealed clear nuclear-exclusion of Calcoco1 protein in unchallenged myoblast cells, suggesting that it may not participate directly in gene regulation. The discovery that Calcoco1 is expressed in skeletal muscle and is induced in response to neurogenic atrophy, in combination with its apparent role in muscle cell differentiation, helps further our understanding of the molecular and cellular events of muscle atrophy and may eventually contribute to the identification of new therapeutic targets for the treatment of muscle wasting.

***Prdm1* Drives a Sensory Hair Cell Fate Switch in Zebrafish**

J. E. Sandler, N. T. T. Tran, S. Chen, T. Piotrowski; Stowers Institute for Medical Research, Kansas City, MO.

One of the causes of permanent hearing loss in mammals is the lack of regeneration in the cochlea following damage to mechanosensory hair cells. Regenerating hair cells is a central strategy for restoring hearing, but triggering their proliferative regeneration and maturation in mammals remains elusive. The zebrafish *Danio rerio* has hair cells both in an array along the trunk, called the lateral line, and in the inner ear. While sharing genetic, functional, and structural similarity with mammalian inner ear hair cells, zebrafish hair cells differ in that they readily and rapidly regenerate following death to restore full function. Therefore, it is our objective to understand the genetic networks driving zebrafish hair cell regeneration to identify gene targets for triggering regeneration in mammals. The transcription factor *prdm1a* is expressed in hair cells of the zebrafish lateral line, but not in hair cells of zebrafish or mammalian inner ears. Previously, mammalian *Prdm1* has been shown to control a fate switch in various cell types, including B lymphocytes and photoreceptors in the retina. The combination of both its hair cell-specific expression and its involvement in cell fate decisions led us to investigate *prdm1a* for its role in hair cell development and regeneration. We mutated *prdm1a* in zebrafish and found a drastically reduced number of hair cells and cell proliferation in the lateral line during development and regeneration. Single cell RNA-seq on *prdm1a* mutants and siblings revealed a cell type fate switch between lateral line and inner ear hair cells, with a multitude of inner ear hair cell-specific genes ectopically expressed in mutant lateral line hair cells. Performing ATAC-seq and ChIP-seq on zebrafish lateral line cells, we found Prdm1 binding sites highly enriched in the promoters and enhancers of ectopically expressed inner ear hair cell genes. Using these enhancers to drive GFP expression in zebrafish confirmed their ectopic expression in *prdm1a* mutant hair cells, but not in siblings. These findings show that Prdm1a plays a crucial role in repressing an inner ear hair cell fate in lateral line organs and highlight Prdm1 as a potential driver of hair cell type specification and regeneration in other vertebrates. Combined, our data show that *Prdm1* is an essential gene to consider in future regeneration attempts in the mammalian cochlea.

Planarian glia in the context of whole brain regeneration

B. Chandra[1], M. Voas[2], E. Davies[2], **R. Roberts-Galbraith**[1]; [1]Cellular Biology, University of Georgia, Athens, GA, [2]Center for Cancer Research, National Cancer Institute, National Institutes of Health, Frederick, MD.

Non-neuronal cells collectively called glia play diverse roles in neurodevelopment and in regulation of neural function across diverse animal species. Roles for glia in regeneration are more complex, with glia playing inhibitory and/or permissive roles in regeneration depending on the species and the injury context. The discovery of astrocyte-like glial cells in planarians—freshwater flatworms with extraordinary regenerative abilities—presents the opportunity to understand glial regeneration and function in the context of successful, whole-brain regeneration. In our laboratory, we are interested in using planarians to uncover mechanisms underlying glial regeneration, to discover functions of glia in a new animal species, and to explore the interplay between glia and neurons in the context of brain regeneration. Here we show that transcription factor *ets-1*regulates glial cell regeneration and cell state in planarians. With a gene in hand to perturb glia, we also explored the effects of glial reduction on neurons and showed that loss of *ets-1* results in locomotion defects, changes gene expression in neurons, and impacts markers of neural connectivity. Finally, we show that planarian neurons regenerate and develop before glia. We are currently testing whether planarian glia require neurons for their specification and proper localization within the nervous system. Our results establish planarians as a model for studying evolution of glia/neuron interactions and interplay between these critical cell types during brain regeneration.

B646/P2316

An Essential Role of Polyhomeotic Homolog 1 (Phc1) in Early Neural Development

A. L. C. Ong[1], M. Shirai[2], N. Sasai[1]; [1]Laboratory of Developmental Biomedical Science, Nara Institute of Science and Technology, Ikoma, Nara, JAPAN, [2]Omics Research Center, National Cerebral and Cardiovascular Center, Osaka, JAPAN.

Polyhomeotic homolog 1 (PHC1), is a component of the polycomb repressive complex 1 (PRC1) that has a role in transcription repression during developmental stages. Phc proteins mainly regulate the PRC1 assembly and polymerization that help in chromatin modification and lead to gene silencing. Previous studies have shown that deficiency of the *Phc1* gene in mice caused eye abnormalities during early embryonic stages. However, little is known about the detailed mechanisms of Phc1. With that, we set to investigate Phc1 and its role in early neural development.For this purpose, we utilized CRISPR/Cas9 system and ES cells-derived differentiation system to generate *Phc1*-knockout (*Phc1*-KO) mouse embryonic stem cells, then differentiate into early-stage neural tissues. *Phc1*-KO cells were unable to differentiate into neural progenitor cells, whereby the neural markers, Sox1 and Pax6, failed to be expressed. The expression of pluripotent genes (Nanog, Klf4 and Zfp42) were upregulated in the absence of *Phc1*. We hypothesized that the high expression of pluripotency markers prevented the *Phc1*-KO cells from early neural differentiation. We then performed CRISPR-mediated targeted knock-in to insert the complete coding sequence of *Phc1* into the *Phc1*-KO genome. The early neural differentiation phenotypes were partially recovered with the exogenous *Phc1* gene. Besides Phc1, there are several protein subunits in the PRC1, including Ring1A/B, Pcgf2/4, Cbx2/4/6/7/8 and Phc1/2/3. Several knockout cells of these subunits were generated and we found that absence of these subunits did not prevent the cells from differentiation into early neural progenitor cells. This suggested that they

could be compensated by their respective paralogs. As Phc1 and PRC1 play critical roles in histone modification and chromatin remodeling, we are now evaluating the genome wide chromatin accessibility, modification and target gene binding with ATAC-sequencing and chromatin immunoprecipitation quantitative real-time PCR.

Intracellular pH dynamics regulates intestinal stem cell lineage specification

Y. Liu[1], E. Reyes[1], D. Castillo-Azofeifa[1,2], O. D. Klein[1], T. Nystul[1], D. L. Barber[1]; [1]University of California, San Francisco, San Francisco, CA, [2]Genentech, Inc., South San Francisco, CA

Intracellular pH (pHi) dynamics is increasingly recognized to regulate myriad cell behaviors, including proliferation, migration, differentiation, and transformation. Here we report a new finding that pHi dynamics also regulates adult stem cell lineage specification. In mouse small intestinal organoids, we identify a pHi gradient along the crypt axis, lower at the crypt base and higher toward the villus, and find that dissipating this gradient by inhibiting Na^+-H^+ exchanger 1 (NHE1) activity genetically or pharmacologically abolishes crypt budding. Using single-cell RNA sequencing and lineage tracing we demonstrate that pHi dynamics acts downstream of ATOH1, with increased pHi promoting differentiation toward the secretory lineage, while reduced pHi biases differentiation into the absorptive lineage. Consistent with these results, disrupting the pHi gradient blocks new Paneth cell differentiation. Paneth cells provide an essential WNT signal to ISCs in organoids, and we find that the loss of crypt budding with inhibiting NHE1 activity is rescued with exogenous WNTs. Our findings indicate that pHi dynamics is tightly regulated in the ISC lineage and that an increase in pHi is required for the specification of secretory lineage, including Paneth cell differentiation that contributes to crypt maintenance. These observations reveal a previously unreported role for pHi dynamics in cell fate decisions within an adult stem cell lineage.

B648/P2318

Intracellular pH Dynamics Regulates Wnt Signaling for Stem Cell Differentiation

H. Virk[1,2], K. Kisor[1], T. Nystul[1], D. L. Barber[1]; [1]University of California, San Francisco, San Francisco, CA, [2]San Francisco State University, San Francisco, CA

Intracellular pH (pHi) dynamics is now recognized as a signal regulating stem cell differentiation and cell fate decisions. Increased pHi is required for the differentiation of mouse embryonic stem cells (mESCs) and adult intestinal stem cells as well Drosophila follicle stem cells (FSCs), although the mechanisms mediating these effects remain unknown. Decreased Wnt pathway activity is necessary for the differentiation of multiple types of stem cells, and we previously reported that increasing pHi attenuates Wnt signaling in epithelial cells by decreasing stability of the effector β-catenin. We reported that a higher pHi increases β-catenin binding to the E3-ligase β-TrCP by deprotonating β-catenin-His35 at the binding site. We now report two advances in our understanding of pHi dynamics, Wnt signaling, and stem cell differentiation. First is that β-catenin binding to BCL9, which is a means for translocating β-catenin to the nucleus for transcriptional responses, is attenuated at higher pH. The crystal structure of BCL9 in complex with β-catenin indicates a salt bridge between BCL9-His358 and β-catenin-Asp162 at the binding interface, and we confirmed with *in vitro* binding using recombinant proteins that a neutral histidine at pH $\geq$ 7.5 decreases binding compared with pH < 7.5. Second, using *in vivo* differentiation of Drosophila FSCs, which requires increased pHi and decreased Wnt pathway activity, we found that a

mutant armadillo-His42R (Drosophila β-catenin-His42R) that is insensitive to pH-regulated stability results in severe morphological defects in the FSC lineage through the expansion of epithelial cells and improper budding of germline cysts. These findings support our previous reports on increased pHi being necessary for stem cell differentiation, and they add mechanistic insight by suggesting the effect is due to a higher pHi in differentiating cells decreasing Wnt pathway activity.

Stem Cells and Pluripotency

PSME4 degrades acetylated YAP1 in the nucleus of mesenchymal stem cells to induce cardiac commitment

G. Kang[1], **G. Eom**[2]; [1]Chonnam National University Hospital, Gwangju, KOREA, REPUBLIC OF, [2]Pharmacology, Chonnam National University Medical School, Hwasun, KOREA, REPUBLIC OF.

Intensive research has focused on minimizing the infarct area and stimulating endogenous regeneration after myocardial infarction. Our group elucidated that apicidin, a histone deacetylase (HDAC) inhibitor, robustly stimulates cardiac commitment of mesenchymal stem cells (MSCs) through acute loss of YAP1. Here we further studied the mechanism of this role of YAP1 in MSCs. We found that acute loss of YAP1 after apicidin treatment resulted in the mixed effects of transcriptional arrest and proteosomal degradation. Subcellular fractionation revealed that YAP1 was primarily localized in the cytoplasm. YAP1 was acutely relocalized into the nucleus and underwent proteosomal degradation. Interestingly, phosphor-S127 YAP1 was shuttled into the nucleus, suggesting that a mechanism other than phosphorylation governed subcellular localization of YAP1. Apicidin successfully induced acetylation and subsequent dissociation of YAP1 from 14-3-3, an essential molecule for cytoplasmic restriction. HDAC6 regulated both acetylation and subcellular localization of YAP1. An acetylation-dead mutant of YAP1 retarded nuclear redistribution upon apicidin treatment. We failed to acquire convincing evidence for polyubiquitination-dependent degradation of YAP1, suggesting that a polyubiquitination-independent regulator determined YAP1 fate. Nuclear PSME4, a subunit of the 26S proteasome, recognized and degraded acetyl YAP1 in the nucleus. MSCs from PSME4-null mice were injected into infarcted heart and aberrant sudden death was observed. Injection of immortalized human MSCs after knocking down PSME4 failed to improve either cardiac function or the fibrotic scar area. Our data suggest that acute ablation of YAP1 in the nucleus by the acetylation-dependent proteasome subunit PSME4 is mandatory for cardiac commitment of MSCs.

Golgi organization is a determinant of stem cell signaling in the small intestine

S. Scharaw[1], A. Sola Cavajal[1], A. Webb[1], I. Belevich[2], N. Pentinmikko[2], S. Das[1], E. Jokitalo[2], R. Coffey[3], P. Katajisto[1]; [1]Karolinska Institute, Solna, Sweden, [2]University of Helsinki, Helsinki, Finland, [3]Vanderbilt University, Nashville, TN

Cell-to-cell signaling between stem and niche cells regulates stem cell function and tissue regeneration. Lgr5+ small intestinal stem cells (ISCs) reside at the intestinal crypt bottom and communicate with their neighboring niche Paneth cells by growth factor signaling. Whereas the key signals have been extensively characterized, the secretory transport of ISC signal proteins is largely unknown. Here, we set up a microscopy-based secretion assay in crypt cells of intestinal organoids and quantified the secretion

efficiency of Epidermal growth factor receptor (Egfr), a key receptor for stem-to-Paneth cell signaling. This showed that ISCs at the crypt center secreted Egfr with a higher efficiency to the cell surface than ISCs at the crypt border. Serial block-face scanning electron microscopy on intestinal crypts revealed ISCs to consist of lateral Golgi complex mini-stacks, and two mini-stacks in center ISCs accounted for their higher secretion efficiency compared to border ISCs with one mini-stack. Mechanistically, Golgi complex mini-stack morphology of ISCs requires A-kinase anchor protein 9 (AKAP9), and AKAP9 inhibition altered Egfr secretion and *in vitro* regeneration capacity of ISCs. Moreover, in aged mice Golgi mini-stack differences between ISCs at the center and border were lost, which caused signal secretion efficiencies of center ISCs similar to those of border ISCs. Our results reveal a Golgi complex morphology arrangement that facilitates a secretion efficiency gradient of ISCs from the center towards the crypt border, which is required for tissue regeneration and is lost in the old epithelium.

B651/P2321

PLEKHA4/*kramer*regulates intestinal homeostasis via wnt signaling in *drosophila*

H. Sun[1], A. Shami Shah[2], A. Bonfini[3], N. S. Buchon[3], J. M. Baskin[1]; [1]Weill Institute for Cell & Molecular Biology, Cornell University, Ithaca, NY, [2]Weill Institute for Cell & Molecular Biology and Department of Chemistry and Chemical Biology, Cornell University, Ithaca, NY, [3]Departments of Entomology, Cornell University, Ithaca, NY.

Wnt/β-catenin signaling is required in animals for the regulation of intestinal stem cells (ISCs) during homeostasis and tissue regeneration. We have previously demonstrated that the phosphoinositide-binding protein PLEKHA4 sequesters the Cullin-3 (CUL3) E3 ubiquitin ligase substrate adaptor Kelch-like protein 12 (KLHL12) in an inactive state at the plasma membrane and thus enhances Wnt/β-catenin signaling by preventing polyubiquitination of Dishevelled (Dvl), a key activator of Wnt/β-catenin signaling, by CUL3-KLHL12 in mammalian cells. However, the potential effects of PLEKHA4 on Wnt/β-catenin signaling has not been examined in vivo. Here, we investigated whether the *Drosophila* ortholog of PLEKHA4, *kramer*, regulates Wnt/β-catenin in vivo using a model for intestinal stem cell (ISC) regeneration following non-lethal infection. We infected wildtype, *kramer* knockout, or tissue-specific *kramer* knockdown *Drosophila melanogaster* with *E. carotovora carotovora 15* (Ecc15), a gram-negative bacterium, and we assessed ISC proliferation in the midgut, the fly equivalent of the small intestine. Knockout and knockdown of *kramer* decreased proliferation of ISCs and certain other cell populations in the intestinal epithelium; moreover, *kramer* knockout also downregulated the expression of Frizzled 3, a Wnt/β-catenin target gene, specifically in the posterior midgut. Our results indicate that *kramer* regulates ISC proliferation via Wnt/β-catenin signaling. Elucidation of Wnt/β-catenin activation in ISCs, as well as additional roles for non-canonical Wnt signaling pathways impacted by *kramer*, will provide insights for identifying novel therapeutic targets for the treatment of diseases caused by the dysregulation of Wnt signaling pathways.

The role of Wnt pathway in activation of Hair Follicle Stem Cells during cyclic hair regeneration

P. Mazurek, K. Tchórz, K. Łukaszyk, K. Kobielak; Laboratory of Stem Cells, Tissue Development and Regeneration, Centre of New Technologies University of Warsaw, Warsaw, POLAND.

In the sense of a mini-organ, the hair follicle is an excellent model for studying the molecular mechanisms that govern the transition between quiescence and cyclic activation of the hair follicle stem

cells (hfSCs) during hair growth. Our previous finding revealed that a competitive balance between two well-known molecular pathways, wingless/integrated pathway (Wnt) and bone morphogenetic protein pathway (BMP) is crucial for hfSCs homeostasis *in vivo*. We found that hfSCs with suppressed BMP signaling show up-regulation of several WNT activators, including the Wnt7b ligand. This ligand was identified as a potential target of BMP signaling in hfSCs *in vivo*. Although we revealed that loss of Wnt7b function during the hair cycle results in a delay of hfSCs activation, there has been no evidence regarding how Wnt7b works at the molecular level on hfSCs regulation during the hair regeneration cycle. To answer this question, we created a genetic mouse model to simultaneously label and specifically inactivate the Wnt7b pathways within the hfSCs. Using this approach, we were able to isolate living Wnt7b knockout hfSCs marked by eYFP using fluorescence-activated cell sorting (FACS). Total RNAs from isolated cells were used to perform RNA-seq analyses, which allowed us to analyse the expression of hfSCs genes after inactivation of Wnt7b and thus characterize target genes relevant for Wnt7b signaling. We identified 2240 gene expression changes after the inactivation of the Wnt7b ligand. Bioinformatic analysis showed that more than 90% of the axial genes of the hfSCs internal oscillator were altered. Interestingly, more than 83% of the genes are altered in the same way as in the BMP pathway inactivation, resulting in premature activation of stem cells. Surprisingly, the molecular mechanism we discovered shows that the deletion of the Wnt7b ligand for the WNT canonical pathway in hfSCs is compensated for by activating the expression of two other ligands for the WNT canonical pathway, which correlates with the inhibition of two other ligands and Fzds receptors for the non-canonical WNT pathway. In summary, our discovery fits into the internal oscillator model we previously discovered, which explains that this naturally occurring mechanism of compensation and coupling of genes responsible for regulating hair regeneration adapts to changing molecular conditions. Moreover, to investigate the mechanism of action of other WNT pathway modulators during hfSCs activation, we are also using the CRISPR/Cas9 system. This approach allows us to inactivate several genes of interest within the hfSCs in vitro at the same time and then further investigate their biological functions, again, returning to the *in vivo* model using the chamber graft assay.

B653/P2323

Deletion of the von-Hippel Lindau (Vhl) gene in bone cells leads to aberrant hematopoiesis in mice

B. Chicana Romero[1,2], H. Taglinao[2], J. O. Manilay[2]; [1]Fred Hutch Cancer Reserach Center, Seattle, WA, [2]University of California Merced, Merced, CA.

Stabilizers of hypoxia-inducible factors (HIFs) are proposed treatments to alleviate bone loss. One strategy to stabilize HIF is via inhibition of the von-Hippel Lindau protein (VHL). VHL regulates hypoxia-inducible factor degradation and is involved in responses to low oxygen environments. Osteoblasts (OBs) and osteocytes (OCYs) are bone cells known to support hematopoiesis in the bone marrow. However, the specific interaction of bone cells and local bone marrow microenvironments that contribute to the regulation of hematopoiesis are not fully understood. We utilized *Dmp1*-Cre;*Vhl* conditional knockout mice (cKO), in which *Vhl* is deleted in OBs and OCYs. When a longitudinal analyses of cKO mice were performed at 3, 6, 10 and 24 weeks of age, a time dependent increase of high bone mass and reduction of the bone marrow cavity was gradually observed. In transplantation experiments, reciprocal bone marrow chimeras showed significant reduction of % B cells in the WT→cKO, while B cell development was normal in the cKO→WT chimeras, suggesting a cell-extrinsic effect of *Vhl* on B cells development within the cKO bone marrow microenvironment. Observed drastic defects in B cell development were associated with reduced levels of CXCL12 and IL7, increased apoptosis and

quiescence of early B cell progenitors, and indications of hypoxia in local B cell niches. We also hypothesized that distinct subsets of myeloid cells were differentially affected in the cKO bone marrow. Using flow cytometry, we discovered increased frequencies (%) of common myeloid progenitors (CMP) and granulocyte-monocyte progenitors (GMP) but no difference in % frequency of neutrophils, dendritic cells and monocytes. In contrast, we observed similar % of myeloerythroid progenitors (MEP) in cKO and controls, but enhanced erythropoiesis in the cKO, including a significant increase in CD71- TER119+ orthochromatic erythroblasts in the bone marrow. These discoveries provided a potential mechanism by which VHL/HIF signaling in osteocytes serves as a regulatory niche for distinct hematopoietic lymphoid and myeloid lineages in the bone marrow. Additionally, these studies are important for understanding how HIF stabilization in skeletal cells can affect hematopoiesis.

B654/P2324

Dynamic patterns of ERK activity encode skeletal tissue size during zebrafish fin regeneration

A. Rich[1], Z. Lu[1], A. De Simone[2], K. D. Poss[1], S. Di Talia[1]; [1]Cell Biology, Duke University, Durham, NC, [2]Department of Genetics & Evolution, University of Geneva, Geneva, SWITZERLAND.

Mammals possess a limited capacity to regenerate appendages following traumatic injury and amputation, including regenerating digit tips and healing bone fractures. In contrast, zebrafish can regenerate entire appendages following amputation. As in development, regenerated appendages are scaled appropriately to body size. Extensive genetic and pharmacological experiments have established that canonical signaling pathways, such as Fgf and Wnt, are reactivated following injury to promote the cell proliferation, migration, and differentiation that drives appendage regeneration. However, how these pathways encode size and shape is unclear. Here, we study the molecular underpinnings of size control during the regeneration of caudal fin osteoblasts, bone matrix secreting cells. Osteoblast proliferation must be tightly controlled in time and space to regenerate bony rays of appropriate length. Extracellular signal-regulated kinase (ERK) is an established regulator of cell proliferation and is known to regulate osteoblast differentiation. ERK is also a canonical downstream target of Fgf signaling, which is required for caudal fin regeneration. We developed a live-imaging platform to quantitatively investigate whether ERK activity controls osteoblast proliferation and encodes tissue size during caudal fin bone regeneration. We find dynamic, long-range gradients of ERK activity that persist throughout regeneration, and we show that the probability of proliferation within a region of regenerating osteoblast tissue quantitatively depends on ERK activity. Furthermore, both average ERK activity and osteoblast proliferation decrease as regeneration progresses. Importantly, these relationships are conserved between longer lateral and shorter medial rays. Using these experimental observations, we modeled ray growth rate as a function of fraction of regeneration completed and found that our prediction of this relationship agrees with previously published measurements of ray growth during fin regeneration. Altogether these results suggest a universal law, molecularly controlled by ERK activity, describes skeletal tissue growth during fin regeneration.

In Vitro Culture of Skin Samples Excised from an Accidentally Deceased One Month Old Goat Kid up to 14 Days of Postmortem Interval Upon Storage at 4°C

M. Singh, T. Stephens, X. Ma, A. Abosede; Animal Science, Fort Valley State University, Fort Valley, GA.

The objective of this study was to assess the postmortem time limits within which live and proliferative cells can be recovered from newborn goat kid skin tissues stored in refrigerator (4°C) after their death. Small (3-4 mm^2) explants (n = 20) from ear skin stored at 4°C postmortem were cultured in 35 mm dish after 0, 7, 14, 21 and 28 days of storage in DMEM media supplemented with 10% FBS, 50 units/mL of penicillin, 50 µg/mL of streptomycin and 2.5 µg/mL of fungizone. Presence or absence of the fibroblast cell outgrowth around the explants was scored. We observed outgrowth of cells around explants up to 14 days of postmortem interval in all the explants (100%) that adhered to dish surface. Cells started outgrowing from the explants at day 3, 5, and 8 in 0-dpm, 7-dpm and 14-dpm time intervals, respectively. The level of confluence, as recorded on day 10-12 of culture initiation, decreased with increasing postmortem time interval. The outgrowing cultures were trypsinized to recover the cells upon reaching around 90% confluence, in each time point, and the number of recovered cells counted using trypan blue dye exclusion method. The average number of cells recovered from each explant was calculated to be 26.11 x 10*4, 7.10 x 10*4 and 2.40 x 10*4 cells/mL for 0-dpm, 7-dpm and 14-dpm cultures, respectively. When equal number of these passage 0 primary cells sub-cultured into a new dish for each postmortem time interval, we observed comparable growth profile and morphology to that of fresh tissue derived cell populations. Taken together, these results suggest that live, proliferative, and usable cells can be recovered from newborn goat kid skin tissues up to 14 days of postmortem interval, if the skin tissues are stored at 4°C. Reprogramming of these cells to clone the dead goat genetics remain to be seen in future studies.

Mechanisms of vascular maturation and maintenance captured by longitudinal imaging of live mouse skin

C. Kam[1], I. D. Singh[1], C. Matte-Martone[1], D. G. Gonzalez[1], P. Sola[2], G. Solanas[2], J. Bonjoch[2], E. D. Marsh[1], K. K. Hirschi[3], V. Greco[1]; [1]Genetics, Yale University, New Haven, CT, [2]IRB Barcelona, Barcelona, SPAIN, [3]Cell Biology, University of Virginia, Charlottesville, VA.

A functional network of blood vessels is essential for organ growth and homeostasis. Yet, how the vasculature matures and maintains adult homeostasis remains elusive in live mice. To shed light on these fundamental biological processes, we performed longitudinal imaging in the skin of live mice using 2-photon microscopy, which allows for non-invasive tracking of cell populations over long periods of time. We systematically evaluated the same capillaries and endothelial cells (ECs) in neonatal mice over periods of days to weeks, tracking their behaviors as the skin plexus expanded with organismal growth and reached adulthood. Counterintuitively, we found that capillary plexus expansion is driven by network-wide vessel regression and transient angiogenesis during neonatal stages. These processes involve migratory ECs that relocate from regressed segments to neighboring vessels. Furthermore, we observed that all ECs dynamically rearrange their positions within maturing capillaries, independent of their remodeling status. These rearrangements regulate EC density by ensuring an even cellular distribution during plexus expansion. As the skin approaches adulthood, plexus regression rates decrease, and ECs become positionally stable. However, upon discrete local injury via targeted laser

ablation, neighboring ECs do not proliferate but collectively elongate or migrate towards damaged sites to repair vessels. This mechanism is in direct contrast to the proliferative repair observed during large scale ablation of blood vessels. Remarkably, we found that injured adult ECs, rather than dying, survive through the activation of a plasmalemmal self-repair response whereby ECs are able to excise and discard damaged portions of their cell membranes prior to regenerating. In contrast, neonatal ECs are disposed to be eliminated via apoptosis in response to injury, causing the regression of the vessel segment in which they reside. Lastly, neonatal vessel regression and adult vascular maintenance are orchestrated by temporally restricted VEGFR2 dependent signaling. Acute blockade of VEGFR2 during neonatal stages accelerates the rate of vessel regression and network maturation. Surprisingly, when revisited in adulthood, these animals display widespread vessel tortuosity, an indicator of unhealthy vasculature. Our work sheds light on fundamental tissue, cellular, and molecular mechanisms that underlie both vascular maturation and adult homeostasis in vivo.

B657/P2327

Activated platelet derived growth factor signaling pathway enhances ovarian function in injured rat ovary *via* pericyte recruitment

H. Park[1,2], D. Lee[1,2], K. Na[1], W. Jeong[1], J. Seok[3], J. Lim[4], G. Kim[1,2]; [1]CHA University, Seongnam-si, KOREA, REPUBLIC OF, [2]PLABiologics.Co.Ltd, Seongnam-si, KOREA, REPUBLIC OF, [3]University of Chicago, Chicago, MD, [4]Hyejeon College, Hongsung-gun, KOREA, REPUBLIC OF.

Vascular abnormalities in the ovary cause ovarian dysfunction due to a microenvironment of barren ovarian tissues. Platelet-derived growth factor signaling is critical pathway in maturation stage of follicular development and ovarian function. It is major factor in vascular stabilization and maturation by pericyte recruitment. In previous reports, we demonstrated placenta-derived mesenchymal stem cells (PD-MSCs) overexpressing phosphatase regenerating liver-1 (PD-MSCs^{PRL-1}) restores ovarian function via antioxidants effect. However, there is still unclear the therapeutic mechanism between ovarian function and vascular function (e.g., vascular structure, vascular permeability, and so on). Therefore, we examined whether PD-MSCs^{PRL-1}, which is correlated with angiogenesis in reproductive systems, could maximize the angiogenic effects in an injured ovarian rat model and regulates the PDGF signaling by enhanced vascular function via pericyte recruitment. One week after Sprague-Dawley (SD) rats with ovariectomy, PD-MSCs and PD-MSCs^{PRL-1} were transplanted into the injured rat model by tail vein. After transplantation, the expressions of factors for angiogenic and follicular development were analyzed. Vascular structures in ovarian tissues (e.g., thickness and lumen area) showed changes in the PD-MSCs and PD-MSCs^{PRL-1} transplantation (Tx) groups compared to the non-transplantation (NTx) group. Especially, PD-MSCs^{PRL-1} induce to increase the expression of PDGF compared to the NTx (*p<0.05). The pericyte recruitment (NG2) was significantly enhanced in PD-MSCs^{PRL-1} compared to the NTx and PD-MSCs *via* activated PDGF (*p<0.05). The expression of genes related to vascular permeability (e.g., erg-3) and follicular development (e.g., Nobox, BMP15 and EGFR) in ovarian tissues was significantly improved in the PD-MSCs^{PRL-1} compared to the NTx and PD-MSCs (*p<0.05). Also, PD-MSCs^{PRL-1} enhanced the vascular formation and decreased permeability of human umbilical vein endothelial cells (HUVECs) *via* activated the PDGF signaling. The expression of PDGF was significantly decreased in si-PRL-1 or PDGFR inhibitor treatment compared to control. However, their expression was significantly increased in PD-MSCs and PD-MSCs^{PRL-1} cocultivation group compared to si-PRL-1 or PDGFR inhibitor treatment (*p<0.05). Our results show that increased PRL-1 restored ovarian function by enhanced vascular function *via* activated pericyte and PDGF signaling pathway. These findings offer new insight into the

effects of functionally enhanced stem cell therapy for reproductive systems and should provide new avenues to develop more efficient therapies in degenerative medicine.

Interpreting geometric rules of early kidney formation for synthetic morphogenesis

J. Viola, J. Liu, L. Prahl, A. Huang, T. Chan, G. Hayward-Lara, C. Porter, **A. Hughes**; University of Pennsylvania, Philadelphia, PA

The kidney develops through coordinated growth of ureteric epithelial tubules (the future urinary collecting ducts), stroma, and nephron progenitors in the cap mesenchyme that surrounds each ureteric tip as they branch. Dynamic interactions between these tissues set nephron numbers for life, impacting the probability of adult disease. How then are the rates of nephron formation and ureteric tubule duplication balanced? Here we study the geometric and mechanical consequences of tubule tip packing at the embryonic kidney surface for tip organization and nephron formation. We find that over developmental time, kidney curvature reduces and 'tip domains' pack more closely, which together create a semi-crystalline tip geometry at the kidney surface. We apply a geometric parameter of tip domains called the shape index to predict a rigidity transition to more solid-like tissue properties at later developmental stages and confirm by micromechanical measurements. At the level of individual tips we use the shape index to define a tip 'life-cycle' between branching events, and find that nephrogenesis rate varies over this life-cycle. Applying force inference techniques adapted from a cell vertex model and validating with laser ablation shows that tip domains experience a cyclical mechanical transient over each life-cycle. We then hypothesized that tip duplication periodically creates a mechanical microenvironment permissive to nephrogenesis. Indeed, mimicking a mechanical transient in human iPSC-derived nephron progenitor organoids increased Wnt-driven commitment to early nephron cell aggregates. The data suggest that temporal waves of mechanical stress within nephron progenitor populations could constitute a clock that synchronizes nephron formation and ureteric tubule duplication. Ongoing work to understand the spatial and temporal regulation of nephron induction will clarify variation in nephron endowment between kidneys and advance engineered replacement kidney tissues for regenerative medicine.

Coupled oscillators in growth and patterning- cell cycle and the segmentation clock

U. Kadiyala, Q. Yang; University of Michigan, Ann Arbor, MI.

Coordinated regulation of cell proliferation and differentiation is fundamental to the growth and patterning of multicellular structures. During vertebrate development, the process of somitogenesis captures this delicate balance of cell proliferation and differentiation in an intricate manner. Here, several molecular oscillators and spatial gradients temporally pattern the formation of somites. The details of how the patterning and growth of somites are regulated is less understood. Here we study the interactions between the cell cycle and the segmentation clock to understand how cell proliferation and patterning are coupled during somitogenesis. Using a 3D zebrafish embryonic tissue model and confocal microscopy, we demonstrate that the phase dynamics of the cell cycle and segmentation clock are spatially coupled. The two oscillators appear to be in phase at the anterior end and out of phase at the posterior end of the elongating tailbud. We find that the number of posteriorly positioned progenitor cells and the rate at which they differentiate and move into the presomitic mesoderm (PSM) is tightly

regulated. A ratio of 1:3, progenitors to PSM cells, appears to be maintained throughout development. Here, we propose a general framework where the spatially coupled phase dynamics of the cell cycle and the segmentation clock could maintain the ratio and distribution of cell types and their proliferation rate during segmentation.

B660/P2330

Activated HGF signal pathway by PRL1 regulate glucose metabolism *via* ATF5/PDX1 interaction in STZ injured liver rat model

W. Jeong[1], S. Kim[1], J. Kim[2], J. Jun[3], S. Bae[4], G. Kim[1]; [1]CHA University, Seongnam-si, KOREA, REPUBLIC OF, [2]University of California, San Diego, CA, [3]Duke University, Durham, NC, [4]Catholic University, Seoul, KOREA, REPUBLIC OF.

The precise balance of glucose metabolism is one of the important factors involved in various cellular events such as proliferation, metabolism, differentiation and cell death. Glucose metabolism that is not homeostatically controlled causes various diseases including diabetes as well as liver disease. In particular, abnormal glucose metabolism not only causes oxidative stress in mitochondria, but also causes abnormal ATP production, which affects the normal survival of cells. Recently, it was reported that hepatocyte growth factor (HGF) protects the survival of islet beta cells and regulates glucose transport and metabolism. In previous reports, it was confirmed that the efficacies for anti-fibrotic effect and liver regeneration were increased when placenta-derived mesenchymal stem cells overexpressed with phosphatase of regenerating liver-1 (PRL-1) known as a marker for liver regeneration (PD-MSCs^{PRL-1}) were transplanted into an animal model of hepatic cirrhosis. However, their mechanism between PRL-1 and glucose metabolism was still unclear. The objectives of the present study are to analyze the expression of HGF and demonstrate glucose metabolic pathway in diabetes model after PD-MSCs^{PRL-1} transplantation. If the HGF signaling activated by PD-MSCs^{PRL-1} regulates glucose metabolism, we demonstrated how it improve hepatic functions regulating the interaction between ATF5/PDX1 in the liver of diabetes model after PD-MSCs^{PRL-1} transplantation (Tx). One weeks after intraperitoneal injection (I.P) by streptozotocin (STZ, 60mg/Kg), PD-MSCs and PD-MSCs^{PRL-1} were transplanted into the diabetes rat model by tail vein.. The expression of HGF was significantly increased in PD-MSCs^{PRL-1} compared to PD-MSCs (*p<0.05).The expression of gene related to islet beta cells (e.g., ATF5, PDX1) was significantly increased in PD-MSCs and PD-MSCs^{PRL-1} Tx groups compared to non-transplantation group (NTx) (*p<0.05). The levels of mitochondrial stress of PD-MSCs^{PRL-1} Tx group was significantly decreased compared to PD-MSCs (*p<0.05). Also, the expression of genes related to regeneration of hepatocytes (e.g., albumin, cyclin D1, HNF1a, HNF4a) were increased in PD-MSCs and PD-MSCs^{PRL-1} Tx groups compared to those of NTx group. Taken together, PD-MSCs^{PRL-1} improved hepatic function through activated HGF signaling via ATF5/PDX1 interaction in liver of STZ-injured rat model. Therefore, these results provide useful data for the development of functional enhanced MSC-based stem cell therapy for hepatic diseases in diabetes. **Funding:** This research was supported by the Korean Fund for Regenerative Medicine (KFRM) grant funded by the Korea government (the Ministry of Science and ICT, the Ministry of Health & Welfare). Cytonemes coordinate asymmetric signaling and organization in the*Drosophila*muscle progenitor niche.

A. Patel[1], Y. Wu[2], X. Han[2], Y. Su[2], T. Maugel[1], S. Roy[1]; [1]University of Maryland, College Park, MD, [2]Laboratory of High-Resolution Optical Imaging, National Institute of Biomedical Imaging and Bioengineering, National Institutes of Health, Bethesda, MD.

Tissue development and homeostasis rely on the ability of stem cells to efficiently balance their fates between self-renewal and differentiation. These stem cell fate decisions are made in the context of the niche and are governed by asymmetric signaling and organization in the niche. Niche cells present self-renewal growth factors selectively only to stem cells, but not to their neighboring non-stem cell daughters, located just one cell diameter away. Understanding how this signaling asymmetry arises is critical to understanding how stem cells determine their identity and prime differentiation in an organized pattern to generate/regenerate tissues. We investigated the basis of asymmetric signaling and cell organization using the Drosophila wing disc that creates an adult muscle progenitor (AMP) niche. We discovered that AMPs extend polarized actin-based filopodia, named cytonemes, to contact the wing-disc epithelial junctions and physically adhere themselves to the niche. AMP cytonemes localize FGF-receptor (FGFR) to selectively adhere to the FGF-producing niche and receive FGFs in a contact-dependent manner. Activation of FGF signaling in AMPs, in turn, reinforces the niche-specific cytoneme polarity/adhesion to maintain niche occupancy. This interdependence between the cause and effect of cytoneme-mediated polarized signaling enables AMPs to sense different FGF-producing niches and self-organize diverse niche/signal-specific patterns. The intrinsic self-regulation of cytoneme polarity by signaling activation is spatiotemporally coordinated by extrinsic patterns of localized expression and restricted presentation of different FGFs in distinct wing-disc niches. Loss of cytoneme adhesion to an FGF-producing niche promotes AMPs to lose niche occupancy and FGF signaling and enables AMPs to occupy a disc-distal position to acquire morphological hallmarks of differentiation. These findings provide new insights into how contact-mediated polarized FGF signaling via cytonemes can play critical roles in generating and maintaining asymmetric signaling and organizations. This work is funded by NIH R35GM124878 to S.Roy.

Mechanisms and Function of Sibling Cell Size Asymmetry in *Drosophila* Neural Stem Cells

M. K. Delgado, C. Cabernard; University of Washington, Seattle, WA

Asymmetric cell division (ACD) is a widely conserved process which creates diverse cell populations. ACD can be molecular, physical or a combination of the two. Molecular asymmetry generates daughter cells inheriting distinct sets of RNA and proteins while physical asymmetry is manifested in sibling cells differing in their size. Although much is known regarding molecular ACD, we know very little about the mechanisms and function of sibling cell size asymmetry. A useful system to study sibling cell size asymmetry is *Drosophila* neural stem cells (called neuroblasts; NBs). During mitosis, *Drosophila* NBs exhibit a spatiotemporally regulated flow of Non-muscle Myosin II (Myosin, hereafter), producing a large self-renewing NB and a small differentiating Ganglion Mother Cell (GMC). Our lab has identified a poorly characterized serine-threonine kinase, Protein Kinase N (Pkn), that induces the flow of Myosin towards the basal NB cortex in early anaphase. However, the mechanisms by which Pkn initiates this apical to basal Myosin flow and the function of sibling cell size asymmetry are not known.

We found Pkn's kinase domain is required for proper spatiotemporal dynamics of Myosin and without this domain abnormal cell shape changes during ACD occur. To gain a better understanding of the molecular mechanisms underlying sibling cell size asymmetry, we conducted pull-downs on eGFP tagged Pkn *Drosophila* embryos followed by mass spectrometry. Using this approach over 50 potential binding partners were identified. Currently, we are genetically characterizing the top candidates Lethal Giant Larvae and Shaggy to determine their role in Myosin flow and sibling cell size asymmetry.
To understand the function of sibling cell size asymmetry, we altered sibling cell size via a nanobody approach. In *Drosophila* larval brains, we found that permanently trapping Myosin to the apical cortex alters sibling cell size resulting in cases of inverted as well as symmetric ACD. We also determined alterations to sibling cell size affects cell cycle timing. Lastly, our preliminary immunohistochemistry data suggests that changes in sibling cell size asymmetry alter the number and nuclear size of cells postulated to have an NB fate. Future research will be conducted to determine if changes to sibling cell size result in abnormal neurogenesis. Taken together, these findings begin to elucidate the mechanisms and function of sibling cell size asymmetry which may be conserved in other organisms that undergo physical ACD.

B663/P2333

Smurf ubiquitin ligases regulate development processes in embryonic stem cells

J.-H. Shin[1], X. Xu[1], Y. Tang[1], Y. Du[2], C. Liu[2], Y. E. Zhang[1]; [1]National Cancer Institute, NIH, Bethesda, MD, [2]National Heart, Lung, and Blood Institute, NIH, Bethesda, MD

Smad ubiquitination regulatory factors (Smurfs), are HECT domain containing E3 ubiquitin ligases. There are two Smurf genes, Smurf1 and 2 in mammals, and which are originally found to be negative regulators of TGFβ/BMP signaling. Subsequently, Smurfs have been shown to play key roles in many biological processes. Mouse lacking Smurf1 and Smurf2 are embryonic lethal, and more than one third of them displayed gastrulation defects. To understand the role of Smurfs in early embryonic development, we established ESC lines using E3.5 blastocytes with *Smurf2*$^{fl/fl}$ (herein referred to as "*control*" or "*WT*") and *Smurf1*$^{-/-}$*;Smurf2*$^{fl/fl}$ (referred as "*SF1KO*") alleles. Then, the floxed Smurf2 alleles in above ESC lines were removed after treating them with TAT-CRE recombinase to establish ESC lines with *Smurf2*$^{\Delta/\Delta}$ (referred as "*SF2KO*") and *Smurf1*$^{-/-}$*; Smurf2*$^{\Delta/\Delta}$ (referred as "*DKO*") alleles. We found that *Smurf*-deletion had no effect on ESC morphology, alkaline phosphatase staining, or pluripotent marker expression as assessed by real-time quantitative PCR (RT-qPCR) or immunofluorescence. Moreover, control and *Smurf*-deficient ESCs supported teratoma formation to a similar degree in vivo, confirming that Smurf1 and Smurf2 are not required for maintaining pluripotent potential of ESCs. However, when cultured these ESCs during embryoid body (EB) formation, we observed that the size of DKO EBs were considerably smaller than that of control, SF1KO or SF2KO EBs. H&E staining revealed that the DKO EBs were less differentiated than that of control EBs. Further RNAseq and RT-qPCR assays revealed that depletion of both Smurf1 and Smurf2 causes the developmental delay and arrests cells at the gastrulation stage. These observations were also confirmed using monolayer neuronal differentiation assay. Besides higher level of Smad-dependent TGFβ signaling in DKO EBs or differentiated cells, several other developmental signaling pathways were also affected by Smurf DKO. These results indicating that Smurfs regulate developmental process in embryonic stem cells by affecting multiple signaling pathways, including TGFβ signaling.

B664/P2334

Injury induces wild-type cell proliferation to suppress oncogenic Ras cells

S. Gallini, V. Greco; Yale University, New Haven, CT

Healthy skin is a tapestry of wild-type and mutant clones. Although injury can cooperate with Ras mutations to promote tumorigenesis, the consequences in genetically mosaic skin are unknown. Here, we show that wild-type cells suppress oncogenic Ras-induced aberrant growth after injury. Although $Hras^{G12V/+}$ and $Kras^{G12D/+}$ cells outcompete wild-type cells in uninjured, mosaic tissue, their expansion is prevented after injury due to a selective increase in wild-type cell proliferation. Mechanistically, we show that, unlike $Hras^{G12V/+}$ cells, wild-type cells respond to autocrine and paracrine secretion of EGFR ligands and their differential activation of EGFR pathway explains the competitive switch during-injury repair. Inhibition of EGFR by both drug and genetic approaches specifically abolishes the proliferative advantage of wild-type cells after injury leading to the expansion of $Hras^{G12V/+}$ cells. Increased wild-type cell proliferation through a global loss of the cell cycle inhibitor p21 counteracts the expansion of $Hras^{G12V/+}$ cells even without injury. Thus, injury plays an unanticipated role in switching the competitive balance between oncogenic and wild-type cells in genetically mosaic skin.

Temporal Transcriptome Analysis of Epithelial to Mesenchymal Transition (EMT) in Human iPSCs reveals Greater Variation in Lineage Progression at Time Points Associated with Key EMT Behaviors

N. C. Gomez, . Allen Institute for Cell Science, T. Knijnenburg; The Allen Institute for Cell Science, Seattle, WA

The Allen Institute for Cell Science aims to understand the principles by which human induced pluripotent stem cells (hiPSCs) establish and maintain robust dynamic localization of cellular structures, and how cells transition between states during differentiation and disease. EMT is a hallmark cellular state change from non-motile to motile in both normal and pathological conditions. Apart from the switch in cell behavior, it's also characterized by changes in protein expression and cellular organization. To understand the interplay between these aspects, we use large-scale imaging and multimodal quantitative assays on gene-edited hiPSCs from the Allen Cell Collection (allencell.org). Our study is based on the finding that increasing WNT signaling, via a small molecule (GSK-3β inhibitor) directs hiPSCs into a mesodermal fate, marked by consistent colony-wide contraction and cellular migration by 24 and 30 hours, respectively. To correlate transcription with cellular behavior, we collected GSK3-inhibited hiPSCs every three hours over 48 hours and performed scRNA-seq. First, we confirmed that cells cluster by time point using dimensionality reduction of our high-resolution temporal dataset. Next, we reconstructed a continuum of hiPSC differentiation during EMT via pseudotime analysis. We found that time points associated with major cell behavior changes, such as cellular migration at 24 hours, demonstrated greater variation in lineage progression than earlier time points. Using differential expression analysis, we found that groups of genes with distinct expression patterns cluster throughout EMT and are enriched in specific biological processes such as junctional proteins during migration. To relate transcriptional changes with cellular behavior, we are implementing a sparse regression model approach. This will identify one or more core gene signatures that could then be used by multiplexed RNA-FISH to classify and identify cells undergoing behavioral changes such as migration. Applying our transcriptional signature to other models of EMT will allow us to assay the similarities and differences between them. Integrating our large-scale imaging data with transcriptomics will ultimately allow us to

associate gene expression with distinct cellular shape and behavior changes, and in turn reveal the fundamental mechanisms that occur during cell state transitions.

Smart glues: coordinating robust pattern formation and morphogenesis with an adhesion code

M. Ryan, C. Chiu, **T. Tsai**; Developmental Biology, Washington University in St. Louis, St. Louis, MO.

An outstanding question in embryo development is how pattern formation and tissue morphogenesis are coordinated to generate tissues with reproducible pattern and shape. The zebrafish spinal cord is a remarkable example. In just 4 hours, the tissue undergoes dramatic shape changes from a plate to a tube, altering its height and width by 5-fold. At the same time, cells are instructed by opposing spatial gradients of morphogen signals (Shh/BMP/Wnt) to choose among 13 distinct cell fates and form stereotypic stripe patterns. Despite the dramatic changes in tissue shape and pattern, the developmental outcome is highly reproducible. We found a cell-type-specific adhesion code is instrumental to coordinate patterning with morphogenesis during zebrafish spinal cord development. The adhesion specificity for each cell type promotes cohesion among cells of the same type to improve patterning precision. Extending from our published work (Tsai et al, 2020), we have combined single cell transcriptomics with multiplex *in situ* hybridization to identify several additional cadherin-family adhesion molecules with cell-type-specific expression patterns. Our expanded adhesion code significantly increased the orthogonal adhesion modes available for adhesion specificity of all thirteen cell types in the spinal cord. In addition to the roles in patterning, we found coordination among these cadherin genes are critical to ensure robust spinal cord morphogenesis, as combinatorial loss of these cadherin genes result in defective tissue convergence and greater fluctuations in the final tissue shape. We also identified genetic conditions where the whole neural tube tissue failed to maintain cohesion and split into two neural tubes, a previously undocumented phenotype. Our ongoing studies will illuminate deeper cellular mechanisms of how different cadherin genes collaborate to simultaneously ensure robust pattern formation and morphogenesis during zebrafish spinal cord development.

Sonic Hedgehog Stimulated Endocytic Recycling Drives Cytoneme Loading for Mammalian Tissue Patterning

E. T. Hall[1], E. R. Cleverdon[1], M. E. Dillard[1], Y. Zhang[1], R. Wakefield[2], C. G. Robinson[2], S. M. Pruett-Miller[1], S. S. Ansari[1], Y. Wang[1], D. Stewart[1], A. Johnson[2], M. Tanes[2], Y. Ryu[2], J. Steinberg[2], S. K. Ogden[1]; [1]Cell and Molecular Biology, St. Jude Children's Research Hospital, Memphis, TN, [2]St. Jude Children's Research Hospital, Memphis, TN.

During development, morphogens like Sonic Hedgehog (SHH) instruct cell fate by inducing distinct transcriptional programs through graded concentrations and durations of signal exposure. Directly visualizing morphogen gradient establishment *in situ* has been impossible, so the molecular mechanisms by which target cells achieve appropriate signal thresholds for tissue patterning remain ambiguous. To tackle this longstanding problem, we developed a mouse model for compromised SHH morphogen dispersion. We mutated an essential Furin cleavage site in the SHH release protein Dispatched (DISP), which attenuates its ability to release ligand from producing cells. DISP mutation led to severe

developmental phenotypes including hydrocephalus, cerebellar dysfunction, and failure to thrive. Cell culture analysis revealed altered membrane localization of DISP mutants. Live imaging and biochemical assays of cultured cells revealed that DISP mutants were unable to undergo effective endocytic recycling with SHH, which attenuated SHH vesicular loading for entry into signaling filopodia called cytonemes. We optimized methods to preserve cytonemes in embryonic tissue for advanced microscopy and discovered that cytonemes containing endogenously expressed SHH connect signal-producing and -responding cell populations in developing neural tubes. SHH is depleted from cytonemes of DISP mutant mice, which corrupts the signaling gradient and compromises progenitor fate specification. Thus, cytonemes are essential conduits for SHH dispersion and may provide similar functionality for other morphogens contributing to mammalian tissue development.

B669/P2338

Analysis of the individual and collective behaviors of signaling filopodia during Notch-mediated patterning

S. Kundu, T. Smith, **G. L. Hunter**; Department of Biology, Clarkson University, Potsdam, NY.

Signaling filopodia, or cytonemes, are long, dynamic cellular protrusions that facilitate cell-cell communication. During the formation of the bristle spot pattern in the Drosophila thorax, actin-rich signaling filopodia extend from the basal surface of all epithelial cells in order to support long-range, Notch-mediated, lateral inhibition. The mechanisms that regulate signaling filopodia formation, as well as how signaling filopodia interact with each other in order to propagate signaling, are not well understood. The objective of this work is to analyze signaling filopodia in individual cells and their interactions across a patterning tissue, using a combination of Drosophila genetics and quantitative microscopy. We have found that an unconventional MyTH4-FERM myosin, Myosin XV, plays a role in regulating the formation of signaling filopodia in individual cells. Myosin XV localizes along the length of these structures, in a manner that is dependent on specific MyTH4-FERM domains. We find that signaling filopodia make complex interactions with each other during patterning. We observe transient collective filopodia structures that move across small regions of the tissue, and use a particle image velocimetry based strategy to analyze their movements. We find that these structures move without alignment to any specific body axis throughout late patterning stages. We are currently working on an ex vivo strategy to block the collective movement of signaling filopodia in order to test if they are required for late stage patterning. Altogether, these results support the role of signaling filopodia in long-range lateral inhibition, and indicate that the range of Notch signaling may not only result from the activity of individual cells, but from their collective behavior

B670/P2339

The expression pattern of *calca* in the zebrafish

T. Liang[1], J. Zhang[2], J. Y. Jang[1], **D. W. Jang**[1], S. Y. Choi[1]; [1]Biomedical Sciences, Chonnam National University Medical School, Hwasun 58128, KOREA, REPUBLIC OF, [2]Neurology, Tangdu Hospital, Fourth Military Medical University, Xi'an, Shaanxi 710038, CHINA.

Calcitonin gene-related peptide (CGRP) is a 37-amino acid neuropeptide, which has two major forms (α and β). These peptides act on an unusual receptor family, consisting of calcitonin receptor-like receptor (CLR) linked to an essential receptor activity modifying protein (RAMP) that is necessary for full functionality. CGRP is a highly potent vasodilator and possesses protective mechanisms that are

important for cardiovascular system and wound healing. CGRP is primarily released from sensory nerves and thus is implicated in pain pathways. The proven ability of CGRP antagonists to alleviate migraine has been of most interest in terms of drug development. To determine the expression pattern of *calca (calcitonin related peptide α)* in zebrafish, we performed whole-mount in situ hybridization on wild-type zebrafish embryos and found that *calca* is predominantly expressed in the nervous system. Then we cloned a 5-kb *calca* promoter region and generated a *calca* reporter line, *Tg(calca:gfp)*. GFP expression was observed in the central nervous system, lips, nose, barbel, gill and skin. In particular, the expression pattern of skin GFP in *Tg(calca:gfp)* was reminiscent of that of Merkel cells, which are oval receptor cells found in the skin of vertebrates that have synaptic contacts with somatosensory afferents. Currently, we are generating a Ca^{2+} reporter line, *Tg(calca: GCaMP6s-P2A-mCherry)*, *Tg(calca:GFP-NTR)* line based on Nitroreductase/Metronidazole (NTR/MTZ) cell ablation system which will cause the death of the $calca^{+}$ cell when exposed to the prodrug MTZ, and $calca^{-/-}$ line using CRIPSR-Cas9. These lines would help us identify the nature of $calca^{+}$ cells in zebrafish.

How the gut got its spots: mesenchymal dewetting drives tissue patterning and interfacial folding to build intestinal villi

T. R. Huycke[1], H. Miyazaki[1], T. J. Häkkinen[1], C. S. McGinnis[1], A. Kalantari[1], E. Barruet[1], D. Boffelli[2], O. D. Klein[2], Z. J. Gartner[1]; [1]Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA, [2]Orofacial Sciences, University of California, San Francisco, San Francisco, CA.

Intestinal villi arise during development as a consequence of signals and forces that sculpt an initially flat epithelium into a periodic pattern of folds. The detailed mechanisms driving villus formation are thought to differ between mammals and birds, and have been the subject of considerable debate. Here we identify a biomechanical mechanism essential for villus patterning and folding in both species, but which operates in unique ways and at distinct stages of intestinal morphogenesis in each organism. In mice, we find that the aggregation of subepithelial mesenchymal cells into condensates is sufficient to initiate villus formation by generating the forces that produce curvature of overlying tissue interfaces and specify villus location. Cellular condensation initiates upon fluidization of the subepithelial mesenchyme, a process that is dependent on metalloproteinase activity and characterized by a loss of anisotropy in cell shape and matrix alignment, the acquisition of enhanced actomyosin-dependent motility and neighbor exchange, and the expression of a unique cell-matrix adhesion program. In chick, the same program acts at the late stages of intestinal morphogenesis to sculpt zig-zag patterned ridges into villi. To gain further insight into this unique biomechanical program, we parameterize both cell-based and continuum models of mesenchymal condensation and interface bending using quantitative live imaging data from mouse tissue explants. These models predict multiple and unanticipated aspects of condensate formation, patterning, and dynamics that we validate experimentally. Together, our data suggest that villus initiation is analogous to the behavior of thin liquid films, which de-wet from surrounding interfaces when decreasing their surface-to-volume ratio minimizes the total surface energy of the system. Similar tissue-scale dewetting might be common across developmental systems as a mechanism to organize morphogenesis at tissue interfaces.

Biomechanical regulation of adhesion-mediated cell patterning

R. M. Garner, S. G. Megason; Systems Biology, Harvard Medical School, Boston, MA.

The self-organization of cells into patterns is essential for proper development. One widespread mechanism that is critical for patterning dozens of embryonic tissues across diverse organisms is adhesion-mediated sorting. In this scheme, distinct adhesion molecules are differentially expressed on the surface of different cell types, driving cells to group together based on compatible adhesion molecule expression (see our recent review on this topic: Tsai, Garner, & Megason, ARCDB, 2022). However, while there is ample evidence that cells *can* sort by adhesion compatibility, almost nothing is known about how cells move through the tissue, find partners with similar adhesion protein expression, and eventually stop moving to lock in the sorted pattern. In particular, we fundamentally lack an integrative understanding of how cell mechanical and migratory properties control the ability of cells to sort. Here, I present my progress towards developing a combined experimental and theoretical approach to address this gap, using developing zebrafish embryos as a model system. First, I will discuss the "in toto" imaging and image analysis pipeline I have established to (1) visualize the dynamics of cells and their interfaces at high resolution, (2) perform automated 3D segmentation and tracking of *all* of the cells within a developing tissue, and (3) quantify cellular rearrangements in the tissue over time. Second, I will show how I utilized this approach to measure how perturbations to adhesions and actin biomechanics affect the ability of cells to move within the tissue and exchange neighbors. Finally, I will present my efforts to develop a physically-realistic computational model of cellular patterning in 3D multicellular systems, which integrates both adhesion-mediated sorting and actin biomechanics.

Development drives changes in tight junction morphology and myosin II patterning

R. E. Stephenson, A. L. Miller; Department of Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI.

Tight junctions closely adhere epithelial cells to one another, creating a barrier that regulates the passage of ions, water, and macromolecules across the paracellular space. When viewed by fluorescence microscopy, tight junctions typically appear as a relatively straight, narrow band that encircles the apical most planes of each epithelial cell. Change in tight junction appearance (e.g., increased waviness) is frequently observed following alteration to the actin cytoskeleton or protein composition of the tight junction. However, the molecular regulation and functional consequence of changes to tight junction morphology are poorly understood. Previously, we used gastrulating *Xenopus laevis* embryos to study how cell shape change impacts tight junction integrity, and we identified that local breaks in tight junctions are repaired by Rho flares. Rho flares are local accumulations of active RhoA, F-actin, and myosin II that repair tight junction breaks via junction contraction. When analyzed individually, the size and shape of Rho flares varies dramatically. Here we present population-level analysis of Rho flares suggesting that tight junction morphology and myosin II patterning are correlated with changes in Rho flare morphology and frequency, as well as the developmental stage of the embryo. Using a semi-automated image analysis pipeline, we generated a categorization framework of *Xenopus* epithelial tissue dynamics based on analysis of Rho flare characteristics and corresponding changes in myosin II patterning, tight junction morphology, and cell geometry. We speculate that these changes in epithelial tissue properties and junction organization occur in order to meet the challenge of

maintaining epithelial integrity as the embryo transitions from a hollow ball of cells to an elongated form with distinct germ layers. Understanding the relationship between tight junction morphology and local repair events will further our understanding of the functional consequence of changes in tight junction morphology.

An ancestral mycobacterial effector promotes dissemination of infection

M. I. Sweeney[1], J. W. Saelens[1], G. Viswanathan[1], A. M. Xet-Mull[1], J. Coers[1], J. E. Stout[2,3], D. M. Tobin[1]; [1]Department of Molecular Genetics and Microbiology, Duke University, Durham, NC, [2]Department of Medicine, Duke University, Durham, NC, [3]Department of Infectious Diseases and International Health, Duke University, Durham, NC.

Mycobacterium tuberculosis (*Mtb*), the human-adapted pathogen that causes tuberculosis disease (TB), has evolved to subvert the human immune system and become one of the most successful pathogens in human history. We analyzed a clinical TB outbreak in North Carolina and identified an ancestral secreted *Mtb* effector that induces a dramatic phenotypic change in infected host cells. Clinically, *Mtb* strains that express the full-length effector, EsxM, cause a high rate of disseminated disease. The full-length effector is expressed in ancestral strains of *Mtb* but is truncated by an early stop codon in modern strains. We find that EsxM mediates changes in infected macrophages via the modulation of the host actin cytoskeleton. We first show that expression of full-length EsxM but not the modern truncated version in zebrafish macrophages, a key host cell niche for infecting mycobacteria, induces increased motility and migration. Utilizing a macrophage-specific F-actin reporter line, we identified changes in the macrophage cytoskeleton during migration and infection. Additionally, *M. marinum* zebrafish infection experiments demonstrated that EsxM-expressing *M. marinum* possesses an increased capacity for dissemination from established sites of infection and a tropism for bone infection, consistent with human clinical data from the outbreak. In human cells, we find that infection with EsxM-expressing *Mtb* leads to dramatic filopodial projections, F-actin and Arp2/3 rearrangement, and increased cell migration when compared to infection with *Mtb* strains lacking the effector. Currently, we are following up on the potential host interacting partner of EsxM, a member of the WASH complex. This Arp2/3 nucleation promoting factor has been studied primarily for its role in endocytic trafficking, but less is known about its potential role in macrophage migration, or as a target of intracellular bacteria. We hypothesize that EsxM may be mediating its effects via an interaction with the WASH complex, subverting its normal function in cells. Overall, these studies uncover an evolutionary relationship between a secreted effector and the transition of *Mtb* from a generalist pathogen causing disseminated infection to a specialized inhabitant of the human lung. Furthermore, we identify a potential interaction between mycobacteria and the host cytoskeleton that leads to dysregulation of cell motility and ultimately disseminated infection.

ISG15 modification of the Arp2/3 complex restricts pathogen spread

Y. Zhang[1], B. Ripley[1], W. Ouyang[2], R. Coloma[3], M. Sturtz[1], E. Upton[1], E. Luhmann[1], N. Schwery[1], S. Anthony[4,5], A. Goeken[4], T. Moninger[6], J. Harty[4], A. Klingelhutz[1], E. Lundberg[2], D. Meyerholz[4], C. Stipp[7], B. Manicassamy[1], S. Guerra[3], L. Radoshevich[1]; [1]Department of Microbiology and Immunology, University of Iowa, Iowa City, IA, [2]Science for Life Laboratory, School of Engineering Sciences in Chemistry, Biotechnology and Health, KTH Royal Institute of Technology, Stockholm, SWEDEN, [3]Department of Preventive Medicine, Public Health and Microbiology, Universidad Autónoma, Madrid, SPAIN, [4]Department of Pathology, University of Iowa, Iowa City, IA, [5]Integrated Research Facility at Fort Detrick, Frederick, MD, [6]Central Microscopy Research Facility, University of Iowa, Iowa City, IA, [7]Department of Biology, University of Iowa, Iowa City, IA.

During infection the ubiquitin-like protein, ISG15, can act as a cytokine or can covalently modify host and pathogenic proteins. While progress has been made in identifying sites of modification on target proteins, the molecular consequences of ISGylation on individual protein substrates are still unknown. Here by using a model of enhanced ISGylation, we identify that ISG15 modifies the ARP2/3 complex following both bacterial and viral infection. ISGylation significantly slows *Listeria*-actin comet tail speed leading to morphologically shorter and denser comet tails. For Vaccinia virus, this results in reduced spread, whereas while *Listeria* is initially restricted, over time the bacteria divide while remaining tightly attached to actin filaments resulting in multi-headed comet tails that move as a group. These structures contribute to spread in both human and murine cells and in vivo in mice with unchecked ISGylation, which leads to increased mortality. ISG15 modification of the Arp2/3 complex also affects cortical actin density, cell motility, and adhesion. Furthermore, ISG15-deficient neonates have aberrant epidermal epithelia, which correlates with observed defects in wound healing in a subset of human patients who lack ISG15. Our discovery identifies a conserved molecular mechanism of ISG15 modification of the Arp2/3 complex which directly restricts pathogen spread.

The Role of Bacterial Filamentation in the Protection Against Human Cathelicidin Antimicrobial Peptide LL-37

N. Porco, M. Tomlinson, R. J. Botelho, J. B. McPhee; Toronto Metropolitan University, Toronto, ON, CANADA.

Urinary tract infections are one of the most common type of bacterial infection. Uropathogenic E. coli (UPEC) are the primary bacterial species that cause persistent urinary tract infections. Infection begins via colonization of bladder epithelial cells by UPEC forming intracellular bacterial communities. The bacteria inside these intracellular bacterial communities go through morphological changes including filamentation, which prevents them from dividing but allows them to keep growing. Filamentation can be triggered in response to environmental stressors like reactive oxygen species which are produced during the immune response. The immune response against urinary tract infections is complex but, includes recruitment of macrophages and neutrophils and the release of antimicrobial peptides such as LL-37. Since filamentation is a stress response and LL-37 is secreted during infection, we hypothesized that bacterial filamentation may protect bacteria against LL-37. Our data support this hypothesis since filamentation of UPEC strains and non-pathogenic bacteria driven by different mechanisms all promoted bacterial survival in the presence of LL-37. Next, we analysed LL-37 binding patterns in filamentous and

non-filamentous cells to understand why filamentous cells are better protected. We found that LL-37 appears to target regions of significant negative curvature in non-filamentous bacteria, while LL-37 bound more randomly in filamentous bacteria. We postulate that filamentation reduces membrane curvature, which may be required for LL-37 to insert into bacteria membrane to promote killing. Lastly, we also observed that filamentous bacteria are ingested more slowly by macrophages than coccal forms, further aiding in bacterial survival. This work aims to provide insight into how filamentation acts as a crucial virulence strategy for specific microbes like UPEC.

BMP signaling in regulation of *C. elegans* lipid homeostasis and immune response

K. Yamamoto, C. Savage-Dunn; Queens College & The Graduate Center, CUNY, New York, NY.

Research on innate immunity has focused on aspects that decrease pathogen load, including physical barriers and the upregulation of antimicrobial peptides (AMPs). Less is known, however, about the role of host metabolism in supporting survival independently of anti-bacterial responses. Bone Morphogenetic Proteins (BMPs) are secreted peptide growth factors in the TGF-β family, well known for their roles in development and differentiation, but emerging as homeostasis modulators. The genetically tractable model system *C. elegans* has revealed signaling mechanisms that regulate innate immunity. DBL-1 is the BMP2/4 ortholog in *C. elegans*. Impairment of DBL-1, or components of its signaling pathway, result in increased infection susceptibility and decreased survival after exposure to bacterial pathogens *Serratia marcescens* and *Photorhabdus luminescens*. The BMP pathway also regulates lipid metabolism in *C. elegans*, where changes in DBL-1 signaling result in decreased quantities of lipid stores, and fewer, smaller lipid droplets. Altered lipid metabolism is one potential mechanism for immune tolerance, an alternative response that does not depend on reducing pathogen load. Here we begin to explore the relationship between host metabolism and pathogen tolerance. We hypothesized that DBL-1/BMP regulation of lipid metabolism in *C. elegans* complements its role in the transcriptional regulation of AMP genes and contributes to survival on pathogenic bacteria. We used Oil Red O to conduct lipid staining of animals after exposure to bacterial pathogens *S. marcescens* and *P. luminescens*. In wild type animals, we observed a small, but significant, decrease in lipids. However, in *sma-3* null mutants, exposure to either bacterial pathogen resulted in decreased lipid levels by more than 50%. We conclude that pathogen exposure elicits a lipid mobilization response in the host and that this response is BMP-dependent. To complement our investigation into the effect of lipid metabolism on immune tolerance, we have been more robustly characterizing BMP's regulation of lipid homeostasis. To this end, we conducted a genetic screen to identify novel genes that function downstream of DBL-1 by identifying suppressors of the low-fat phenotype of *dbl-1* using BODIPY lipid stain. We analyzed 8224 genomes and isolated 71 mutants with high-fat phenotypes. Our goal is to define the molecular pathways that act downstream of DBL-1 to regulate lipid metabolism and immune response.

***Cryptosporidium parvum* highjacks a host lncRNA NR_0033483 to suppress intestinal epithelial cell-autonomous antiparasitic defense**

M. Graham[1], M. Li[2], A. Gong[1], S. Deng[2], K. Jin[1], X. Chen[1]; [1]Microbial Pathogens and Immunity, Rush University, Chicago, IL, [2]Medical Microbiology and Immunology, Creighton University, Omaha, NE.

Cryptosporidium is a zoonotic apicomplexan parasite that infects the gastrointestinal epithelium and other mucosal surfaces in humans. It is an important opportunistic pathogen in AIDs patients and the second most common cause of diarrhea in young children in developing countries. The intestinal epithelial cells provide the first line of defense against *Cryptosporidium* infection and play a central role in activating and regulating the host immune response. Increasing evidence suggests that long noncoding RNAs (lncRNA) participate in host-pathogen interactions and play a regulatory role in the pathogenesis of diseases but the underlying molecular mechanisms are not fully understood. The lab previously identified a panel of host lncRNAs that are upregulated in murine intestinal epithelial cells following *Cryptosporidium* infection, including NR_0033483. We demonstrate here that NR_0033483 is upregulated in response to *Cryptosporidium* infection but is not upregulated in response to the immune signaling pathways tested. Additionally, inhibition of NR_0033483 resulted in a decreased infection burden of the parasite while overexpression of NR_0033483 showed an increase in infection burden, suggesting NR_0033483 is acting in a pro-parasitic manner. Various sequencing methods revealed that NR_0033483 suppressed transcription of host defense genes involved in controlling *Cryptosporidium* infection including *Aebp1*, a potent modulator of inflammation and NF-κβ signaling. Interestingly, *Cryptosporidium* carries the *Cryptosporidium* virus 1 (CSpV1), a dsRNA virus coding two dsRNA fragments, CSpV1-dsRdRp and CSpV1-dsCA. Both CSpV1-dsRdRp and CSpV1-dsCA can be delivered into infected cells. We found that cells with *in vitro* transcribed CSpV1-dsCA or CSpV1-dsRdRp displayed increased levels of NR_0033483, suggesting CSpV1 is involved in the upregulation of NR_0033483 during *Cryptosporidium* infection. Our study highlights a new strategy by *Cryptosporidium* to hijack a host lncRNA to suppress epithelial cell-autonomous antiparasitic defense and allow for a robust infection.

B680/P2348

***Mycobacterium tuberculosis* utilizes serine/threonine kinase PknF to evade NLRP3 inflammasome dependent interleukin-1beta secretion.**

S. Rastogi, V. Briken; Department of Cell Biology and Molecular Genetics, University of Maryland, College Park, College Park, MD.

Mycobacterium tuberculosis (Mtb) has evolved strategies to evade host innate immunity and persist inside host cells. Dendritic cells (DCs) act as a bridge between innate and adaptive immunity and thus are the key regulators of immune response against infectious diseases included tuberculosis. Both macrophages and DCs encode the cytosolic sensor proteins, NOD like receptor (NLRs), which recognizes pathogen/danger associated molecular patterns and lead to assembly of the inflammasome signaling complex that activates caspase-1 and results in release of mature IL-1β and host cell death via pyroptosis. Here we show that Mtb inhibits NLRP3 inflammasome activation and subsequent production of IL-1β in an ESX-1 independent manner. We identified the serine/threonine kinase PknF as one protein of Mtb involved in the NLRP3 inflammasome inhibition, since the pknF deletion mutant of Mtb compared to Mtb-infected cells induces increased production of IL-1β and increased pyroptosis in BMDMs and BMDCs. The increased production of IL-1β was found to be dependent on the NLRP3, the

adaptor protein, ASC, and the proteases caspase-1 and -11, as revealed by studies performed in BMDMs and BMDCs derived from the corresponding knockout mice. In addition to NLRP3, we show that Mtb pknF mutant also mediates RIPK3/Caspase8 dependent IL-1β production in BMDCs. Consistently, infection with the Mtb pknF mutant results in increased activation of caspase-1 and caspase-8 in BMDCs when compared to Mtb. The IL-6 production by Mtb pknF mutant remained unchanged compared to Mtb-infected cells, suggesting that the mutant did not affect the priming step of inflammasome activation. In contrast, the activation step was affected since potassium efflux and calcium influx played a significant role in Mtb pknF mutant induced inflammasome activation in BMDCs. However, in Mtb pknF mutant infected BMDMs, potassium efflux, chloride efflux and the generation of reactive oxygen species played a significant role in inflammasome activation but there was no role for calcium fluxes. In conclusion, we reveal a novel role for Mtb PknF in innate immune evasion through inhibition of the NLRP3 inflammasome.

B681/P2349

Spatio-temporal analysis of LC3-associated responses in macrophages during*Mycobacterium tuberculosis* infection

J. Augenstreich, A. T. Phan, C. N. S. Allan, V. Briken; Cellular Biology and Molecular Genetics, University of Maryland College Park, College Park, MD.

Mycobacterium tuberculosis (Mtb) is the causative agent of the pulmonary disease tuberculosis which is still one of the deadliest infections worldwide. Macrophages are its main niche of replication inside the host, so it is crucial to decipher how Mtb survive and evade the bactericidal responses deployed by these cells. Among them, the autophagy could be triggered and eventually control Mtb survival inside macrophages. Specifically, xenophagy can target bacteria after phagosome rupture or escape of the bacterium. However, others showed that Mtb can inhibit autophagic signaling. These results suggest a highly dynamic interplay between the autophagic responses and Mtb that is still poorly understood. We used live-cells imaging approaches to monitor the dynamics of autophagic responses during Mtb infection. The results showed that a large part of Mtb-containing vacuoles (MCVs) exhibited at least one temporary LC3 recruitment during the acquisition. Indeed, about half of the MCVs ended losing LC3 signal, either by disappearance of the LC3 signal or Mtb egress out of the autophagosome, thus showing an active escape from autophagic responses. In term of dynamics, MCVs either showed an early LC3 recruitment (≤ 20min post phagocytosis) or later, from a time ≥ 1h post phagocytosis, up to 10h post phagocytosis. Single cells analysis of the dynamics of LC3 recruitment in regard of the bacterial burden revealed that timing was not a major factor governing LC3 recruitment. However, the amount of MCVs phagocytosed or already present inside the cells when a new MCV is internalized would rather be the trigger. Finally, the maturation level of MCV positive for LC3 was assessed by measuring the acidification at 16h post-infection. Results showed that LC3 positive MCVs did not acidify and that acidified MCVs didn't show LC3 recruitment. In conclusion, we observed that after internalization Mtb largely triggers an autophagic response that the bacteria can successfully avoid or escape, and if not, inhibit its maturation. So, our results did not show that Mtb was actively being killed by autophagic responses in our cell system.

Inhibition of IFN-I signaling by *Salmonella enterica* serovar Typhimurium

M. Shuster, D. Banks, Z. Lyu, J. Ling, V. Briken; University of Maryland, College Park, MD.

Interferons (IFNs) play an important role in the host response to pathogens. Interferon signaling results in the expression of hundreds of genes that upregulate, modulate, and inhibit host immunity. While IFN-II (IFNγ) is well established as beneficial to host immunity in bacterial infections, IFN-I (IFNβ) has a more ambivalent role. In the context of *Salmonella enterica* serovar Typhimurium (STm) infection, IFNβ has a dual effect, being both beneficial and detrimental to host immunity. In the current study, we investigated the interaction of STm with respect to IFNβ-mediated signaling.We show that STm inhibits IFNβ signaling in murine macrophages independent of IFNβ dosage. This inhibition is specific to IFNβ signaling as IFNγ signaling is unaffected by STm infection. Additionally, sustained IFNβ signaling restricts STm growth. This restriction is dependent on reactive nitrogen intermediates (RNIs) as *Nos2* deficient, STm-infected bone marrow derived macrophages have significantly higher bacterial burdens with respect to wild type macrophages. Production of RNIs is dependent on IFNβ signaling as antibody-based blockage of signaling results in reduced RNIs. Inhibition of IFNβ signaling by STm is independent of Salmonella pathogenicity island (SPI)-1, SPI-2, and SPI-6 as mutants for these secretion systems show no loss of inhibition with respect to wild type STm.

B683/P2351

Examination of Endogenous CD147 during Enteropathogenic*Escherichia coli*and*Salmonella enterica*Serovar Typhimurium Cell Culture Infections

A. Dhanda, C. Yu, **J. Guttman**; Simon Fraser University, Burnaby, BC, CANADA.

Many metazoan cell biological processes, such as cell migration and endocytosis, are driven by a highly conserved actin cytoskeletal network. However, any insidious access to the cytoskeleton represents an open avenue for disease. Enteropathogenic *Escherichia coli* (EPEC) and *Salmonella enterica* serovar Typhimurium (*S*. Typhimurium) are two highly infectious gastrointestinal human pathogens that exploit the actin cytoskeleton as part of their disease processes. To initiate infection, EPEC attaches onto the surface of an effaced host cell and generates a characteristic actin-rich membranous protrusion (termed pedestal) to remain on and move atop the host epithelia. *S.* Typhimurium on the other hand triggers large actin-based membrane ruffles to gain access to the host cytoplasm. Interestingly, several non-actin-associated proteins, such as the prolyl *cis-trans* isomerase cyclophilin A (CypA), make up the repertoire of these complex bacterially-induced actin-rich structures. In an effort to expand on this catalog, we set out to examine the distribution of CD147, a host plasma membrane protein and cognate receptor of CypA, during EPEC and *S.* Typhimurium infections. We show that endogenous CD147 clusters at the basolateral membrane regions of EPEC pedestals, but, unlike its cognate ligand, remains absent from the actin-rich core of the structures. Using EPEC genetic mutants, we show that CD147 clustering depends on the pedestal-forming process. Conversely, siRNA-mediated depletion of CD147 reveals that pedestal formation itself does not require CD147 expression in host cells. Lastly, we show that CD147 is also highly enriched throughout *S.* Typhimurium membrane ruffles. In summary, our findings establish CD147 as another host factor that is enriched at pathogen-induced actin-based structures.

B684/P2352

Salmonella actively regulates TFEB in macrophages in a growth-phase and time-dependent mode

S. Inpanathan, E. Ospina Escobar, Y. Cho, N. Porco, J. B. McPhee, R. J. Botelho; Chemistry & Biology, Toronto Metropolitan University, Toronto, ON, CANADA.

Lysosomes are degradative organelles responsible for degrading and recycling endocytic, phagocytic, and autophagic cargo. The transcription factor EB (TFEB) is a scaling transcription factor that can adapt the expression and activity of genes associated with endosomal, lysosomal, autophagic, and immune-protective functions in response to stresses like starvation and infection. In the immune context, TFEB plays important roles in microbe killing, immune cell migration, antigen presentation, and pro-inflammatory transcriptional programs. In fact, we and others previously showed that phagocytosis of bacteria activates TFEB and boosts degradative capacity of macrophages to enhance bacterial killing and that certain microbes like *Salmonella* and *S. aureus* suppress TFEB. However, *Salmonella* has also been suggested to actively stimulate TFEB, which implies a benefit to *Salmonella*. These results appear contradictory at first sight. Thus, we sought to elucidate the complex interplay between *Salmonella* infection and TFEB activity by examining if Salmonella had different effects on TFEB under different contexts such as bacterial growth phase and time of infection. To test this, we compared *Salmonella* grown to late-log versus stationary phases. Late-log Salmonella are invasive and promote their own uptake, while stationary Salmonella are thought to be engulfed by macrophages primarily. In fact, our observations suggest that the effect of Salmonella depends on infection conditions. While late-log grown *Salmonella* caused immediate activation of TFEB in macrophages, phagocytosis of stationary-grown *Salmonella* did not stimulate TFEB after engulfment within the first hour of infection. This was time dependent though and eventually TFEB entered the nucleus of macrophages. Importantly, this early repression of TFEB during phagocytosis of stationary-grown *Salmonella* is driven by the bacteria since i) dead *Salmonella* could not repress TFEB in the first hour of engulfment and ii) we discovered several mutants of *Salmonella* that could not repress TFEB, including mutants of the Type III Secretion Systems required for infection, PhoPQ system, required for bacterial stress adaptation, and other factors that allow *Salmonella* to usurp macrophages. Overall, these observations suggest that *Salmonella* may be able to finetune TFEB activation for its benefit in a manner dependent on the infection conditions. In agreement with this, forced activation of TFEB with phagocytosis, which bypasses the ability of the Salmonella to control TFEB, caused macrophages to kill Salmonella more effectively. This suggests that drugs that can promote TFEB and bypass Salmonella's ability to modulate this protein may have therapeutic value to help resolve infections.

B685/P2353

A siRNA screen to uncover the mechanisms underlying plasma membrane repair of mammalian cells damaged by bacterial pore-forming toxins

M. Prislusky, J. Lam, M. Ng, S. Seveau; Ohio State University, Columbus, OH.

Plasma membrane disruption by pore-forming toxins is a most common and ancient strategy used by bacterial pathogens to infect their host and evade the host immune responses. *L. monocytogenes* is a facultative intracellular pathogen that infects a large variety of host cells including epithelial cells and macrophages. *L. monocytogenes* major virulence factor is a 57 kDa pore-forming toxin called listeriolysin O (LLO) that binds cholesterol-rich membranes to assemble a large transmembrane pore complex. LLO targets the host cell plasma membrane and the phagosome membrane to allow for bacterial

proliferation in the host cell cytosol. Despite LLO attack, the infected cells repair their plasma membrane to maintain homeostasis. To uncover the plasma membrane repair machineries of cells exposed to LLO, we developed a fluorescence-based siRNA screen. The selected library targets 287 host genes controlling endocytosis, exocytosis, intracellular trafficking, autophagy and cytoskeletal assemblies. HeLa cells stably expressing Histone-2B-GFP were reverse transfected with siRNAs (three 11-mer siRNAs per target were pooled in four wells) in 96-well plates for 72 hours and were exposed to 0.5 nM LLO and 1 µM TO-PRO-3 (a small dye that only labeled damaged cells) in Ca^{2+}-containing (repair permissive conditions) and Ca^{2+}-free (repair restrictive conditions). The fluorescence intensities of TO-PRO-3 and GFP were then recorded for 30 min at 37ºC in a multimode plate reader. TO-PRO-3 fluorescence intensity was used to assess plasma membrane integrity and GFP fluorescence to enumerate cells via image cytometry. The dual GFP/TOPRO-3 fluorescence recording allowed to account for potential differences in the proliferation of siRNA-transfected HeLa cells. Although some siRNAs affect final cell density, none of the siRNA treatment conditions exhibited cell detachment after exposure to LLO in the Ca2+-containing and in the Ca2+-free media. The average cell count ratio, defined as the cell count post-kinetic relative to the cell count pre-kinetic, across all siRNA treatment conditions was 1.0061 ± 0.0065 and 1.0059 ± 0.0058 for Ca2+-containing and Ca2+-free conditions, respectively. The Z-factor and SSMD (strictly standardized mean difference) confirmed that this assay has the robustness necessary to identify potential “hits”. In addition, the mixed effects model was used as a statistical tool to evaluate “hits” within a single assay. In conclusion, this screen identified 70/287 targets, that when knocked down, altered membrane resealing efficiency. We identified genes encoding proteins controlling lysosomal biogenesis, membrane fusion, intracellular trafficking, exocytosis, and autophagy.

B686/P2354

The bacterial pathogen *Shigella flexneri* co-opts the human exocyst complex to promote cell-to-cell spread

K. Ireton, T. U. B. Herath, A. Gianfelice, N. Lee; Microbiology and Immunology, University of Otago, Dunedin, NEW ZEALAND.

Shigella flexneri is a gram-negative bacterial pathogen that causes dysentery. Critical for disease is the ability of *Shigella* to use an actin-based motility (ABM) process to spread between cells of the colonic epithelium. ABM transports bacteria to the periphery of host cells, allowing the formation of plasma membrane protrusions that mediate spread to adjacent cells. How these protrusions form is not fully understood. The objective of this study was to test the hypothesis that that efficient protrusion formation and cell-to-cell spread of *Shigella* involves bacterial stimulation of the host process of polarized exocytosis through exploitation of the human exocyst complex. Using an exocytic probe, we found that exocytosis is locally upregulated in bacterial protrusions in a manner that depends on the exocyst. In addition, the exocyst component Exo70 and the exocyst regulator RalA were recruited to *Shigella* protrusions, suggesting that bacteria manipulate exocyst function. Importantly, RNA interference (RNAi)-mediated depletion of exocyst proteins or RalA reduced the frequency of *Shigella* protrusion formation and also the lengths of protrusions, demonstrating that the exocyst controls both the initiation and elongation of protrusions. RNAi-induced knockdown of exocyst components or RalA also impaired cell-to-cell spread of bacteria. The ability of *Shigella* to infect human cells requires a bacterial type III secretion system (T3SS), which injects ~ 25 microbial effector proteins into the host cytosol. Using mutants defective in genes encoding structural components of the T3SS, we found that this secretion apparatus is needed for bacterial-induced recruitment of Exo70 and stimulation of

exocytosis in protrusions. In addition, we have screened a collection of *Shigella* effector mutant strains, and identified at least two effector proteins (IcsB and IpgD) that contribute to stimulation of host exocytosis. Collectively, our results reveal that *Shigella* uses its T3SS to co-opt the exocyst, thereby enhancing dissemination in host cell monolayers. Future work should focus on elucidating molecular mechanisms by which particular *Shigella* effector proteins manipulate exocyst function.

Tracking Extracellular Vesicles (EVs) and their sRNA Cargoes in plant

D. Adekanye[1], T. Chaya[1], P. Snee[2], M. Batish[1], J. Caplan[1]; [1]University of Delaware, Newark, DE, [2]University of Illinois at Chicago, Chicago, IL

Eukaryotic animal cells secrete three types of extracellular vesicles (EVs), each with a definite mechanism of biogenesis- apoptotic bodies, microvesicles, and exosomes. Exosomes are employed by the cell to mediate intercellular communication by shuttling mRNAs and various species of small noncoding RNAs between cells. The shuttled materials remain functional after delivery and can elicit their functions on the recipient cell. The function of EVs in plants has only recently been studied, with a major focus on plant-pathogen interactions. Even though there is evidence of the lipids, protein and RNAs transport between the plant and the fungal cell, it is still unclear as to how these materials cross the plasma membrane and cell wall of both species. Plant EVs have been implicated to be the shuttle in this interkingdom communication. Using quantum dots (QD) based molecular beacon (MB) targeted at sRNAs in EVs, we aim to determine if EVs mediate the cross kingdom communication between plants and fungi using *Sorghum bicolor* and the *Colletotrichum sublineola* as the plant pathosystem interaction, by tracking the movement of sorghum EVs into the fungal cells. Our MB uses click chemistry to attach an oligonucleotide with complementary sequence to a sRNA to a QD. A short oligonucleotide containing a black hole quencher uses Förster resonance energy transfer (FRET) to quench the QD. When the sRNA binds, the oligo with the black hole quencher is released, resulting in an increase in fluorescence. Our QD-based MB detected target sRNA in-vitro and we are now using cell penetrating peptides to load QDs into the EVs isolated from sorghum to track sorghum EV uptake into *C. sublineola*. We have developed a functional molecular beacon that can detect target sequence in-vitro, the MB has been characterized using transmission electron microscope(TEM), Quantum dots electrophoretic mobility shift assay(QEMSA), High performance liquid chromatography(HPLC). We have imaging evidence that suggests efficient loading of EVs with quantum using cell penetrating peptides. We have evidence of sorghum EVs taken up by isolated *C.sublineola* spores.

Unexpected Roles of Toll-like Receptor Adaptors TRIF and Mal/ MyD88 in Microglia Response to Neurotropic Murine BetaCoronaviruses

E. Davis, S. Navas-Martin; Drexel University, Philadelphia, PA

Background: The COVID-19 pandemic highlights the impact of betacoronaviruses (β-CoVs) in human health. Endemic CoVs, as well as the highly pathogenic β-CoVs (SARS-, MERS-, and SARS-CoV-2) cause acute, mild to severe, and fatal respiratory tract illnesses. SARS-CoV-2, however, is associated with frequent neurologic symptoms despite unclear neuroinvasive properties. Murine β-CoVs MHV-JHM and -A59 strains are models of acute encephalitis and chronic demyelination. Microglia, the resident innate immune cell of the central nervous system (CNS), function in immunosurveillance and initiating immune

responses upon infection. Their role in β-CoV neuropathogenesis, however, is poorly understood. While microglia are required for protection against lethal murine CoV encephalitis, they do not restrict SARS-CoV-2 infection in the K18-human ACE2 transgenic mouse model. Importantly, microglia contribute to neuroinflammation in CoV-infected mice. The innate immune sensors that determine how microglia influence host protection and disease progression in response to β-CoV infections remain ill-defined. Here, we assess the role of Toll-like Receptor (TLR) adaptor proteins TIR-domain-containing adapter-inducing interferon-β (TRIF) and Myeloid differentiation primary response 88 (MYD88) in antiviral and inflammatory response following infection with MHV-A59 and -JHM in microglia.
Methods: Murine-derived immunocompetent and TLR-adaptor deficient microglia were challenged with MHV strains A59 and JHM. Constituents of viral replication were examined via immunoblot, plaque assay, and immunofluorescence. Additionally, proteomic secretory profiles were assessed to determine pro-inflammatory cytokine responses.
Results: Surprisingly, CoV replication was drastically reduced in TLR - adaptor deficient microglia. This reduction was most prominent in cells lacking MyD88, with viral titers undetectable upon MHV-JHM challenge. This inhibition correlated with significantly reduced double-stranded RNA intermediates and viral nucleocapsid protein expression. Loss of either adaptor increased the expression of cytosolic dsRNA sensor, MDA-5. Moreover, TRIF was shown to negatively regulate several pro-inflammatory molecules, such as IL-6 and MIP-1β during β-CoV infection. These results highlight several novel, unexpected roles of TLR adaptors as negative regulators of microglia antiviral responses during β-CoV-infection.

Identification of novel phosphoinositide binding *Legionella pneumophila* effector proteins
A. Bolt, M. Neunuebel; University of Delaware, Newark, DE

Phosphoinositide (PIP) lipids serve as molecular beacons directing localization and function as key regulators coordinating many eukaryotic cellular processes. Intracellular bacterial pathogens target PIPs to promote their survival within the host cell. The human pathogen, *Legionella pneumophila,* infects and proliferates within human lung macrophages. The bacterium employs an arsenal of over 300 effector proteins which aid the bacterium in resisting degradation by establishing a replication permissive compartment. Previous studies revealed a growing number of *L. pneumophila* effectors target host PIPs to subvert host vesicular trafficking. However, the full repertoire of PIP-binding *L. pneumophila* effectors is unknown. Here, we performed a screen of 241 effectors with PIP-coated agarose beads. We employed an *E. coli* expression library of His-tagged effectors and optimized effector expression levels using MagicMedia™. Additionally, we tested various additives during cell lysis to improve their stability. Our screen identified previously known PIP-binding effectors and an additional 94 candidates. We then analyzed a subset of effectors in transiently transfected mammalian cells with PIP biosensors and thus far have found that over 10 candidates colocalize with PIP biosensors. These results indicate *L. pneumophila* harbors more PIP-binding effectors, providing an opportunity to better understand how this bacterium manipulates host membrane compartments to establish a replicative niche.

B690/P2358

Characterizing*L. pneumophila*effector Lem8 and its interaction with host cytoskeletal regulators

S. Hackenburg, M. Neunuebel; University of Delaware, Newark, DE

Cytoskeletal rearrangement plays a pivotal role in cell proliferation, migration, and phagocytosis. Given its critical function in coordinating eukaryotic cellular processes, the cytoskeleton and its regulators are often key targets of bacterial pathogens seeking to establish a replicative niche. A recent study found that *Legionella pneumophila* effector Lem8 (Lpg1290), a predicted cysteine protease, interacts with 14-3-3 isoform zeta, a master regulator in cytoskeletal arrangement and cell proliferation. Here, we confirmed this interaction, and we reveal that Lem8 also interacts with host Rho GTPases. Furthermore, we show HaloTag-Lem8 binds lipids *in vitro* and colocalizes with autophagosomes. Remarkably, fluorescence microscopy of RAW264.7 cell infected with *L. pneumophila* expressing HaloTag-Lem8 efficiently detected translocated effector Lem8 early during bacterial uptake. These findings suggest Lem8 acts during the early stages of vacuole formation and biogenesis.

B691/P2359

Delineating the Molecular Basis of Acidic pH and Antibiotic Tolerance in Uropathogenic *Escherichia coli*

F. Guice[1], M. Wiebe[2], T. Bermudez[2], M. Hadjifrangiskou[2]; [1]Biology, Prairie View A&M University, Prairie View, TX, [2]Vanderbilt University, Nashville, TN.

One of the most common bacterial infections in humans is urinary tract infections (UTIs) which affect over 150 million people worldwide every year. Over 75% of UTIs are caused by uropathogenic E. coli (UPEC). UPEC's ability to withstand various environmental stresses is required for its successful pathogenesis. Our lab is interested in two stresses specifically: antibiotic and pH stress. Due to increasing rates of drug resistance toward first-line antibiotics, use of the last-line antibiotic fosfomycin is on the rise. To investigate antibiotic resistance pathways towards fosfomycin, our lab has isolated nonsusceptible subpopulations of UPEC clinical isolates. I have evaluated the relative increase of resistance these subpopulations display and monitored relevant growth defects previously associated with fosfomycin resistance. This will allow for the prioritization of sequencing efforts for possibly uncharacterized routes to fosfomycin resistance. With my efforts I have identified 6 out of 18 NICs that demonstrate atypical growth in nutrient-deficient media, suggesting they contain mutations in genes previously unassociated with fosfomycin resistance. To investigate how UPEC combats pH stress, our lab has generated various strains of UPEC with mutations in acid resistance mechanisms. I have begun to characterize the growth of these mutant strains under normal laboratory conditions and plan to evaluate their growth in conditions that replicate the bladder environment. My work will generate a better understanding of how UPEC adapts to stress encountered in the host caused by last-line antibiotics or acidic conditions.

The intracellular bacterial pathogen, *Brucella* targets host deubiquitin protease through the effector protein, TcpB for facilitating infection of macrophages.

K. Joshi, V. Muzumdar, G. Radhakrishnan; National Institute of Animal Biotechnology, Hyderabad, India

Brucella species are Gram negative intracellular bacterial pathogens that cause the world-wide zoonotic disease, brucellosis. *Brucella* can infect a wide range of mammals, including humans and domestic and wild animals. *Brucella* manipulates various cellular processes to successfully invade and multiply in the professional and non-professional phagocytic cells. However, the host targets and the mechanism behind their modulation remain obscure. Here, we report that *Brucella* downregulates the expression of a host ubiquitin peptidase at its early stage of infection that results in an enhanced uptake of *Brucella* by macrophages through the membrane receptor. Upon silencing and chemical inhibition of ubiquitin peptidase, the membrane localization of the receptor was enriched, which augmented invasion of *Brucella* into macrophages. Further, we found that only live *Brucell*a was capable of suppressing the expression of ubiquitin peptidase suggesting the role of secreted effector proteins of *Brucella* in modulating the gene expression. Subsequent studies revealed that the *Brucella* effector protein, TIR-domain containing protein from *Brucella* (TcpB) plays a major role in downregulating the expression of ubiquitin peptidase by targeting its transcriptional regulators. The TcpB knock-out *Brucella* was unable to modulate the expression of ubiquitin peptidase and this defect was restored when the TcpB expression plasmid was introduced into TcpB knock-out *Brucella*. Besides regulating the invasion of *Brucella*, the host ubiquitin peptidase enhanced the expression of late endosomal markers, suggesting its role in promoting lysosomal killing. Our *in vitro* and *in vivo* studies showed an enhanced multiplication of *Brucella* in the presence of an inhibitor of the ubiquitin peptidase. The present research uncovered a mechanism by which *Brucella* imparts suppression of host ubiquitin peptidase for its enhanced invasion and intracellular survival. Further, our experimental data demonstrate a novel role of ubiquitin peptidase in the host defense against the microbial intrusion. The present study provides insights into the microbial subversion of host defenses and this information may ultimately help to develop novel therapeutic intervention for brucellosis.

Crippled Coronavirus: 5’-PolyU Targeted Oligo Inhibits Development of Infectious Virions

D. Davis, H. Ullah; Howard University, Washington, DC

We are currently facing a global pandemic caused by a strain of virus from the Coronaviridae family, coronavirus disease-2019 (COVID-19). The additional variants have prolonged the effects of the pandemic by enhancing their ability to evade their host immune systems and decreasing the effectiveness of current pharmaceutical treatments. Identification of viral targets that are indispensable for the virus can be targeted to inhibit mutation-based new escape variant development. The 5’-polyU tract of the antigenome offers such a target. Host cells do not harbor 5’-polyU tracts on any of their transcripts, making the tract an attractive, virus-specific target. Inhibiting the 5’-polyU can limit the use of the tract as template to generate 3’ polyA tails of +RNAs of coronaviruses. To counter host evading property, we reported that by targeting the unique 5’ polyU tag on the mouse coronavirus (MHV) anigenome (negative RNA strand) with a complementary oligonucleotide, the virus replication could be prevented (patent pending). As the tag is indispensable for virus replication, it is likely that the virus would not be able to develop escape variants by mutating the tag. This proof-of-concept result shows a

unique mode of action against mouse coronavirus without affecting host cells and can be used for the development of novel classes of drugs that inhibit coronavirus infection in host cells, specifically by the COVID-19-causing virus SARS-CoV-2.

Effects of Decompression Using Drain on Bone Healing of S. aureus Infected Osteomyelitis Mandibular in Rat

S. Kim, B. Sodnom-Ish, K. Mustakim, M. Eo, Y. Cho; Seoul National University, Seoul, Korea, Republic of

Osteomyelitis (OM) of the jaw is usually caused by odontogenic infection or by a variety of other reasons which result in jaw bone destruction. Microorganisms such as Staphylococcus aureus (S. aureus) are known to be significant pathogens at the pathogenesis of OM. Decompression using a drain is a reliable technique, which releases the intraluminal pressure causing reduction of cyst and allows gradual bone regeneration from the periphery. The aim of this study was to analyze the effectiveness of decompression in an OM rat mandible model. A 4 mm diameter defect was made on the mandibles of Sprague-Dawley rats (8 weeks old) and 20 µl of $1x10^7$ CFU/ml S. aureus was inoculated. Two weeks later, the animals were randomly divided into non-treatment control (C1), curettage only control (C2), curettage and decompression using drain (E1), and curettage and decompression using drain with normal saline irrigation (E2) groups. After four weeks, the animals were assessed with micro-computed tomography (micro-CT), histology stained with hematoxylin and eosin (H&E) and Masson's trichrome (MT), and immunohistochemistry (IHC) stained with inflammation-related IL-6 and TNF-α, angiogenesis-related VEGF-A and TGF-β1, and osteogenesis-related OPN and ALP antibodies, followed by statistical analysis. S. aureus infected osteomyelitis model was successfully created in a rat mandible. Most parameters showed significantly lower bone healing in the C1 and C2 groups in micro-CT analysis. Especially in the E2 group, bone mineral density with bone volume was significantly enhanced compared to that seen in the C1 or C2 groups, and bone volume/volume of interest parameter was significantly higher ($p < 0.05$) in the E2 group. In the histological analysis, the E1 and E2 groups showed the most prominent bone healing with a significantly high number of osteocytes found in the defect area ($p < 0.05$). In IHC staining, the E2 group had the weakest expression of IL-6 compared to that of the C1 group. The TNF-α antibody was stained strongly in the E1 group compared to that of other groups. The expression of VEGF-A was the highest in the C1 group compared to the E2 group. The TGF-β1, ALP, and OPN expressions were markedly high in the E1 group, while the C1 group had no TGF-β1, ALP, and OPN expression compared to that of the other groups. The micro-CT, H&E, and MT stained histological analysis, and IHC analyses showed that decompression drains exhibited superior bone healing results compared with that of conventional surgical treatment alone in an OM rat mandible model. Based on these results, it is recommended that clinicians use decompression with drainage and irrigation to treat jaw OM.

Genome analysis of deadly poisonous mushroom *Amanita virosa* using nanopore sequencing technology

K. Soga, S. Yoshiba, J. Narushima, N. Shibata, K. Kondo; National Institute of Health Sciences, Kawasaki, Kanagawa, JAPAN.

The fungus *Amanita virosa (A. virosa),* commonly known as destroying angel and originated in Europe, is one of the deadly poisonous mushrooms in the genus *Amanita*. The mushroom is thought to have genes producing amatoxins and phallotoxins. However, so far the detailed genomic information has not been revealed, and other toxins remain unclear. The reasons are due to (1) the diversity and the difficulty of culturing wild mushrooms in a laboratory; (2) few reference sequences and information concerning related species. In this study, the high-quality genome of *A. virosa* was assembled using nanopore-based long-read sequencing technology and genes associated with poisonings were predicted. *A. virosa* fruit bodies were collected from the fields in Hokkaido. A cap of fruit body was ground in liquid nitrogen. High molecular weight genomic DNA was extracted by the modified CTAB method and purified using a short read eliminator Kit (Circulomics). The DNA library was prepared using Ligation Sequencing Kit. DNA sequencing was performed using the PromethION, nanopore sequencer (Oxford Nanopore Technologies). Obtained raw sequence data (FAST5 format) were base-called using Guppy basecaller v5. The reads including more than 200×deep sequencing data were *de novo* assembled using NECAT v0.0.1, a long read assembler. The assembly was polished using Racon v1.4.20, Medaka v1.5.0, and hypo v1.0.3. The completeness of the assembled genome was evaluated using BUSCO v5.3.1 (fungi_odb10). Homology-based and RNA-seq-assisted gene prediction and annotation were performed using RepeatModeler v2.0.3, RepeatMasker v4.1.2, BRAKER2 v2.16, GeMoMa v1.8, and EnTAP v0.10.8. The resulting assembly of *A.virosa* yielded 69.3 Mb comprising 61 contigs. The N50 and N90 lengths were 2.6 and 0.6Mb, respectively. A total of 97.8% of the 1698 BUSCO genes were detected in the genome, indicating the completeness of the assembly. More than half of the total sequence was occupied by retroelements. *A. virosa* contained more than s 10,000 genes, many of which were DNA replication and repair-related genes. Our data could provide the first report of the draft genome of *A. virosa* and serve as a reference for poisonous mushrooms. We plan to use this genome to search for novel toxic genes.

B696/P2364

Exploring the unconventional cell biology of multi budding yeast, *Aureobasidium pullulans*

C. Petrucco[1], O. Gorman[2], D. J. Lew[2]; [1]Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC, [2]Pharmacology and Cancer Biology, Duke University Medical Center, Durham, NC.

Cells of the same type often display characteristic sizes, shapes, and organelle compositions. Budding yeast (*Saccharomyces cerevisiae*) have sophisticated organelle segregation strategies to ensure that new buds receive appropriate complements of organelles like nuclei, mitochondria, vacuoles and peroxisomes. They also have checkpoints and compensatory pathways so that errors in organelle segregation can be corrected. Unlike *Saccharomyces cerevisiae*, *Candida albicans*, *Cryptococcus neoformans*, *Ustilago maydis*, and other well-studied yeasts, *Aureobasidium pullulans* mother cells can be multinucleate and produce multiple buds within a single division cycle. Initial observations suggest that buds made from a single mother in the same cell cycle have comparable growth rates and final

volumes, but it is not yet clear whether they have uniform or variable complements of different organelles. We are interested in asking whether all sister-buds are endowed with comparable complements of each organelle (which would require precise and potentially novel inheritance mechanisms), or whether sloppy inheritance pathways produce a heterogeneous population (which may reveal how cells deal with unusual organelle compositions). To investigate this interesting cell biology, we are developing a molecular genetics toolbox, including efficient transformation and fluorescent probes for intracellular structures of interest in order to make *A. pullulans* a tractable system for basic cell biology research. We found that most buds inherit exactly one nucleus regardless of the number of nuclei in the mother or the number of sibling buds. However, occasional buds received two nuclei, so that comparably-sized sibling cells could differ two-fold in DNA content. These findings suggest that *A. pullulans* mother cells have a mechanism to ensure that each bud gets at least one nucleus, and that daughter cells can thrive despite large differences in the DNA-to-cytoplasm ratio.

Characterization of an ORFan and Putative Nitrilase from *Saccharomyces cerevisiae*

E. Koyama, A. Nguyen, S. S. Tadesse, S. Walsh; Life Sciences, Soka University of America, Aliso Viejo, CA.

While *Saccharomyces cerevisiae* is a well-studied organism with its genome fully sequenced, there are still over 100 uncharacterized open reading frames, ORFans, with no significant sequence homology to other genes. As ORFan roles cannot be determined solely through sequence homology, their functions remain a mystery until both in vitro and in vivo biochemical and cell biology experiments are performed. In collaboration with the Yeast ORFan Gene Project, we used bioinformatics modules to initially characterize one such ORFan, *YIL165C*. Together with the gene immediately preceding it, *YIL164C* (*NIT1*), these two genes have significant homology to the nitrilase superfamily of proteins, but have low sequence homology to the other two *S. cerevisiae* nitrilases *NIT2* and *NIT3*. We experimentally verified that lab strains of *S. cerevisiae* have a bonafide stop codon breaking up the two proteins in clones from both genomic DNA and mRNA, but the brewing yeast strain WLP001 (White Labs) and other related yeast strains have a SNP (A>G), causing these two proteins to be expressed as a single, continuous polypeptide chain. The YIL164C protein alone contains both the conserved catalytic triad and a region that shares homology with prokaryotic nitrilases that specifically target aromatic, rather than aliphatic, nitrile substrates. To understand the function of both the full-length YIL164C/YIL165C and the individual YIL164C protein, we expressed the proteins in bacteria and began enzymatic assays to understand their substrate preference. We hope to identify distinctions in activity, or the lack thereof, between the longer and the truncated proteins. In addition, we generated yeast which either overexpress the full-length YIL164C/YIL165C or the truncated YIL164C protein or knockout both genes at once. Neither the overexpression or knockout strains have an obvious phenotype distinct from wild-type laboratory strains, particularly in the realm of mitophagy, where knockout of *YIL165C* alone was previously reported to have a strain-specific mitophagy defect. Taken altogether, understanding these enzymes will provide clues to the evolutionary relationships among genes in this superfamily.

B698/P2366

Crosstalk between titanization in the*Cryptotococcus neoformans/gattii*complex and macrophages

Y. Loperena-Alvarez[1], R. J. Colón-Reyes[2], L. Kozobowski[2]; [1]Biology, Pontifical Catholic University of Puerto Rico, Mayaguez, PR, [2]Eukaryotic Pathogens Innovation Center, Clemson University, Clemson, SC.

Cryptococcosis is a fun`gal infection of the lungs and brain that affects both immunocompromised and immune-competent individuals, caused by *Cryptococcus neoformans and Cryptococcus gattii complex* (*C.neo/gat*). The capsule is primarily responsible for the phagocytosis evasion. *C. neo/gat* has the ability to adapt and produce an enlarge capsule called titan cells, a mechanism that limits the attack of macrophages. In the host, it has been observed that TC were engaged, but not engulfed by phagocytic cells such as macrophages, showing a new strategy of the yeast to evade the immune system. Proliferation of cryptococcosis have been characterize by the high levels of M2 macrophages in its chronic stage.The purpose of this research is to better understand the mechanisms that drive the pathogen/host interaction between *C.neo/gat* complex with macrophages. J774 monocytes were allowed to grow for 24 and 48 hrs on DMEM without FBS, following by collection of the media. The media was used to determine which cytokines are present and to treat *C. neoformans* H99 and *C. gattii* 265 for 24hr to determine if the secreted product of macrophages induce titanization. After treatment, it was observed titanization in both strains, being in a higher quantity and size the ones of *C. gattii*. Expression of key genes related to titanization such as cAMP and GPR-5 was significantly affected in the strains, without affecting RIM101. In another set of experiments, J744 cells were treated with regular morphotypes, mixed morphotypes and the titan morphotype in order study the effect of *C.neo/gat* in the phenotype switching. After 24h of treatment, it was observed a population of M2b with both mixed and titan C. neo/gat morphotype, while the regular morphotypes showed M1 phenotype of macrophages. Our data suggest that macrophages secreted products induce titanization in *C. neo/gat* using two different signaling cascades. Additionally, our data indicates that the titan cells have the capacity of switch the phenotype of macrophages to and antiinflammatory one, explaining the phagocytosis evasion of the yeast.

B699/P2367

The fungal pathogen *Cryptococcus* actively manipulates maturation of its phagosome in an immune signal-dependent way.

P. Stuckey[1], E. Santiago-Burgos[2], F. Santiago-Tirado[1]; [1]University of Notre Dame, Notre Dame, IN, [2]Imanis Life Sciences, LLC, Rochester, MN.

Cryptococcus neoformans is a common fungal pathogen responsible for nearly 200,000 deaths yearly. This ubiquitously present yeast affects a diverse group of immunocompromised individuals, which left untreated is invariably fatal. Once *C. neoformans* particles are inhaled and make their way into the lungs they encounter alveolar macrophages. Interactions between these host cells and the fungi will influence whether the infection is cleared or disseminates to the central nervous system. Since *C. neoformans* can survive and replicate inside host macrophages, they represent a safe haven, hidden from the immune response of the body, as well as a vehicle to move throughout the organism, even allowing movement across the blood-brain barrier. The mechanisms *C. neoformans* use to mediate this intracellular

parasitism are not fully understood. Even less is known about how immune signals impact this replicative niche. Therefore, we aim to gain a better understanding of the macrophage-cryptococcal interactions and decipher the properties of the cryptococcal-containing phagosome (CCP), which we believe may be key to determining infection outcome.
Using high-resolution microscopy, we have identified a population of CCPs that display both early endosomal lipid (PI3P) and lysosomal protein (LAMP1) characteristics, a combination that is not normally observed. Using a pH-sensitive dye, we have identified three populations of CCPs with different behaviors: one that gains acidification after phagocytosis but subsequently loses it; some that acidify and remain acidic; and some that never acidify. This is in contrast to phagosomes containing the non-pathogenic yeast *S. cerevisiae*, which rapidly acidify and stay acidic. This suggests that *C. neoformans* can alter its phagosome, explaining the confounding literature regarding the intracellular niche of *C. neoformans* and provide a potential mechanism for intracellular survival that may be driving cryptococcal pathogenesis.
We have demonstrated a delay in acquisition of lysosomal markers to CCPs in comparison to *S. cerevisiae* and latex bead controls. However, when macrophages are stimulated with interferon-γ, acquisition of lysosomal markers occurs more rapidly. Host Rab20 appears to be critical for this promotion of phago-lysosomal fusion and may be key in influencing the infection outcome. Rab20 has been shown to be interferon-γ inducible and promote phagosome fusion and maturation, thereby linking host cell immune status and phagosomal properties during cryptococcal infection.
Our results suggest that *Cryptococcus* actively manipulates the phagosomal environment to avoid killing by targeting Rab GTPases, phosphoinositides, or both, and modulating the pH of its phagosome in a way that is dependent on the host's immune status.

B700/P2368

The *wtf* question: How do extremely diverged Wtf proteins do the same job?

A. Nidamangala Srinivasa[1,2], S. Campbell[1], M. De Carvalho[1], S. Zanders[1,2]; [1]Stowers Institute for Medical Research, Kansas City, MO, [2]Molecular and Integrative Physiology, University of Kansas Medical Center, Kansas City, KS.

Meiotic drivers are genetic parasites that manipulate gametogenesis to be transmitted into more than 50% of the viable gametes produced by a heterozygote. The *wtf* gene family in the *Schizosaccharomycete* fission yeasts includes multiple meiotic drive genes. Each *wtf* driver encodes an aggregating poison protein that targets all the developing gametes in addition to an antidote protein that only rescues *wtf*+ gametes. In one characterized *wtf* driver, *wtf4*, the antidote acts by co-assembling with the poison and promoting its trafficking to the vacuole. Strikingly, Wtf proteins that share less than 17% amino acid identity with those of Wtf4 still function as poisons and antidotes. We are exploring how these Wtf proteins can support the same molecular functions, despite extreme divergence. We propose that low functional constraint on the *wtf* gene family evolution could contribute to their evolvability and promote their long-term success. Additionally, the results of this work could broaden the knowledge on the breadth of sequences that facilitate protein self-assembly and aggregation.

B701/P2369

Quantifying and expanding the halotolerance of the black yeast *Knufia petricola*

G. Murphy[1], G. Hamilton[2], A. Gladfelter[2]; [1]University of Richmond, Richmond, VA, [2]University of North Carolina, Chapel Hill, NC

Knufia petricola is a black yeast and an emerging model organism for the study of eukaryotic extremotolerance. It is found in diverse hostile environments, from bare rock faces to the ocean. *Knufia* exhibit the typical characteristics of extremotolerant black fungi, such as slow yeast-like growth, highly melanized cell walls, the absence of specialized reproductive structures, and the production of orange to red carotenoids. Concurrent with studies exploring other facets of this fungus's polyextremotolerance, this study specifically sought to define the limits of *Knufia*'s halotolerance. We also set out to compare the halotolerance of a terrestrial isolate obtained from marble in Greece (A95) and a marine isolate obtained from a plankton tow off the coast of Woods Hole (WH). We hypothesized that *Knufia* could survive from 5-10% NaCl and that the marine isolate would have a higher tolerance due to the isolate already being subjected to NaCl in the ocean. To test this hypothesis, we created liquid and solid cultures with varying salt conditions and grew A95 and WH strains to compare their growth and morphology. Survival on solid media was quantified using a drop dilution assay. Maximum growth was observed at 5-8% NaCl with limited growth at 9-10% NaCl. For reference the ocean has around 3.5% NaCl, and *Saccharomyces cerevisiae* cannot survive even 3% NaCl. We also observed that the marine isolate, WH, did in fact have a higher survival rate in higher NaCl concentrations when compared to the terrestrial isolate. With the use of directed evolution, I was able to progress the salt limits that *Knufia* could survive in, generating a slightly more halotolerant strain. I also involved another osmotic stress, glycerol, in our experiment. Our preliminary data suggest that osmotic stress from glycerol, an organic solute, and NaCl, an inorganic salt, functioned additively and prevented the *Knufia* from surviving at all. We will continue our directed evolution experiments in order to push and understand the limits of halotolerance in *Knufia*, and CRISPR knockouts will allow us to test the importance of specific genes to *Knufia*'s remarkable extremotolerance. Understanding how a eukaryotic organism evolved to survive in environments as hostile as bare rock faces will help us understand the limits of life on Earth.

Structural cell biology of the invasion organelle from microsporidian parasites

M. Usmani[1], N. Coudray[1], H. Ramchandani[1], M. Kopylov[2], D. Bobe[2], D. Ekiert[1], G. Bhabha[1]; [1]NYU School of Medicine, New York, NY, [2]New York Structural Biology Center, New York, NY

Intracellular pathogens have developed diverse ways to enter and infect host cells. Microsporidia are single-celled eukaryotes that form a sister group to fungi, and are obligate intracellular parasites that have evolved a unique, harpoon-like organelle called the polar tube (PT) to invade host cells. Outside the host, microsporidia exist as dormant spores, in which the long PT is tightly coiled. Upon firing, the PT undergoes a tremendous conformational change to a long, linear tube extruding out of the spore and is thought to pierce the plasma membrane of a target cell. The PT then serves as a tunnel which delivers infectious cargo into the host cell to initiate infection. This entire process occurs on a millisecond timescale and the extruded PT is 20 times the length of the spore it fires from. The architecture of the PT and the large structural rearrangement that occurs upon firing is poorly understood. To gain an understanding of the PT firing mechanism we are using cryo-electron tomography (cryo-ET) to study the 3D architecture of the PT in its pre-firing and post-firing states. By annotating tomograms, we have

gathered insights into how the PT interacts with other organelles in the spore that may play a role in its firing mechanism. We are also using subtomogram averaging (STA) on the PT to gain higher resolution insight into its structure. Using cryo-ET we have been able to resolve new features of the PT in both its coiled and linear states, shedding new structural insights into this unique invasion organelle.

Development of a Genetic Transformation System for the Frog-Killing Chytrid Fungus *Batrachochytrium dendrobatidis*

E. Kalinka, A. J. M. Swafford, E. M. Medina, L. K. Fritz-Laylin; University of Massachusetts Amherst, Amherst, MA

Chytrids are early-diverging fungi that display both animal- and yeast-like cellular features (e.g., actin cytoskeletal components), providing a unique opportunity to study early fungal evolution. Two chytrid species, *Batrachochytrium dendrobatidis* (*Bd*) and *Batrachochytrium salamandrivorans*, are decimating amphibian populations around the world. Efforts to mitigate the damage and spread of *Bd* infections have been limited by the lack of knowledge about its basic biology and molecular genetic tools with which to test core hypotheses about amphibian-chytrid symbiosis. To date, the non-pathogenic species *Spizellomyces punctatus* is the only genetically tractable chytrid (Medina, E.M., 2020). Here, we adapted a previously reported electroporation protocol (Swafford, A.J.M., 2020) for the delivery of exogenous DNA into *Bd* zoospores and quantified transgene expression by performing luciferase assays on transfected cells. We generated DNA constructs that facilitate transient expression of an antibiotic resistance marker and various fluorescent proteins and observed transgene expression for up to four life cycles (12 days). By expressing a LifeAct-tdTomato fusion and using live-cell imaging, we visualized the distribution and dynamics of polymerized actin in *Bd* at each stage of its life cycle. We are now developing a suite of genetic tools to facilitate subcellular localization analysis of endogenous proteins, stable transgenesis, and CRISPR-mediated genome editing in *Bd*. These new tools will pave the way for addressing fundamental questions of chytrid cell and evolutionary biology by molecular genetic approaches, and aid in the establishment of ecological mitigation strategies.

Bioassay System for Evaluating Branched-chain Higher Alcohols Titerby Using Yeast Double Deletion Strains with Isobutanol Hypersensitivity

G. Sato, K. Kuroda; Graduate School of Agriculture, Kyoto University, Kyoto, Japan

[Objective]: Branched-chain higher alcohols (BCHAs) production by yeast is a promising process for providing advanced biofuels toward sustainable society. However, the further development of yeasts producing BCHAs requires costly and time-consuming titer-evaluation processes using chromatography instruments. The transcription factor-based biosensor was recently proposed as a rapid BCHAs titer-evaluation process. Nevertheless, it was limited to intracellular detection of intermediate of BCHAs biosynthesis [1], and direct detection of BCHAs is still unavailable in yeasts. Therefore, we propose a novel bioassay system for the direct evaluation of BCHAs titer in the yeast fermentation broth.
[Methods and Results]: The biomolecules that can detect BCHAs are unknown in yeasts. Thus, we conceived a novel bioassay system based on the inhibition of yeast growth by BCHAs. We previously identified deletion strains of *Saccharomyces cerevisiae* that are highly sensitive to isobutanol (IbOH), one of the BCHAs, while maintaining ethanol tolerance [2]. Based on our knowledge, we constructed

various double deletion strains as candidates for BCHAs sensors. By evaluating growth inhibition of candidate sensors by IbOH in the yeast fermentation broth, a strain with sensitivity to under 0.2% IbOH was identified, and its sensitivity was maintained in the fermentation broth. As a bioassay system, the sensor was added to filter-sterilized fermentation broths produced by each strain of the yeast IbOH producer library and cultured to measure growth inhibition of the sensor. The growth inhibition of the sensor showed a significant correlation to IbOH titer of producers. Furthermore, to examine the direct detection of BCHAs, partial least square regression (PLSR) model of the sensor growth was constructed from high-performance liquid chromatography and refractive index detector chromatogram peak areas of fermentation broths. As a result, IbOH concentration was the most important factor in the PLSR model of sensor growth among all detected metabolites in the fermentation broths, suggesting direct detection of BCHAs. **[Conclusion]:** Measuring growth of the double deletion strain with IbOH hypersensitivity was proposed as a novel bioassay system for evaluating the IbOH titer of yeast producers. Investigating the Effectiveness of Antimicrobial Reagents on Environmental Mold Samples

V. Adams, K. Hodges, A. Shukwit, C. Davis, C. Jones Carter, M. Van Stry; Lane College, Jackson, TN

There are millions of mold species found on Earth that grow in the damp places of homes, college dorms, and classrooms. Indoor mold such as *Alternaria alternata*, *Aspergillus fumigatus*, and *Cladisporium cladosporioïdes* have a greater effect on human health. After spores have been released into the environment and inhaled, illnesses such as respiratory diseases, asthma, and bronchitis can occur. The greater amount of mold infestation the more extensive the damages and associated cost-related restoration. The goal of this study is to isolate mold found on the college campus and to test the antimicrobial properties of cost effective treatments. The analysis and experimentation of indoor mold species benefits the school and other historical black colleges or universities (HBCU's) who are struggling with this problem. Seventeen (17) mold samples were isolated from three (3) locations on campus, and three (3) of six (6) samples were used based on phenotypic interest. Antimicrobial reagents such as bleach, hydrogen peroxide, mold armor, vinegar, and tea tree oil were tested using two (2) different methods: treating one group immediately with each reagent and the other group after three (3) days of growth. The results showed the most effective reagent at preventing mold growth was Mold Armor and the least effective was tea tree oil. The potential hydrogen (pH) of each reagent was also tested to determine a possible cause and effect relationship. Future directions include the three (3) remaining samples to determine any of the extent relationship amongst samples.

NOX2-derived Reactive Oxygen Species shape the inflammatory response through GSDMD post-translational regulation

D. Stanga, F. Touzot; Immunology and Cancer, CHU Sainte-Justine Research Center, Montreal, QC, CANADA.

Redox signaling is known to be the principal driver of inflammation. This is mainly achieved through transcriptional modulation and post-translational modifications of the multiprotein complexes of the inflammasomes, which are involved in mediating cellular inflammation in response to various damaging agents. Redox signaling is induced by reactive oxygen species (ROS) that are produced either by the mitochondrial respiratory chain also called mitochondrial ROS or by the NADPH oxidases called cytosolic ROS. While excessive ROS production is a well-recognized trigger of an excessive inflammatory response, little is known about the consequences of low redox signaling on inflammation. The need for fine-tuning of ROS production is well exemplified by the NOX2 deficiency model, an inborn error of immunity that abolishes the function of the NADPH oxidase complex 2. Interestingly, the defective cytosolic ROS production observed in NOX2 deficiency leads to an enhanced inflammatory response. This biological picture is intriguingly similar to the one observed in pathological conditions with excessive ROS production.In our study, we investigate the biological consequences of defective cytosolic ROS production on the inflammatory response in humans using primary cells from NOX2-deficient patients and a CRISPR-engineered NOX2-deficient CYBBko THP-1 cell line. We provide evidence that low cytosolic ROS production increases the transcriptional priming of NLRP3 and IL-1β. This priming is IL-1β dependent through auto/paracrine stimulation of the NF-KB pathway downstream of the IL-1β receptor. We also show that, in NOX2-deficient human macrophages, the NLRP3 inflammasome activation is triggered by increased K+ efflux and cytosolic release of mitochondrial DNA, which are enhanced by the presence of cleaved Gasdermin D (GSDMD) at the plasma and mitochondrial membranes. This observation refines the role of GSDMD as an enhancer of the inflammatory response rather than only a terminator through pyroptosis. Finally, our deep study of the NOX2 deficiency model unveils the crucial role of GSDMD Serine 252 residue, whose phosphorylation is critical in enhancing GSDMD cleavage and membrane pore formation.Thus, our study brings two key messages: (1) revealing the role of NOX2-derived ROS in tempering the inflammasome cascade at the transcriptional and post-translational levels, thus rebalancing our view on the function of the redox signaling in regulating the inflammatory response (2) evidencing GSDMD S252 phosphorylation as an important event in regulating GSDMD pyroptotic activity and offering a new drug target for inflammasome -driven pathologies.

B708/P2375

Rac-mediated hyperphagocytosis in mammalian immunodeficiency

M. Rodriguez; MCDB, University of California, Santa Barbara, Santa Barbara, CA.

Rac2 is amongst the numerous signaling molecules essential for engulfment of fluid, apoptotic bodies, and pathogens. Loss of function mutations in the hematopoietic-expressed Rac2 gene causes immunodeficiencies due to impaired migration and survival of neutrophils, macrophages, and lymphocytes. Human patients with germline mutations that hyperactivate the Rac2 protein exhibit unexplained clinical features ranging from lymphopenia to severe combined immunodeficiency.

Specifically, patients who carry a $Rac2^{E62K}$ amino acid substitution exhibit repeated respiratory infections and B and T cell lymphopenia. There are no defects in the development of B and T cells, thus the cause of the lymphopenia in patients remains a mystery. Recently, our lab discovered that hyperactive Rac is sufficient to drive one cell to engulf another living cell in a process known as cell cannibalism. First discovered in *Drosophila*, we found this effect is conserved in mammals. The objective of this study is to decipher how a dominant activating mutation in Rac causes mammalian immunodeficiency. Normally, phagocytes engulf and kill activated B and T cells to resolve inflammatory responses and to turn over cells at the end of their life cycle. So, we hypothesized that $Rac2^{E62K/+}$-expressing macrophages might prematurely engulf and kill lymphocytes, just as border cells expressing active Rac prematurely engulf and kill nurse cells in the *Drosophila* ovary model. Using the $Rac2^{E62K}$ mouse model that phenocopies the human genetic disease, we found that $Rac2^{E62K}$ macrophages engulf and kill significantly more T cells than wildtype macrophages. We discovered that $Rac2^{E62K}$ macrophages are not only hyperphagocytic, but T cells are more vulnerable to engulfment compared to B cells. In addition, despite the loss of circulating B cells we found a striking increase in B cell numbers in the spleens of $Rac2^{E62K}$ mice compared to wildtype littermates. These data suggests that the dominant activating Rac2 mutation functions cell-autonomously in these immune cells to cause the lymphopenia. Together, these results demonstrate that hyperactive Rac enhances engulfment of target living cells when those cells express a specific ligand and when the Rac-expressing phagocyte expresses the receptor. This work builds on a discovery made in *Drosophila* to provide a novel cellular and molecular explanation for an otherwise mysterious rare immunodeficiency in patients. We propose that though harmful as a germline mutation, we can harness this Rac-mediated behavior in macrophages to improve CAR macrophage (CAR-M) cancer immunotherapies.

B709/P2376

Defining the activation of CD16 by phosphorylation of CD3ζ in human natural killer cells

H. Fatima, M. J. Shannon, E. M. Mace; Columbia University Irving Medical Center, New York, NY.

The Fc receptor CD16 (FcγRIIIa) is expressed on $CD56^{dim}$ peripheral blood natural killer (NK) cells and a subset of human blood monocytes. CD16 mediates antibody-dependent cellular cytotoxicity (ADCC) upon binding the Fc region of antibodies coating abnormal cells. CD16 ligation at the immunological synapse initiates the exocytosis of perforin and granzyme resulting in the lysis of target cells. This response is important for the clearance of tumor cells and pathogens and in the context of monoclonal antibody (mAb) treatment. Rituximab is a mAb that binds CD20 on B-cells, which become targets for NK cell directed ADCC. CD16-mediated clearance of tumor cells by NK cells mediates the clinical response to Rituximab treatment in lymphoma patients. CD3ζ activation and kinase-based signal amplification is coupled to CD16-Rituximab binding, but little is known about the spatiotemporal organization of these molecules required for their function.

Here, we use detection of CD3ζ by confocal microscopy as a proximal marker for CD16 activation and demonstrate that Rituximab-induced NK cell activation leads to increased levels of phosphorylated CD3ζ compared to immobilized ICAM-1, the ligand for LFA-1 expressed on NK cells. This was concluded by quantifying the number of foci of phosphorylated CD3ζ at the plane of the activated glass surface. The existence of large CD3ζ foci around smaller instances of CD16 visible by confocal microscopy has encouraged us to employ single molecule imaging to better understand how CD16 spatial localization and activation changes in response to Fc binding. Preliminary results demonstrate that we can visualize CD16 at single molecule resolution. We used direct stochastic optical reconstruction microscopy

(dSTORM) and the Python-based localization software 'Picasso' to acquire nanoscale point maps of molecular positions. Our results provide new insight into the first steps of CD16 activation during the process of ADCC and have exciting implications for better understanding how monoclonal antibody therapies exert function.

Honey Mediated Gold Nanoparticles Attenuate Macrophage Secretion of IL-6 Following LPS Exposure

J. Duncan, S. Basu, P. Vivekanand; Susquehanna University, Selinsgrove, PA.

Interleukin-6 (IL-6) is a pleiotropic cytokine that coordinates host immune responses to infection. Though essential to the acute phase response, prolonged IL-6-mediated recruitment of mononuclear cells has been implicated in chronic inflammatory diseases such as rheumatoid arthritis, psoriasis, and Chron's disease. Accordingly, identifying novel therapeutics that diminish circulating IL-6 levels should benefit individuals suffering from chronic inflammation. Under normal circumstances, in immunocompetent hosts, bacterial lipopolysaccharide (LPS) recognition by toll-like receptor 4 (TLR4) prompts macrophage secretion of IL-6. Interestingly, both citrate-stabilized and 'green' synthesized gold nanoparticles (AuNPs) have been shown to modulate the cytokine responses of LPS-induced macrophages. Here, we demonstrate that AuNPs, synthesized with commercial and locally sourced honey, downregulate LPS-induced macrophage secretion of IL-6 *in vitro*. After 1 hr. of LPS exposure, macrophages derived from a THP-1 human monocytic cell line were treated with 25 and 50 µg/ml concentrations of commercial, locally sourced dark, and light honey mediated AuNPs. Compared to LPS-only controls, a concentration dependent inhibition of IL-6 levels was observed for all three types of honey AuNPs. Further investigation into the anti-inflammatory properties of honey AuNPs may yield novel therapeutics for the treatment of chronic inflammation.

Ataxin-1 is epigenetically regulated in B cells upon multiple sclerosis and exerts an immunomodulatory function against autoimmune demyelination

Q. Ma[1], J. R. Oksenberg[1], **A. Didonna**[2]; [1]Neurology, University of California San Francisco, San Francisco, CA, [2]Anatomy and Cell Biology, East Carolina University - Greenville, NC, Greenville, NC.

More than 200 genetic loci have been found convincingly associated with an increased risk of developing multiple sclerosis (MS), an autoimmune disease of the central nervous system (CNS) characterized by lymphocyte infiltration, demyelination and axonal injury. Among them, the strongest signal in the risk locus mapping at chromosome 6p22.3 lies within the *ATXN1* gene, which encodes the polyglutamine protein ataxin-1. This chromatin-binding protein works as a transcriptional co-repressor in a large multimeric complex, and it was previously found implicated in the etiology of the neurodegenerative disorders spinocerebellar ataxia type 1 (SCA1) and Alzheimer's disease (AD). On the contrary, very little is known about the function and the regulation of ataxin-1 in the context of CNS autoimmunity. To fill this gap, we analyzed via bisulfate DNA sequencing (BS-seq) four peripheral immune cytotypes (CD4+ and CD8+ T cells, CD19+ B cells, and CD14+ monocytes) isolated from a cohort of untreated MS patients at symptoms onset. Here, we show that *ATXN1* is hypomethylated upon MS at four different sites, exclusively in the B cell population. Importantly, these sites overlap with other regulatory epigenetic marks and their hypomethylation leads to an increase in *ATXN1* expression as confirmed by luciferase assays and RNA-seq transcriptomic profiling. In the MS animal model

experimental autoimmune encephalomyelitis (EAE) ataxin-1 is upregulated in the immune system at the peak of disease and its ablation results in an aggravated EAE course. Consistent with the human data, immunophenotyping and cell activation studies on ataxin-1 null mouse splenocytes narrowed down the main target of ataxin-1 activity to the B cell compartment. In detail, we found that ataxin-1 controls specific genetic programs underlying B cell proliferation, activation, antigen presentation, and antibody secretion. In this light, conditional ablation of the ataxin-1 interactor capicua (CIC) in B cells was able to recapitulate the exacerbated EAE phenotype of ataxin-1 null mice. Altogether, our results pinpoint a previously undocumented key role of ataxin-1 in B cell biology as part of a novel homeostatic mechanism to control the aberrant immune response.

B712/P2379

Immunomodulatory effects of resolvin D2 in a 2-hit infection model

P. Kadiyam Sundarasivarao, J. Walker, A. Rodriguez, B. Spur, K. Yin; Rowan University, Stratford, NJ

Dysregulated hyperinflammatory host immune response to underlying bacterial infections can lead to sepsis. In sepsis, bacteria often trigger abnormal hyperinflammatory responses which can cause multiple organ failure and if sustained can lead to an immunosuppressive phase where the host is susceptible to secondary infections caused by opportunistic bacteria like *Pseudomonas aeruginosa* (*P. aeruginosa*). In our study, we used a 2-hit model of cecal ligation and puncture (CLP) followed by *P. aeruginosa* secondary lung infection to investigate cellular and molecular mechanism in the beneficial action of resolvin D2 (RvD2). Resolvins of the D-series are a group of Specialized Pro-resolving Mediators (SPMs) synthesized endogenously from docosahexaenoic acid (DHA) by different immune cells including neutrophils and macrophages during infection and inflammation. In CLP sepsis, we observed that production of RvD2 in spleens had returned to basal levels by 48 hours after CLP surgery. Administering RvD2 (100 ng/mouse, i.v.) in CLP mice at this time point where endogenous RvD2 synthesis is low enabled CLP mice to clear blood bacteria more efficiently at 24 hours after administration compared to saline controls. There was no significant difference in plasma cytokine production. To further understand cellular and molecular mechanisms, we used flow cytometry to identify different immune cells in spleen and found that RvD2 treatment increased splenic neutrophils ($Ly6G^+$) and myeloid-derived suppressor cells (MDSCs: $CD11b^+Ly6G^+Ly6C^+$) compared to vehicle treated mice. RvD2 treatment increased oxidative burst in splenic neutrophils but not in splenic MDSCs compared to vehicle treated mice. These results provide evidence that RvD2 can expand splenic neutrophil and MDSC numbers to effect greater blood bacterial clearance even when given 48 hours after primary infection. When mice were challenged with *P. aeruginosa* (intranasally; 24 h after RvD2 treatment) we found RvD2 increased bacterial clearance in lungs, increases alveolar macrophage numbers and reduced IL-23. These results suggest that late RvD2 administration boosted host defense to reduce infection and inflammation. This study provides insight into immunomodulatory effects of RvD2 in a 2-hit infection model of sepsis.

B713/P2380

ACE and ACE-2 as potential biomarkers in multiple sclerosis

M. S. Al-Keilani[1], H. M. Abdelrazeq[2], S. Jaradat[2]; [1]Clinical pharmacy, Jordan University of Science and Technology, Irbid, JORDAN, [2]Genetics and biotechnology, Jordan University of Science and Technology, Irbid, JORDAN.

Background: Multiple sclerosis (MS), one of the common diseases in the Eastern Mediterranean region, is a chronic autoimmune neurodegenerative disease characterized by demyelination in the centralnervous system (CNS). It is thought to result from a complex interaction between multiplepredisposing genes; the majority of them are related to the immune function in addition to severalenvironmental factors. However, the exact etiology remains a mystery yet.Due to the genetic differences between individuals, MS patients show great heterogeneity in termsof clinical expression, histopathological and radiological changes, and response to therapy. Thisemphasizes the urgent need for the identification of novel biomarkers to allow the earlierdiagnosis, better prediction of disease severity and progression, as well as to allow personalizationof therapy in complement with MRI and clinical markers of MS.Renin-Angiotensin System (RAS) has a pivotal role in autoimmune inflammation in the CNS.Angiotensin-converting enzyme (ACE) and its homolog ACE-2 are considered two of the major enzymes in the RAS system. The results of the previous studies showed that there are differences between MS patients and healthy individuals in terms of gene and protein expression levels of these enzymes.In the current study, we aimed to measure protein levels of ACE and ACE2 in the serum obtained from MS patients and healthy controls, and to find significant associations with demographics and clinical characteristics of patients.**Methods**: This was a case-control study that was carried out on 74 MS patients and 73 age and sex matched healthy controls. Serum levels of the target markers was measured using human enzyme-linked immunosorbent assay (ELISA) technique.**Results**: Median serum ACE and ACE-2 levels were significantly higher in MS patients (206.66 pg/ml and 2026.21 pg/ml, respectively) compared to healthy controls (142.04 pg/ml and 938.30 pg/ml, respectively) (p-value<0.001). Cut-off values of 170 pg/ml for ACE and 1395 pg/ml for ACE2 were found to discriminate MS patients from healthy controls (sensitivity = 68.9% and 89.2%, and specificity = 61.6% and 83.6%, respectively). Significant correlations were revealed between serum ACE level and EDSS level (p-value=0.028), and MS disease duration (p-value=0.001).**Conclusion**: Serum ACE and ACE-2 can be potential diagnostic biomarkers for MS, and serum ACE level may predict disease severity in MS patients.

Is Green Tea All It Is Brewed Up To Be? Our Results Suggest It May Not Be.

A. Mattern, C. Azar, J. B. Slee; Biology, DeSales University, Center Valley, PA.

Inflammation underlies multiple disorders such as cardiovascular disease, diabetes mellitus, and cancer. Naturally occurring compounds have historically been investigated for potential medicinal benefit. Published literature indicates that Epigallocatechin gallate (EGCG), derived from green tea leaves, has antioxidant, anti-inflammatory, anti-cancer, and anti-microbial properties. Through multiple experiments, we determined that EGCG is strongly proinflammatory at 10 µM and cytotoxic at 50 µM, concentrations utilized in multiple published reports, in both vascular endothelial cells and monocyte-derived macrophages. Furthermore, EGCG suppressed wound healing in vascular endothelial cells at both 10 µM and 50 µM. 1 µM EGCG treatment appeared to have no effect on vascular endothelial cells

or monocyte-derived macrophages when treated for less than 3 days. 1 µM, 10 µM, and 50 µM EGCG were assessed for the ability to promote the biocompatibility of polymers using a THP-1 cell adhesion assay and a Chandler Loop *ex vivo* model of blood perfusion using whole equine blood. No significant decrease in the number of adhered cells were seen in either assay, suggesting that EGCG does not promote the biocompatibility of commonly used polymers in medical devices. Taken together, our results indicate that EGCG is proinflammatory and not suitable as a therapy to promote biocompatibility.

B715/P2382

Investigation of inflammation-mediated secondary organ damage as a consequence of mast cell tumor degranulation.

R. M. Edwards, S. L. McNally, J. Fellmeth; Biology, Millersville University, Millersville, PA.

Benign mast cell tumors (MCTs) are rare in humans, but relatively common in dogs. Under typical circumstances, mast cells release proinflammatory components as part of an antigen-mediated immune response, which is normal and crucial to survival. During tumorigenesis, however, there is the potential to cause secondary damage through the excess release of pro-inflammatory components, a process referred to as mass degranulation. As of current, correlations have been found suggesting that there is a functional link between the existence of the benign MCT and inflammatory diseases, like chronic renal failure. We propose that during episodes of mass degranulation, these tumors secrete specific cytokines and instigate a cascade of intercellular signals, which result in immune-mediated organ dysfunction. One such cytokine, tumor necrosis factor (TNF-α), has been found to mediate this type of damage through Th1 T-cells. We expect to reiterate similar findings within mast cells and aim to expand current knowledge of mast cell involvement in secondary organ damage, with an emphasis on renal damage. To test this hypothesis, we collected canine MCT samples with paired healthy tissue from local veterinary offices. qRT-PCR was performed to probe for specific cytokines, proteases, and interleukins, all having been found to participate in inflammatory cascades. By comparison to healthy control tissue, we expect to see a notable increase in expression of these components across specimens. To identify specific cellular populations containing these factors, it is our hope to further probe our samples via immunohistochemistry. In its essence, this research has the potential to provide the veterinary medical community with further insight into secondary immune-mediated organ damage.

B716/P2383

Adaptive immune receptor repertoire profiling for biomarker discovery

A. Chenchik[1], M. Makhanov[1], T. Liu[1], D. Hu[1], **K. Ghias**[1], P. Diehl[2], L. Kobzik[1]; [1]Cellecta, Inc., MOUNTAIN VIEW, CA, [2]Cellecta, Inc., Mountain View, CA.

Adaptive Immune Receptor (AIR) Repertoire profiling and characterization of antigen-activated immune cells is essential for the discovery of novel prognostic and predictive biomarkers and for studying immune response mechanisms in cancer, auto-immune and other diseases.To facilitate these studies, we developed a novel technology for combined, unbiased profiling of all human TCR and BCR variable regions; and phenotypic characterization of immune cells in bulk, sorted fraction, and single immune cells. This method involves multiplex RT-PCR amplification and sequencing of CDR3 regions of TCR and BCR genes along with immunophenotyping with a set 500 highly expressed T- and B-cell subtyping and activation marker genes. Bioinformatic analysis of NGS data allows comprehensive AIR repertoire profiling, identification of antigen-activated TCR and BCR clonotypes, and detailed phenotypic

characterization of T and B cells induced by adaptive immune responses. Preliminary phenotypic AIR profiling studies in metastatic tumor samples and Humira®-treated rheumatoid arthritis blood samples indicate that AIR immunophenotyping technology has unparalleled throughput and sensitivity for the discovery of immunity biomarkers.

B717/P2384

Identifying Novel Intracellular Pathogen Response (IPR) triggers by intestinal wounding in C. elegans

A. Alvarado, S. Snipes, J. N. Sowa; Biology, West Chester University of Pennsylv, West Chester, PA.

The development and maintenance of immune responses to various stressors are crucial to organismal survival. Due to their simplicity, *Caenorhabditis elegans* serve as useful model organisms to study host-pathogen interactions since they rely on innate immunity, eliminating the complexity associated with adaptive immune responses. The Intracellular Pathogen Response (IPR) is an immune response that serves as a defense mechanism in *C. elegans* against stress and pathogens. Localized to the intestinal epithelial tissue of the organism, the IPR is triggered in response to invasion from viral pathogens in an attempt to eliminate the threat. Currently, viral infection, proteasome stress, and heat stress are known triggers of the IPR. Preliminary evidence from our lab has shown that intestinal wounding via feeding *C. elegans* sulfate-based detergents or ethanol triggers IPR gene upregulation. As a result, we hypothesize that intestinal wounding may be a separate branch of the IPR activation pathway. However, what induces and characterizes this pathway is currently not known. To determine those factors, we pursued an ethanol-based treatment that showed promise for high-throughput IPR activation. To quantify the level of activation, we use a nanoluciferase dual reporter assay to measure expression of nanoluciferase, which is expressed from the *pals-5p* IPR promoter. In addition, our transgenic strains contain an internal control of firefly luciferase expressed from the *sur-5* promoter. Through our analysis, we hope to identify a novel intestinal wounding method that causes IPR induction and can be applied in a high-throughput manner to facilitate genome-wide screening.

B718/P2385

Improving Bacteriophage Compatibility with the Mammalian Immune System for Therapeutic Applications

C. Carmody, S. Nugen; Cornell University, Ithaca, NY.

The World Health Organization has deemed antimicrobial resistance a global crisis. Bacteriophages (phages) are viruses that infect bacteria hosts and kill them upon completion of their lytic replication cycle. Phages are highly abundant, do not show viral tropism for mammalian cells, and are continuously evolving alongside their bacteria hosts, offering a sustainable long-term option for pathogenic bacteria mitigation. A limitation to phage therapy is the strong mammalian immune response elicited by phages resulting in their rapid clearance from the body by immune cells. Immune system clearance relies on recognition and adherence to structural features of substances, influenced by their size, shape, hydrophobicity, and surface charge. For phages, the capsid is a key structural feature in determining bloodstream half-life with certain capsid proteins allowing for increased interactions with immune cells and proteins. To overcome this issue my hypothesis for this study is, phage capsid modifications to reduce interactions with mammalian immune cells and proteins will decrease strong immune response and rapid clearance of phage. This will be assessed via two objectives. (1) Creating a phage with a synthetic polymer, polyethylene glycol, shielding the capsid. (2) Creating a phage capable of selectively

binding a native mammalian protein, albumin, to camouflage the capsid. My approach is to utilize CRISPR/Cas9 for phage genome editing to translationally fuse affinity peptide genes to capsid genes, allowing for site-specific binding of PEG or albumin. Immune response to modified phages will be evaluated in mouse model. The overall goal of this study is to develop broadly applicable, site-specific phage capsid modifications that increase phages' therapeutic potential. Results to date include successful design and screening of CIRSPR/Cas9 gRNA that cleave the targeted gene, sanger sequencing confirmed donor DNA plasmids for creating modified phages, whole genome sequencing confirmed modified phage genome, approval of the mouse study experimental plan, and optimization of PEG length for lowest modified phage infectivity reduction (30kDa). Based on previous studies in the literature utilizing PEG and albumin to modify virus capsids of similar size and structure, we predict our modified phages to result in increased bloodstream half-life and decreased immune response compared to wild type.

B719/P2386

Deciphering the underlying dynamics of cells and gene expression during injury-induced skin inflammation using unannotated single-cell data

R. Chatterjee, A. Rahnavard, B. Shook; The George Washington University, Washington, DC.

In response to damage, tissues must undergo a complex series of cellular responses that promote inflammation and subsequent repair to restore tissue function. In particular, efficient skin wound healing requires the communication of numerous tissue resident cells with infiltrating immune cells. While recent studies have identified cellular communication that supports later reparative processes, little is known about mechanisms that promote and resolve early inflammatory processes. Given that manipulating early inflammatory events can impact progression through the healing process, there is a great need to understand the cellular communication networks and their relationships dictating the recovery process. The recent development of single-cell RNA-sequencing has provided the power to extract transcriptomic, spatial, and lineage information for each individual cell and affords a unique opportunity to study the interactions occurring during skin wound healing. In this study, we elucidate the precise cell populations and their early changes in gene expression caused by injury to the skin using non-injured tissue as a comparator. We developed a pipeline "cellSight", which utilizes standard tools for targeted clustering based on marker genes, and integration and analysis of cells from both uninjured and injured skin samples for differentially expressed genes across both conditions. The pipeline also utilizes differential effect size calculation using Tweedie models, infers cell to cell communication occurring during early inflammation, and identifies key genes marking biological changes due to injury.

The role of *N*-acetyl aspartate in inflammation

M. Nassef, K. Hiller; TU - Braunschweig, Braunschweig, GERMANY.

N-acetylaspartate (NAA) is an amino acid derivative synthesized from aspartic acid and acetyl-coA by the enzyme *N*-acetyltransferase 8-like protein (NAT8L). NAA is highly abundant in the brain and it is a major transport and storage form of acetyl-coA. Moreover, it plays a role outside the CNS in brown adipose tissue and in cancer cells. Similar to the CNS, NAA was found to be a storage and transport form of acetate. Moreover, NAA might be providing an alternative pathway of lipogenesis in adipocytes. Apart from adipose tissue and cancer cells, NAA might be also playing a role in macrophages. To investigate

the function and the role of NAA in macrophages, RAW 264.7 cells were virally transduced with lentivirus containing the *NAT8L* overexpression plasmid. After successfully transducing the cells and the selection procedure, it was possible to detect the increased NAA production on metabolic level through gas chromatography - mass spectrometry (GCMS) analysis. Moreover, the mRNA levels of *NAT8L* showed to be highly upregulated. To have a proper control for the *NAT8L* overexpression cell line, further RAW 264.7 cells were virally transduced with lentivirus containing the β-galactosidase gene (*LacZ*) plasmid. After further investigation of the RAW 264.7 *NAT8L* overexpression cell line, the high levels of NAA showed to affect metabolism of the cells in various ways. Furthermore, experiments with labeled [U-13C]-glucose and [U-13C]-glutamine showed high relative abundance of labelled carbons in NAA. This proves that the cells use glucose and glutamine as carbon sources to provide for the production of acetyl-coA and aspartic acid needed for the synthesis of NAA. To sum up, NAA seems to be involved with immunometabolism and mounting the inflammatory response. Further research is needed to have a better understanding of the function of NAA in immunity.

Phenotypic Evaluation of TREX1 Null Mice as a Model for Lupus-like Autoimmune Disease

J. Ling[1], Z. Chen[1], S. Xu[1], **Z. Li**[2], H. Tong[3], A. Zong[3], C. Ju[2], J. Zhao[3], X. Gao[3]; [1]GemPharmatech Co. Ltd., Nanjing, CHINA, [2]GemPharmatech, Wilmington, DE, [3]GemPharmatech, Nanjing, CHINA.

TREX1 (DNase III) is the major 3'-5' DNA exonuclease of mammalian cells. It has been proposed to have a major role in cell death and genomic DNA degradation. It has been suggested that dysfunction of Trex1 may activate immune response by self DNA as suggested by the TREX1 null mice which develop an inflammatory myocarditis similar to autoimmune cardiomyopathy and produce type 1 IFN. Moreover, TREX1 D18N mutation causes a monogenic, cutaneous form of lupus called familial chilblain lupus, and the TREX1 D18N enzyme exhibits dysfunctioned dsDNA-degrading activity, providing a link between dsDNA degradation and nucleic acid-mediated autoimmune disease. Here we generated the $Trex1^{-/-}$ mice and performed comprehensive phenotyping to evaluation the loss of function of TREX1 and its potential application in SLE study.

$Trex^{-/-}$ null mice were generated by knocking out the coding sequence in exon 2. There was a dramatically increased morbidity of both female and male Trex1 null mice post weaning. Serum ALT, AST and LDH levels were dramatically increased in both male and female $Trex^{-/-}$ mice compared with wild type and $TREX^{+/-}$ mice at 6 weeks of age, indicating injuries of liver and heart. Pathohistological analysis showed inflammatory cell infiltration in liver, heart, spleen, kidney, lung and skin. Interestingly, the level of ALT, AST and LDH gradually deceased from 8 weeks to 10 weeks of age. Since Trex1 is the major DNA exonuclease, we hypothesized that dsDNA was the antigen that caused the organ injury. We found that serum total anti-dsDNA antibody levels were significantly increased in $TREX^{-/-}$ male and female mice compared with wildtype and heterozygous mice, which was kept high from 7 to 13 weeks of age. Protein to creatinine ratio measured in the urine showed no difference between $Trex^{-/-}$ and wildtype mice.

In conclusion, the $Trex^{-/-}$ null mice we generated in this work showed lupus-like inflammatory autoimmune response with increased anti-dsDNA levels and inflammation in multiple organs, providing a useful tool to study TREX1-mediated autoimmunity and to evaluate potential treatments for lupus.

Anti-inflammatory effect of CSS extract in RAW264.7 cells

J. SHIM; Semyung Univ., Jecheon, KOREA, REPUBLIC OF.

This research was designed to evaluate the possible anti-inflammatory effects of CSS extract on the skin using RAW 264.7 cells. The assessments of these effects were based on cell viability assay, mRNA expression levels of interleukin-1 alpha (IL-1α), interleukin-1 beta (IL-1β), IL-6, tumor necrosis factor alpha (TNFα), and levels of nitric oxide (NO)/prostaglandin E2 (PGE2) production. Quantitative real-time polymerase chain reaction showed that treatment with CSS extract decreased the mRNA levels of iNOS, COX2, IL-1α, IL-1β, IL-6, and TNFα. Furthermore, from the production levels of PGE2/NO, it can be inferred that CSS extract exhibited anti-inflammatory properties. These results suggest that CSS extract contains anti-inflammatory compound(s). Consequently, the extract may be a potent cosmeceutical material for anti-inflammatory effects against atopic dermatitis. Taken together, further studies on the anti-inflammatory mechanisms of CSS extract would not only facilitate the development of cosmeceutical but also engender pharmacological treatments.

Macrophages phase separate and cooperate to phagocytose cohesive cellular targets

L. J. Dooling, J. C. Andrechak, B. H. Hayes, S. Kadu, D. E. Discher; University of Pennsylvania, Philadelphia, PA.

Macrophages are abundant in many solid tumors and are potential effector cells for monoclonal antibody-based immunotherapies because they could phagocytose IgG-opsonized cancer cells. However, it remains unknown whether phagocytic macrophages can overcome the cohesive forces among phagocytic targets in solid tumors. We show that maximum phagocytosis of B16 melanoma cells cultured as cohesive ‘tumoroids’ requires IgG opsonization and knockout of the macrophage checkpoint ligand CD47. Under these conditions, phagocytic macrophages cluster or ‘phase separate’ and eliminate B16 cells with kinetics that indicate cooperativity with respect to macrophage number (i.e. Hill exponent $|n| > 1$). Experiments using chelating agents to disrupt phagocytic macrophage clusters specifically implicate Mg^{2+}, which forms part of the ligand binding site of macrophage integrins. Cytokine treatments and myosin-II inhibition further indicate roles for integrins and phagocytic surface receptors as well as the actomyosin cytoskeleton in macrophage clustering that can impact tumoroid phagocytosis. Although tumor-associated macrophages correlate with negative prognoses in many cancers, our findings are the first to reveal the advantage of high macrophage numbers, macrophage clusters, and resulting cooperative effects when combined with opsonizing antibodies and CD47 blockade.

B724/P2391

Phagocytosis-dependent activation of macrophage Nrf2 curbs intracellular ROS levels to strengthen the inflammatory response.

G. Clemente, H. Weavers; University of Bristol, Bristol, UNITED KINGDOM.

The production of reactive oxygen species (ROS) during the ‘respiratory burst’ is an effective weapon exploited by leukocytes to neutralize dangerous pathogens and degrade cellular debris. Nevertheless, because of their exceptionally reactive nature, ROS could induce indiscriminate bystander damage,

causing a progressive deterioration of cellular functions. Therefore, to sustain full functionality under these hostile conditions, immune cells must orchestrate a complex and robust self-protection network. This program allows leukocytes to mitigate the undesirable side-effects of the constant oxidative challenge while allowing low levels of ROS for crucial cellular signalling. Here, we investigate the molecular nature of these self-protective strategies, exploring *in vivo* their precise mechanism of activation and physiological relevance. We show that, in *Drosophila* macrophages, a conserved Calcium-PI3K-NOX axis drives the release of ROS downstream of corpse uptake and consequent activation of the redox-sensitive transcription factor Nrf2. By performing RNAi experiments, we find that the Nrf2-mediated antioxidant response is vital to promote *Drosophila* macrophage tolerance to oxidative stress during normal homeostatic behaviour, preserving efficient basal motility and allowing a robust and timely detection of epithelial wounds. Moreover, we find that, by reducing the oxidative burden, macrophage Nrf2 crucially restrains the accumulation of dangerous oxidative damage and delays the onset of immune senescence. Finally, we propose that, by preserving a healthy immune system, leukocyte Nrf2 might exert important paracrine effects by delaying premature systemic aging and improving organismal lifespan. We suggest that future therapeutic interventions aimed at boosting immune self-protection may be beneficial to delay immune aging and alleviate correlated morbidities.

HIV-1 p55 Gag Immunization mediated via Imiquimod by adjuvant effects on dendritic cells

A. De Freitas-Suarez[1], J. Roldan-Kalil[2], S. Vendrell-Gonzalez[1], F. Reyes-Ortiz[1], G. Jimenez-Jordan[1], J. Alves[1], M. Inyushin[1]; [1]University of Central Del Caribe, Bayamon, PR, [2]University of Puerto Rico Medical Sciences Campus, San Juan, PR

The ravaging HIV pandemic has been claiming lives since the 1980's. This incurable disease has long been a threat due to danger it poses to the immunological system. A key to halting this threat may lie in developing an effective HIV vaccine. A difficulty for developing an effective HIV vaccine results in the ability of the virus to suppress the specific immunity, rendering it ineffective if the response is slow. The most notable expected benefit of an effective HIV vaccine resides in the ability to prevent acute infection by rapidly diminishing the viral load. This project takes on a different scope for developing such vaccine by targeting dendritic cells (DC). The purpose of our work is to pre-activate in-vivo dendritic cells before HIV vaccinations using certain adjuvants that interact with DC's in order to achieve rapid enhancement of immune response. These DC's play a crucial role in maintaining T cell (TC) immunity. DC's are antigen presenting cells that can alter TC's by activating them (or attenuating during hyperimmunization). For this reason DC's have been gathering interest for additional vaccination intentions. DC's contain G-protein coupled Toll-like receptors (TLR7) which have specific agonist, Imiquimod. Thus, Imiquimod is an imidazoquinoline amine with properties capable of modifying immune response. To carry out the procedure in-vivo models used were 4-6 week old *BALB/c* mice. DNA plasmids were constructed resulting in our p55-Gag-HIV plasmid. Imiquimod was employed as an adjuvant in ranging concentrations of 25, 50 and 100nM to properly observe the effect of DC stimulation on the effectiveness of an HIV-1 p55 Gag DNA vaccine in-vivo. Subsequently a cell culture was performed in order to quantify the p55 protein production after the immunization via Western blot analysis. To understand the immune response of TC's an ELIspot assay and ELISA were performed to measure the frequency and production of IFN-γ -secreting cells, IFN-γ and IL-4. Our results show that the adjuvant effects of Imiquimod rely on concentration. We observed that low concentrations of Imiquimod were found to effectively stimulate Gag production by up to 25% as well as the magnitude of

T-cells response, whereas higher concentrations reduced vaccination effects up to 55%.

Assessment of Anti-SARS-CoV-2 Spike RBD Antibody Responses Using a Multiplexed Serological Assay and Advanced Flow Cytometry

M. Carter[1], J. Lovchik[1], A. Munitz[2], M. Gerlic[2]; [1]Sartorius BioAnalytical Instruments, Inc., Albuquerque, NM, [2]Tel Aviv University, Tel Aviv, Israel

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the causative agent of COVID-19, continues to be a global public health threat. SARS-CoV-2 initiates entry into target cells through the interaction of the receptor binding domain (RBD) of its envelope Spike protein with the angiotensin-converting enzyme 2 (ACE2) on human cells. Antibodies directed against the RBD of the SARS-CoV-2 Spike protein demonstrate potent neutralizing activity by blocking virus interaction and entry into host cells. Several isotypes (IgM, IgG and IgA) of these neutralizing antibodies have been identified. In this study, we examined the anti-Spike RBD antibody isotype profiles induced in COVID-19 patients and individuals vaccinated with COVID-19 mRNA vaccines. In order to quickly assess the levels of all three major isotypes of anti-Spike RBD antibodies, we utilized the iQue® SARS-CoV-2 kit which provides a rapid, robust, and sensitive flow cytometry assay for the simultaneous measurement of IgG, IgM and IgA anti-Spike RBD antibodies in a single sample of human blood (serum or plasma) in either a 96 or 384-well plate format. The results revealed the heterogeneity of anti-Spike RBD antibody responses induced in both COVID-19 patients and vaccine recipients. In COVID-19 patients, the levels of all three isotypes of anti-Spike RBD antibodies generally increased as the disease progressed, with some individuals producing very high levels of IgA anti-Spike RBD antibodies. IgM and IgA anti-Spike RBD antibody levels then started to decline after 56 days-post symptom onset (DPS), while IgG levels remained relatively stable out to 84 DPS. Variable levels of IgG, IgM and IgA anti-Spike RBD antibodies were also observed in response to vaccination with the Moderna (Spikevax) or Pfizer-BioNTech (Comirnaty) mRNA COVID-19 vaccines. Notably, accurate detection of seroconversion in both COVID-19 patients and vaccine recipients was found to depend on analysis of multiple isotypes since not all isotypes were present in every individual. Overall, this study shows the importance of measuring the quantity and kinetics of all three major isotypes of anti-Spike RBD antibodies to accurately assess the antibody response against SARS-CoV-2 in COVID-19 patients, as well as to evaluate the induction and duration of the anti-Spike RBD antibody response in vaccinated individuals.

High-carbohydrate diet impacts hepatic IL1beta expression in rainbow trout

A. Vasil'eva[1,2], S. Matrosova[2], E. Borvinskjaya[3], **I. Sukhovskaya**[1,2]; [1]Institute of Biology of Karelia Research Centre of RAS, Petrozavodsk, Russian Federation, [2]Petrozavodsk State University, Petrozavodsk, Russian Federation, [3]Irkutsk State University, Irkutsk, Russian Federation

Cytokines arethe polypeptide mediators involved in regulation of immune defense responses through binding specific cellular receptor complexesin vertebrates. Interleukin-1β (IL1β), a key pro-inflammatory

cytokine, is produced by many cell types including hepatic Kupffer cells. To assess the effect of the feed composition on the artificial rearingtrout, the juvenile rainbow trout (average weight 70-76 g) were fed either a balanced diet (control group) or a diet enriched with carbohydrates (experimental group) during54 days; both rationswere ofthe same energy value. The IL1βtranscripts werequantifiedby RT-PCR technique withelongation factor and β-actin as reference genes. Being acarnivorespecies, trout prefers a high-protein diet, and experimental high-carbohydrate feedingwas expected to induce inflammation at the morphological and molecular levels. We observed morpho-pathological changes in 65% of high-carbohydrate fed fish, including surfaceerosions, liverdiscoloration and petechia, and posterior intestineinflammation. Despite well-documentedIL1βvalue asindicator of inflammation inhumans, our study showed no significant differences in the hepatic IL1β expressionbetween the trout with or without ichthyopathological signs of inflammation. We can assume both low inflammatory response to non-infectious alimentary agentand low sensitivity of IL1βas inflammatory markerin fish.Consideringtissue-specific cell signaling pathwaysof cytokineexpression,other tissues may be more responsive to carbohydrate-induced enteritis. The interdisciplinary research in the partnership with Irkutsk State Universitywas supported bythe Russian Science Foundationgrant No. 20-66-47012.

Skin fibroblast subsets contribute to injury-induced inflammation through spatiotemporal changes in pro- and anti-inflammatory gene expression.

V. Balick, B. Shook; The George Washington University, Washington, DC

Skin wound healing requires an initial phase of myeloid cell recruitment and inflammation, which must subsequently resolve for the tissue to transition to a reparative state. Pro-inflammatory signals are known to arise from epithelial and immune cells; however, the contribution of mesenchymal cells to injury-induced inflammation remains under-studied in acute wound healing. Since fibroblasts contribute to acute inflammation in other tissues and chronic inflammatory skin diseases, we hypothesized that dermal fibroblasts support acute inflammation after skin injury. To identify fibroblast-derived factors which could mediate this effect, we characterized fibroblast gene expression with RT-qPCR and RNA sequencing in a murine skin wound model at multiple time points throughout acute inflammation. Dermal fibroblasts acquired a pro-inflammatory gene expression profile at time points representing early and peak inflammation, upregulating cytokines and chemokines known to contribute to an inflammatory environment and immune cell recruitment. These factors influence the quantity of the immune cells in the tissue, as fibroblast-specific deletion of the chemokine *Ccl2* significantly reduced the number of monocytes and macrophages present in wounds at the peak of inflammation. As inflammation resolved, the fibroblast gene expression profile changed to reflect the tissue's shift to an anti-inflammatory, pro-remodeling environment. At this late inflammation time point, fibroblasts expressed secreted factors associated with extracellular matrix formation and the dampening of immune responses. To complement our gene expression analysis, we performed RNA fluorescence *in situ* hybridization to spatially map fibroblast inflammatory gene expression at the wound periphery throughout tissue inflammation. We identified distinct patterns of spatial bias for numerous cytokines, chemokines, and tissue remodeling enzymes. Since fibroblast subsets can be defined based on their location in the skin, these biases suggest that distinct fibroblast populations contribute to the inflammatory environment, cell recruitment, and tissue organization after injury. Overall, these results convey that dynamic changes in gene expression allow multiple populations of skin-resident fibroblasts to actively participate in the induction and resolution of inflammation during wound healing.

CRISPR-Cas9 Whole-Genome Screens Identify Genes Critical for Neutral Lipid Metabolism in Bone-Marrow Derived Macrophages and Highlights mTOR Regulating Genes as Mediators of Lipid Droplet Degradation

K. Wanniarachchi; South Dakota State University, Brookings, SD

Atherosclerosis-related heart diseases are the leading causes of death in the United States and worldwide. Atherosclerosis is primarily caused by the over-accumulation of modified low-density lipoprotein (LDL) cholesterol within artery walls. Macrophages serve as critical contributors to atherosclerotic plaque formation. Macrophages internalize modified LDL-cholesterol within the artery walls and store neutral lipids in lipid droplet organelles. While macrophages efficiently degrade lipid droplets and efflux free cholesterol in healthy circumstances, these processes become pathological in the disease condition. However, the molecular mechanisms of neutral lipid uptake, storage, lipid droplet degradation and cholesterol efflux are not clearly understood in macrophages. Here, we report CRISPR/Cas9 whole-genome screens results to identify critical genes for neutral lipid metabolism in macrophages using a combination of fluorescence-activated cell sorting (FACS) and next-generation sequencing methods. We identified hits and ranked them using model-based analysis of genome-wide CRISPR/Cas9 knockout (MAGeCK). Using gene set enrichment analysis (GSEA), we identified mTOR signaling and autophagy as key pathways in neutral lipid metabolism. We validated screen hits and successfully recapitulated screen phenotype using a targeted CRISPR/Cas9 gene disruption of screen hits. Identified hits might regulate cellular processes such as neutral lipid or cholesterol accumulation, lipid droplet degradation, or cholesterol efflux. Our screens identified mTOR-regulating genes including *Rraga, Rragc, Flcn*, and *Lamtor4* as positive regulators of lipid droplet degradation. To investigate the role of these genes, we disrupted them with CRISPR/Cas9 and studied proteins of the mTOR and autophagy pathway. Currently, there is limited understanding about the role of mTOR regulation of lipid droplet degradation in macrophages. In this study, we interrogate how genes regulating mTOR activity mediate lipid droplet degradation in macrophages. We observed that macrophages have high mTOR activity in the absence of *Rraga, Rragc, Flcn,* and *Lamtor4*, thus leading to defective autophagy and persistent lipid droplets. Specifically, we observed increased p62 accumulation in these cells, indicating reduced autophagy flux. Interestingly, mTOR inhibition with rapamycin restored normal p62 levels and lipid droplet degradation in macrophages. This study demonstrates that *Rraga, Rragc, Flcn,* and *Lamtor4* regulate lipid droplet degradation via an autophagic process that is inhibited by mTor activity. Overall, this work can help expand our current mechanistic understanding of cholesterol metabolism and lipid droplet dynamics in macrophages.

The Link Between Altered Secondary Hemoglobin Structure and Augmented Hypoxia-Induced ATP Release from Erythrocytes in ApoE/LDLR Double-Deficient Mice

F. C. Alcicek[1], J. Dybas[1], A. Blat[1,2], K. Bulat[1,3], T. Mohaissen[1,4], D. Y. Dogan[5], I. Hornung[5], W. Rutkowska[1,2], A. U. Steinbicker[5], K. M. Marzec[1,6]; [1]Jagiellonian Centre for Experimental Therapeutics, Jagiellonian University, Krakow, POLAND, [2]Faculty of Chemistry, Jagiellonian University, Krakow, POLAND, [3]Łukasiewicz Research Network - Krakow Institute of Technology, Krakow, POLAND, [4]Faculty of Pharmacy, Jagiellonian University Medical College, Krakow, POLAND, [5]Department of Anesthesiology, Intensive Care Medicine and Pain Therapy, University Hospital Frankfurt, Goethe University, Frankfurt am Main, GERMANY, [6]Łukasiewicz Research Network, Krakow Institute of Technology, Krakow, POLAND.

Red blood cells (RBCs) play a role in the regulation of vascular tone via release of adenosine triphosphate (ATP) into the vasculature. ATP release occurs in response to various stimuli including lower oxygen tension and causes vasodilation and increased blood flow. Interestingly, ApoE/LDLR double deficient (ApoE/LDLR$^{-/-}$) mice, a murine model of atherosclerosis, display higher exercise capacity compared to age-matched controls. However, it is not known whether increased exercise capacity in ApoE/LDLR$^{-/-}$ mice is linked to altered ATP release from RBCs. Therefore, we characterized the ATP release feature of RBCs by exposing them to 3V cocktail (contains 10 µM isoproterenol, 30 µM forskolin, and 100 µM papaverine) and hypoxia in female and male 8- and 24-week-old ApoE/LDLR$^{-/-}$ mice compared to their age-matched controls (N=4-13). Also, alterations in secondary structure of hemoglobin (Hb) and 2,3-diphosphoglycerate (2,3-DPG) levels in RBCs were measured. In addition, we analyzed the expression of pannexin 1 (PANX1) protein on RBC membranes as a conduit for ATP release. The results indicate notable changes in the secondary structure of Hb and higher 2,3-DPG levels in RBCs from ApoE/LDLR$^{-/-}$ mice compared to their age-matched controls. This may suggest that alterations in Hb structure in ApoE/LDLR$^{-/-}$ mice are irreversible. 3V-induced ATP release from RBCs occurred at comparable levels for all groups, which indicates the activity of adenylyl cyclase and the components of upstream signal-transduction pathway are intact. Moreover, hypoxia-induced ATP release from RBCs was higher in ApoE/LDLR$^{-/-}$ mice compared to their age-matched controls, a potential contributing factor and a finding in line with the higher exercise capacity. Taken together, augmented hypoxia-induced ATP release from RBCs in ApoE/LDLR$^{-/-}$ mice indicates a possible altered component in the ATP release pathway. Previously, the role of confirmational change of Hb in hypoxia-induced ATP release from RBCs had been reported. We speculate that the altered Hb structure, or another component related, could lead to the exhibited results in ApoE/LDLR$^{-/-}$ mice. Additionally, the expression of PANX1 protein confirmed its function as the conduit for ATP release. Further studies to characterize the altered components of the ATP release mechanism in ApoE/LDLR$^{-/-}$ could lead to pharmacological modification of pathologically impaired microcirculation. **Acknowledgments:** This research was funded by the Polish National Science Centre, No. UMO- 2020/38/E/ST4/00197.

M6A Epitranscriptome Mediated RNA Stress Gradule Assembly Governs Blood Development and Regeneration

R. Gunage; Boston children's hospital, Boston, MA

Hematopoietic stem cell (HSC) form diverse cell types and requires transcription and translation regulation. Using CD34+ human hematopoietic stem and progenitor cells combined with N6-methyladenosine (m6A) seq we identified a novel, stress granule regulation during erythropoiesis. Transcriptome-wide single-nucleotide resolution m6A analysis identified ~4800 transcripts to be m6A modified and showed demethylation (>2-14 fold) during erythropoiesis. Genome-wide CHIP-seq of CD34+ cell erythropoiesis with anti-Gata1 showed an enhancer enrichment at the Alkbh5 RNA demethylase gene. CD34+ cell Alk5 CRISPR Cas9 KO led to erythropoiesis failure validating Alk5 role in erythropoiesis. CD34+ Alk5 KO cells showed a failure of RNA m6A demethylation and we discovered stress granule (SGs) transcripts m6A levels to be upregulated (>2-4 fold, p=0.01). SGs are membrane-less organelles composed of various RNA-binding proteins. SGs form a hub in the cytoplasm, govern RNA metabolism and global proteome by translational regulation. We show ATXN2, G3BP1/2, Tia-1, and PABPC1 SGs transcripts are m6a modified at 3'UTR. K562 cell Alk5 KO erythropoiesis model led to massive m6A upregulation on ATXN2 3'UTR (>14 fold, p=0.001) and other SGs transcripts. Mass spectrometry of CD 34+ Alk5 KO cell proteome showed ATXN2 downregulation (>2 fold, -log P value2), confirming 3' UTR m6A mediated regulation. Alk5 KO led to the aggregation of SGs protein in the cytoplasm due to altered SG protein stoichiometry(>4-10 fold, p=0.001). Our Zebrafish Alk5 KO has defective blood development characterized by anemia, and increased myeloid and lymphoid lineages indicating early lineage bias. CD34+ ATXN2 KO cells with colony formation assay showed defects in erythroid and myeloid lineages. Super-resolution microscopy of CD34+ ATXN2 KO cells phenocopied the presence of disease-associated ALS (amyotrophic lateral sclerosis) stress granules with TDP-43, G3BP1/2, PABPC1, and Tia-1 enriched for m6A mRNAs. Next, the K562 Alk5 KO erythropoiesis model and ATXN2 lentiviral overexpression effectively resolved stress granules and rescued erythropoiesis. In summary, ATXN2 mRNA m6A regulates SG biology to affect HSC function, impacting blood development. SG- mediated regulation of HSC fate may highlight new therapeutic strategies for blood disorders.

B732/P2399

How does the red blood cell lose its nucleus: intrinsic and extrinsic factors regulating erythroid enucleation

L. M. Newton[1], C. B. Wölwer[1], K. Lim[1], E. D. Hawkins[2], P. O. Humbert[1]; [1]La Trobe University, Melbourne, Australia, [2]The Walter and Eliza Hall Institute, Melbourne, Australia

Red blood cells (RBCs) are produced rapidly in the bone-marrow of mammals, and undergo a series of cell divisions during development, culminating in the asymmetric separation of the future erythrocyte and its nucleus, in a process termed enucleation. Enucleation is the rate limiting step in the production of erythrocytes *in vitro* and our work aims to better understand enucleation to improve the production of RBCs for transfusion medicine. Our lab identified cyclin-dependent kinase-9 (CDK9) as a novel cell-intrinsic regulator of the enucleation process. To understand how CDK9 drives enucleation, I have utilised primary mouse models and human cell line models of erythroid differentiation to characterise the expression and localisation of CDK9 during erythroid differentiation and enucleation and have identified CDK9-associated proteins using mass spectrometry. Surprisingly, our data suggests a novel

role for CDK9 in enucleation independent of its usual role in RNA polymerase II-mediated transcription. In this talk, I will share how CDK9 localises to the future erythrocyte during enucleation and acts upstream of other enucleation regulators, including actin polymerisation and calcium signalling. To examine cell-extrinsic factors in enucleation, we have conducted studies to identify the enucleation "niche" for erythroblasts within the bone marrow. Enucleation is thought to occur in structures termed erythroblastic islands which consist of a central macrophage surrounded by developing erythroblasts. Importantly, it is unclear if or how these erythroblastic islands modulate enucleation, and how they respond to various disease states like anaemia. Here, we have used confocal microscopy in optically clear mouse bone marrow with erythroid and macrophage lineage transgenic fluorescent reporter mice to quantitate sites of enucleation and their proximity to vascular sinuses and bone marrow resident macrophages within the enucleation "niche" *in vivo*. This analysis has been complemented with live imaging of erythroblast enucleation *in vitro* by scanning-disc microscopy and *in vivo* using intravital imaging of mouse bone marrow. These studies provide novel insights into the dynamic nature and heterogeneity of erythroblastic islands and the intrinsic and extrinsic factors regulating erythroid enucleation.

Highly Multiplexed Tracking of Signaling Dynamics in Organoids Using Biosensor Barcoding

J. Yang, C. Chen, C. Huang, S. Wang, L. Wood, T. Larman, C. Huang; Pathology, Johns Hopkins Unive, Baltimore, MD.

To understand cellular processes at the molecular level, it is often necessary to monitor the temporal dynamics of multiple signaling, metabolic, and other molecular activities as well as their responses to perturbations. Genetically encoded fluorescent biosensors are powerful tools to track these activities in real time in live cells. However, the availability of spectral space limits the number of biosensors that can be simultaneously imaged. We recently overcame this problem by developing the "biosensor barcoding" method. In this method, a pair of barcoding proteins composed of spectrally separable fluorescent proteins targeted to distinct subcellular locations are used to label cells expressing different biosensors. Our method achieves simultaneous tracking of dozens of signaling activities in live cells, but it has only been tested in immortalized 2D cell lines, which do not preserve the 3D cell-cell interactions that govern various cell behaviors. In this regard, organoids derived from primary tissues or tumors recapitulate the 3D cell connections and are better models to address a range of questions such as development, tumor heterogeneity, drug screening, and tumor/microenvironment interactions. The biological and morphological features of organoids pose unique challenges when applying the methods and analysis pipeline developed in 2D cell lines. To extend biosensor barcoding to 3D organoids, the objectives are: 1) to establish a biosensor barcoding expression system in organoids; 2) to train deep learning models for efficient and accurate identification of barcoded organoids; and 3) to simultaneously image barcoded organoids expressing different biosensors. Using a set of lentiviral vectors, we successfully expressed barcoding proteins in two types of organoids with different morphologies: those derived from normal mouse intestinal epithelium and those derived from human pancreatic ductal adenocarcinoma. Images

of barcoded organoids revealed distinct subcellular localization of barcoding proteins that are used for optimizing deep learning models. Moreover, co-expression of barcoding proteins and biosensors in organoids showed robust spectral separation. In conclusion, our results demonstrate the feasibility of biosensor barcoding in organoids and pave the way for highly multiplexed imaging of the complex dynamics of molecular networks in cells interacting in a 3D environment.

High-dimensional morphology analysis enables identification and label-free enrichment of heterogeneous tumor cell populations

A. Jovic, K. Saini, T. Pham, C. Corona, J. Mei, M. Phelan, S. Boutet, K. B. Jacobs, J. Kim, C. Johnson, V. Lu, N. Li, M. Salek, M. Masaeli; Deepcell, Inc, Menlo Park, CA.

Studying cancer at single cell resolution is crucial in elucidating tumor heterogeneity and guiding targeted therapy options. However, current isolation of tumor cells from tissue typically relies on biomarkers, such as EpCAM, which miss EpCAM-negative but interesting populations. The Deepcell platform enables high-dimensional morphology analysis of unlabeled single cells using artificial intelligence (AI), advanced imaging, and microfluidics allowing for higher resolution of population heterogeneity beyond protein expression markers. We report application of the Deepcell platform by training a convolutional neural network classifier to identify and enrich for carcinoma cells from non-small cell lung cancer (NSCLC) dissociated tumor cell (DTC) samples based on morphology. The enriched NSCLC cells are label-free, unperturbed, and viable, making them amenable to diverse molecular and functional analyses. The cell images are used to generate high-dimensional morphological profiles that can be visualized by UMAP to uncover heterogeneity within cancer cell populations. Additionally, these morphological signatures can also be used to sort out subpopulations for further molecular and discovery work.

We verified enrichment of malignant cells by performing genomic analysis on Deepcell-sorted samples. scRNA-Seq analysis showed cell populations with high levels of EpCAM expression in sorted, versus pre-sorted cells. CNV analysis demonstrated increased amplitude of deletion and amplification peaks relative to pre-sorted DTC samples. Further, mutational analysis showed increased allele frequency of mutations, including P53 and KRAS, in sorted versus pre-sorted samples.

Multiple clusters of morphologically distinct tumor cell populations were detected by UMAP analysis. We further trained the AI classifier to detect and enrich for each of these subpopulations, and subsequent CNV, mutation, bulk RNA-Seq, and scRNA-Seq analyses revealed molecular differences between the morphologically distinct subgroups. Together, our data suggests AI-detected morphological differences between cell populations may establish a biologically significant link between morphology and molecular signatures. Thus, we demonstrate the use of the Deepcell platform to perform high-dimensional morphological profiling of NSCLC tumor cells from DTCs, revealing a new dimension for identifying heterogeneous tumor cell populations.

T cell expansion and viability from filtered media

A. Basu[1], J. Smith[1], J. Broe[2], A. Chatterjee[2]; [1]MilliporeSigma, Burlington, MA, [2]MilliporeSigma, Bedford, MA.

Contamination-free medium containing cytokines, serum, and related supplements keep T cells viable and ready for therapies and implantation. Filter-sterilization is the preferred method using sterile, vacuum-based filter cups to remove particulates and contaminants (ex. microorganisms, bacteria, etc.) greater than the rated pore size. Preserving key growth factors and supplements post-filtration is paramount for T cells to function. Cytokines like Interleukin-2 (IL-2), when added to growth medium, help in expansion, viability, and related functional activities like abating inflammatory responses and equally priming naïve T cells for regulating immune responses. The objective of this study was to evaluate filtered prepared media for T cell culturing. We formulated T cell medium (Hematopoietic cell medium, Human Serum, and IL-2) and filtered the media once (1x), five times (5x), and up to ten times (10x) using sterile, low protein binding filter cups containing 0.22 µm polyethersulfone (PES) or polyvinylidene fluoride (PVDF) membranes. We looked at the impact of filtration of key media components for T cell expansion and viability by utilizing tools like flow cytometry (multiplex flow assays and growth curve examination), IL-2 ELISA, metabolite and glucose culture parameter detection, and hand-held automated cell counters. The results show that the different T cell phenotype markers, $CD3^+$ (≥ 99%) and $CD4^+/CD8^+$ (≈65%/≈35%), are consistently expressed regardless of filtration type and frequency after initial experimentation and at day 5. IL-2 concentration in control and all filtered media (up to 6 days) remained comparable (≈ 2 ng/ml). T cell viable cell density, concentration, and diameter (average: 12.7 ± 0.4 µm) also showed no significant deviation from each filtered media set and different culture periods. Our data highlights the ability to expand T cells in PES- and PVDF-filtered media without a noticeable effect on T cell viability. Vacuum-based filtered media can present a worry-free expansion and constant viability for T cells, aiding in the production of T cell therapeutics.

A framework for high-throughput and comparative cell biology

P. Avasthi, D. Matus, D. Mets, **R. York**; Arcadia Science, Berkeley, CA.

Cells display an astonishing amount of phenotypic variation. Mapping the extent of this diversity - and the evolutionary processes sculpting it - could accelerate the discovery of novel cellular mechanisms, organisms, and, potentially, general biological principles. A central need in this effort are tools for the unbiased measurement and comparison of cellular traits (which are often high-dimensional, time varying, and complex). Here we present our attempts toward generating some of these tools, focusing first on an especially nuanced functional trait: cellular motility. Using both publicly available and novel data sets, we show that the movement of diverse cell types can be represented with a discrete set of canonical cellular shapes. These shapes can be used to generate a low-dimensional universal 'motility space' that captures the full range of cellular dynamics available. Variation across many aspects of movement can be mapped using this space, identifying broad differences within and among cell types. Furthermore, complex cellular structure-function relationships can be uncovered and we develop a metric for comparing these relationships across evolution. Finally, we discuss this framework in the context of a larger effort to perform high-throughput phenotypic and genomic measurements among diverse microbial eukaryotes. This work intends to provide open and broadly-available tools for

comparing cellular phenotypes across evolutionary scales, potentially opening new pathways for dissecting the origins and generation of cellular diversity.

B5/P2404

SmartHeart - a novel 3D *in vitro* assay for improved assessment of cardiac drug efficacy and toxicity

M. Seguret[1], P. Davidson[2], S. Robben[2], C. Jouve[1], C. Cerveau[2], J. Hulot[3], M. Le Berre[2], **R. S. R. Ribeiro**[2]; [1]INSERM, PARCC, Université de Paris, Paris, FRANCE, [2]4Dcell, Montreuil, FRANCE, [3]INSERM, PARCC, Université de Paris and CIC1418 and DMU CARTE, Assistance Publique Hôpitaux de Paris (AP-HP), Hôpital Européen Georges-Pompidou, Paris, FRANCE.

According to WHO, every year there is an average of 18 million people dying out of cardiac diseases. A substantial part of these diseases is due to cardiomyopathies that affect many young people. Despite all the advances made in medicine in the last decades, there is still a long way to go before having robust disease models and efficient development of new therapies. Nowadays, cardiac tissue engineering is becoming one of the most common ways to mimic the main events encountered in these types of pathologies. To answer to these questions, we have developed a novel 3D cardiac assay, which enables both the formation and maturation of cardiac organoids based on cardiomyocytes derived from hiPSC as well as the acquisition of the most relevant redouts, all in single platform. To form the cardiac organoids, cell culture plates (96WP) are coated with a 3D structured PEG hydrogel that has an array of conical-shaped microwells containing a central pillar. When cells are seeded on top of these microstructures, they are guided towards the ring-shaped cavity, self-assembling into a circular organoid, which surrounds a hydrogel central pillar. Cell contractility force, beating rate and beating amplitude are easily measured through the contraction of the central pillar, whose stiffness is known and can be adjusted to the cell model. Using this model contraction of the tissue, i.e. restored cell beating, was observed in less than 24 hours after cell seeding. In addition to this, the effect of calcium channel blockers (Verapamil) was investigated, showing an inotropic effect in agreement with the literature. The effect of calcium concentration increase in the medium was also studied, demonstrating an increased contraction force until a plateau is reached around 1 mM. Due to the design of the microwells and the optical transparency of the hydrogel, the assay is completely compatible with image-based acquisition techniques. Therefore, besides the readouts previously stated, ionic exchanges such as calcium transients have been observed using a calcium sensitive dye, revealing an expected increase of intensity during CMs contraction. Similarly, spatial organization of cells and intracellular morphology was observed using immunofluorescence, showing for instance, the elongation of the CMs in the tissue. To summarize, the SmartHeart assay enables the fast assembly and maturation of functional cardiac organoids and the acquisition of many relevant read-outs, all of this in a single platform. In the future it can be used to test new compounds or assess toxicity of drugs targeting other types of pathologies, as it can be simply scaled to fit HTS and HCS requirements.

B6/P2405

Toward long-term lineage tracing and event recording in mammalian cells

T. B. Loveless, C. C. Carlson, C. A. Dentzel Helmy, V. J. Hu, C. C. Liu; Department of Biomedical Engineering, University of California-Irvine, Irvine, CA.

During the development of multicellular organisms, and in aberrant developmental processes such as cancer, cells undergo a series of stresses, gene expression changes, and other transient events, some of

which determine their ultimate fates. The historical events preceding most cell fates are unknown. Even less is known about which historical events *cause* a cell fate and which merely accompany it. DNA recorders are synthetic biology tools that enable cells to make a durable DNA record of ephemeral events in their history, in principle enabling biologists to correlate any type of cellular event to long term changes in the cell's phenotype. Moreover, by recording the relative timings of the events and the fate changes, DNA recorders should make it possible to form better hypotheses about which events cause which fate changes. Our DNA recorder, peCHYRON, uses prime editor to make insertion mutations at a genomic locus in temporal order. The mutations are directed by a collection of prime editor guide RNAs (pegRNAs); each pegRNA can add to the locus, and the exact mutation added indicates exactly which pegRNA directed it. Therefore, peCHYRON could in principle be used to record, in parallel, many different types of events. Here, we will report peCHYRON recording over weeks to months.

B7/P2406

Learning a meaningful representation of cell fate using variational autoencoders

A. R. Lowe[1], C. Soelistyo[2], G. Vallardi[2], G. Charras[2]; [1]Alan Turing Institute/UCL, London, UNITED KINGDOM, [2]UCL, London, UNITED KINGDOM.

Cell fate has an important role in many cellular quality control mechanisms. However, our understanding of how cell-scale topological and physical parameters determine cell fate remains elusive, largely due to the complexity of manually analyzing a time varying system of many cells. Here, we explore the idea of using machine learning to decipher the biophysical determinants of cell fate directly from a large corpus of time-lapse microscopy data. Our approach uses unsupervised deep learning to extract interpretable features of the image data, coupled to a temporal model to predict the fate of each cell in a mixed epithelium. Remarkably, once trained, our model is able to accurately predict the fate of each cell, given only a sequence of images prior to a fate being observed. Further, we show that the model is interpretable; learning to represent cell type, local tissue topology and nuclear morphology amongst many other parameters, directly from the image data. Remarkably, in the case of mechanical cell competition, our model learns to represent local cellular density, and use this to make accurate predictions of cell fate. Finally, we use genetic perturbations and drugs that block signaling pathways involved in the mechanism to test the learned representation. Since the model generates hypotheses for the fate of each cell based on the observations, we can use it to identify systematic deviations arising from perturbations of the underlying mechanism. Our results suggest that machine learning can be a powerful new tool to decipher the timescale and determinants of cell fate, enabling a new platform for automated hypothesis generation and directed experimental studies.

Classification and enrichment of carcinoma cells in real-time based on high-dimensional morphology enables increased sensitivity of molecular and cytology analysis

A. Mavropoulos[1], J. Cruz[1], J. Nieto[1], K. Saini[1], W. Austin[1], M. Phelan[1], J. Mei[1], J. Kim[1], W. Yu[2], C. Johnson[1], V. Lu[1], S. Boutet[1], T. D. Lee[2], N. Li[1], J. Rao[2], M. Salek[1], M. Masaeli[1]; [1]Deepcell, Inc, Menlo Park, CA, [2]University of California, Los Angeles, Los Angeles, CA.

Cytopathology studies and diagnoses disease at the cellular level, but it is currently restricted by low-throughput, subjective, laborious methods and low sensitivity. For example, the low abundance of malignant cells in a high non-malignant cell background limits the use of effusion samples for liquid

biopsy purposes. The Deepcell platform combines artificial intelligence (AI) and advanced imaging to classify and sort unlabelled cells in real-time, and generate quantitative morphology data. Here, we applied the Deepcell platform to the sensitivity challenges of effusion samples and demonstrated the ability to image, classify, and enrich carcinoma cells from patient-derived ascites and pleural effusions based on high-dimensional morphology and increase sensitivity of cytology and molecular analysis.
The Deepcell model was trained using >3 million cell images from malignant effusion samples, and in silico validation showed high model classification performance to identify malignant cells (AUC=0.96). The model detected carcinoma cells in 100% of cytologist-defined malignant effusion specimens (n=22), and percent frequency was concordant to ground truth. High-dimensional, quantitative morphology data from the cell images were used for UMAP analysis of the embeddings, which showed carcinoma and benign cells clustered distinctly. This suggests the AI captured morphological differences in carcinoma and benign cells, and more interestingly, that these morpholomic signatures correspond to cell biology. Furthermore, Papanicolaou staining showed higher purities in sorted versus pre-sorted samples, verifying carcinoma cell enrichment by the platform. CNV analysis and targeted sequencing of sorted samples showed increased amplitude of deletion/amplification peaks and increased TP53 mutation frequency, respectively. scRNA-seq analysis showed EpCAM+ tumor cell enrichment, and interestingly, EpCAM-Claudin4+CD24+ tumor cell subsets.
Thus, results of the Deepcell platform are consistent with cytology and biomarker-based results, with added benefits of greater sensitivity and enrichment of live carcinoma cells present in effusion samples. Additionally, high-dimensional morphology analysis provides a new dimension that can be integrated into single cell multi-omic modalities to elucidate tumor cell heterogeneity within effusions to ultimately improve precision medicine.

B9/P2408

Combined Immunofluorescence - In Resin Fluorescence Morphology (IF-FIRM) Microscopy provides histologic and cellular context to highly resolved fluorescence markers

C. Chalouni, A. Kumar Katakam, M. Sagolla, M. Reichelt; GENENTECH, South San Francisco, CA.

Immunofluorescence labeling and imaging of cell and organelle markers in cells and tissues is a key method of cell biology and biomedical research. Single, multiplex or superplexed immunofluorescence microscopy is used in biomedical research involving tissues in addition to more classic approaches that combine immunohistochemistry with chromogenic stains and morphological stains like H&E. One advantage of using IF isthe ability to perform higher order multiplexing of targets of interest.A major limitation of performing immunofluorescence imaging in complex tissues is the lack of histological cellular and subcellular morphological context. Similar to landmarks in a geographical map, morphological context provides valuable information about the localization of a fluorescence marker in a particular tissue region, cell type or relative to histopathological changes.To address these shortcomings, we have established IF-FIRM (Fluorescence in Resin Morphology) that combines immunofluorescence labeling of resin-embedded tissue sections with the staining of the sections with the organic dye cresyl violet (chemical formula: $C_{19}H_{18}ClN_3O$) to visualize tissue morphology. To establish and evaluate our IF-FIRM method we used resin-embedded pancreas or kidney tissue, and labeled it with antibodies against insulin and pancreatic alpha-amylase, or the kidney marker podocalyxin, respectively. In addition, the labeled sections were stained with the commercially available FIRM stain (cresyl violet) purchased from Electron microscopy sciences (EMS). For imaging we used an epi-fluorescence microscope (Zeiss Axioimager) or a fully spectral confocal microscope (Leica SP8 with white

light laser andspectral detectors) to enable better spectral separation of the FIRM fluorescent signal from the fluorophores used in the IF staining.With this approach we could readily identify by morphology particular tissue regions, such as the Islet of Langerhans in the pancreas, or glomeruli in the kidney sections. In addition, blood vessels, endothelium, epithelium, erythrocytes and subcellular structures and organelles such as nuclei, nucleolus, heterochromatin, basement membranes are unequivocally identifiable by the morphological FIRM stain.Combination of morphology signal (image) with the specific immunofluorescence stains (insulin, amylase, podocalyxin) localized these markers correctly within the histologic context of the Islet of Langerhans or kidney glomeruli.In conclusion, IF-FIRM provides valuable histological and cellular context to highly resolved immunofluorescence markers for fluorescence microscopy applications in tissue research.

CRISPR-Cas9 genome editing in iPSCs for functional genetic screening

N. Isachenko[1], D. Hu[1], A. Chenchik[2], **P. Diehl**[1], D. Tedesco[1]; [1]Cellecta, Inc., Mountain View, CA, [2]Cellecta, Inc., MOUNTAIN VIEW, CA.

Induced pluripotent stem cells (iPSCs) are widely used for disease modeling, drug discovery, and cell therapy development. However, iPSCs are difficult to engineer with an efficient CRISPR/Cas9 system for functional genetic screens. We used WTC11 human iPS cells to generate functionally validated lentiviral transduced Cas9 lines, characterized by high gene-editing activity and sustained potential to differentiate. Flow cytometry was used to check for the expression of pluripotency markers Oct3/4, TRA1-60, and SSEA-4 in the iPS-Cas9 cells, and their actual pluripotency was then confirmed by testing the ability to differentiate into the three germ layers: ectoderm, mesoderm, and endoderm. Furthermore, genome-wide transcriptome analysis was performed to confirm the expression of germ layer-specific markers in the differentiated cells. Sustained Cas9 activity was confirmed in the differentiated cells. This study provides proof-of-principle that patient-derived iPSCs can be used to enable CRISPR/Cas9 functional genetic screening technology in reconstituted patient-specific tissues/ disease models.

The Cyto R1: A Multifunctional Biophysical Sample Preparation Tool for Sorting, Filtering, and Enrichment

R. Barua[1], K. E. Degen[1], D. Thomas[1], D. Keck[1], A. Straka[2], S. Manns[3], K. Kinskie[2], C. Coogan[4], A. Nelson[2], K. David[2], R. V. Davalos[2], A. R. Hyler[1]; [1]CytoRecovery, Inc., Blacksburg, VA, [2]Biomedical Engineering and Mechanics, Virginia Tech, Blacksburg, VA, [3]Bioengineering, George Mason University, Fairfax, VA, [4]Biochemistry, Virginia Tech, Blacksburg, VA.

The Cyto R1 is an integrated benchtop platform providing multifunctional solutions for sample preparation. The core of the platform is a microfluidic device, Cyto Chip, that utilizes a unique array of over 25,000 insulating microcylindrical posts positioned between two parallel electrodes in order to generate a nonuniform electric field, a technique called dielectrophoresis (DEP). The unique architectural design and positioning of the micro-posts and electrodes facilitates the creation of electrical traps that can be used to capture and hold a targeted cell subpopulation while sustaining a sterile and untouched sample with high viability. This dielectrophoretic Cyto Chip exploits the interaction of the targeted cell with a nonuniform electric field to exploit biophysical properties of cells

such as cell size, membrane morphology, and nuclear size. The strength and direction of the DEP force on a targeted cell is dependent on the frequency of the applied electric field as well as the dielectric properties of the cell and suspending media. Preliminary experiments with the Cyto R1 Platform have demonstrated the use of our technology for cell sorting, filtration, and enrichment. The Cyto R1 successfully facilitated the separation of peripheral blood mononuclear cells (PBMCs) from a co-culture with ovarian cancer stem cells (CSCs), both from mice. From a 56.2% CSCs and 43.8% PMBCs co-culture, we were able to deplete 50% of the PMBCs while retaining the original CSC population. Similarly, the Cyto R1 chip has demonstrated its potential for filtering biological debris and satellite glial cells in order to purify a sample of murine trigeminal ganglia (TG) neurons. Lastly preliminary evidence has indicated the use of the Cyto R1 to enrich cell concentrations from 10^3 to 10^5. Ongoing work is the continued development of the Cyto R1's enrichment capabilities and quantifying the throughput and effectiveness of enrichment.

B12/P2411

Bioelectric regulation of tissue hydrostatic pressure in tissue spheres and organoids

G. Shim[1], I. Breinyn[1], A. Calvo[1], D. J. Cohen[2]; [1]Princeton University, Princeton, NJ, [2]Princeton Bioengineering Institute; Mechanical Engineering, Princeton University, Princeton, NJ.

Direct-Current (DC) electric fields exist throughout the body and are involved in a range of cellular responses, from directed cell migration (electrotaxis) to transcriptional regulation. New approaches to use electrical stimulation to program and control biological systems will therefore be very useful. Previously we focused on electrical control of collective migration in epithelial monolayers, but here we demonstrate how those same electrical cues reprogram 3D growth in lumenized tissues such as hollow kidney spheroids and intestinal organoids. In particular we found that electrical stimulation induced a rapid, powerful, and reversible swelling in these tissues by regulating water transport. Here, we discuss how external electrical stimulation can control the inflation of lumenized structures and cellular mechanisms mediating the response.We first studied hollow kidney spheroids (MDCK) within a hydrogel (Geltrex) and integrated into our SCHEEPDOG electrobioreactor. This allowed complete timelapse imaging (phase contrast, epi-fluor, and confocal) during electrical stimulation. Lumenized MDCK spheroids inflated significantly with 4 hrs of electrical stimulation with the volume almost doubling due to water transport. The rate and magnitude of inflation increased as the magnitude of the electrical field increased, with overly strong field gradients inducing 'popping'. We hypothesized that the dense actomyosin network at the apical surface of the structures provided a physical limit to the inflation response, and showed that inhibiting actomyosin contractility prevented rupture and increased the maximum swelling volume. We used ion channel inhibitors to determine that the majority of the response can be attributed to the CFTR ion channel (apical chloride channel) and NKCC channel (basal sodium/potassium channel) ultimately driving water flux into the tissue lumen and generating pressure. We have also developed a computational model relating applied direct-current electric fields, electrochemistry, and tissue hydrostatic pressure. This model can accurately describe the bulk swelling response, and also predicts an asymmetric distribution of ions around the spheroid. This is consistent with 3D imaging data demonstrating that cells on the cathode-side of the spheroid swell slightly while cells on the anode-side dramatically thin and stretch. Finally, we are now exploring how general electrically mediated swelling is, and we have recently replicated key swelling data using mouse intestinal organoids. That ionic electric currents can regulate or program tissue hydrostatic pressure

could help inform our understanding of how environmental factors regulate multicellular development, as well as possibly providing a new tool for tissue engineering.

B13/P2412

Polymerized Laminin-521 Promotes Large-Scale Human iPSC Expansion at Low Protein Concentrations

C. Hochman-Mendez; Regenerative Medicine Research, Texas Heart Institute, Houston, TX.

Laminins (LN) play a central role in the self-assembly and maintenance of basement membranes and are involved in critical interactions with cells and other extracellular matrix proteins. Among defined and xeno-free ECM culture matrices, LNs, namely LN-511 and LN-521, have emerged as promising coating systems for large-scale expansion of induced pluripotent stem cells (iPSCs). LN's biological activity stems from its self-polymerization into a cell-associated network. Polylaminin (polyLN) is an acidification-induced LN polymer that can recapitulate the native-like polymeric array in a cell-free system. Here, we show for the first time that polyLN-521 displays a hexagonal-like structure and that polyLN-521 permits large-scale human iPSC expansion at basal and low concentrations. Human iPSCs expanded with polyLN-521 maintained the pluripotent state, and the karyotype stability and telomere length were not impaired. These results suggest that polyLN-521 is a stable and cost-effective coating for large-scale iPSC expansion and illustrate the ability of polyLN-521 to reproduce a native-like polymeric structure.

A New Service Network for Cryo-Electron Tomography

A. Hoenger, K. Luger, M. H. B. Stowell; Mol. Cell. and Dev. Biology, University of Colorado-Boulder, Boulder, CO.

The CU Boulder Center for Electron Tomography or CCET is part of an NIH common fund initiative to broaden access to high resolution cryo-electron microscopy and tomography. More information about the initiative can be found at the URL shown https://www.cryoemcenters.org/. CCET is part of a network four centers including the Stanford SLAC Specimen Preparation Center (SCSC) the National Center for In-Situ Tomographic Ultramicroscopy (NCITU) and the Midwest Center for Cryo-Electron Tomography (MCCET) which serves as the network hub.CCET has a dedicated staff for assisting users in sample preparation for cryo-ET. Staff members are trained in the use of modern cryo-ET methods including high-pressure freezing, plunge freezing, FIB-SEM milling, correlative light and electron microscopy (CLEM), tomographic data collection and modelling. We welcome relevant projects from a nationwide audience for consulting and help with data collection. We host visitors for training and education.

Probing mechanotransduction pathways through visualization and control of vinculin conformation

M. Choi*, J. M. Szulczewski*, S. Hu, K. M. Hahn; Pharmacology, University of North Carolina At Chapel Hill, Chapel Hill, NC.

*These authors contributed equally.

Vinculin is important in multiple contexts where cells must measure and respond to mechanical force. It acts via a conformational latch mechanism where stretching produces an open conformation that enables binding to downstream effectors. We are specifically studying how cells use vinculin-containing structures called podosomes to probe the rigidity of potential targets during phagocytosis, and how

cancer cells navigate between tumors and the vasculature by sensing the rigidity of aligned collagen. Podosomes oscillate like pistons against phagocytic targets, with frequency dependent on target stiffness. Metastatic cells use vinculin-containing focal adhesions to monitor and respond to the rigidity of collagen fibers. In each case it is difficult to probe hypotheses coupling mechanical changes in vinculin to downstream signaling because interactions are transient and localized. We are therefore developing vinculin analogs for use in living cells to 1) report vinculin conformational state, and 2) control vinculin activity with light. To visualize the exposure of hidden binding sites in vinculin, a short peptide chain was inserted where it is exposed only in the open, "stretched" conformation. When exposed, the tag can be accessed by a small fluorescent protein, so simple colocalization of vinculin and this protein indicates the open conformation. To control vinculin's transmission of force, we sought to allosterically modulate vinculin-actin interaction. Previous studies have shown that protein activity can be controlled by inserting the LOV2 domain, which undergoes conformational changes when irradiated. We have thus made photoinhibitory and photoactivated vinculin analogs. We will show initial application of these analogs and fluorescent biosensors to study cell motility on micropatterned substrates that mimic the tumor microenvironment.

Spatial and temporal localization of nucleic acid targets in FFPE tissue samples with the novel loopRNA™ ISH technology

D. M. Holzapfel, PhD, J. Coleman, PhD; Enzo Biochem, Farmingdale, NY

Spatial and temporal localization of DNA or RNA targets in formalin-fixed, paraffin-embedded (FFPE) cells and tissue samples can be achieved with *in situ* hybridization (ISH) technique, while preserving the morphology of the cell or tissue. ISH is used for the identification and localization of viral infections, analysis of transcriptionally active nucleic acid and its distribution in cells and tissues and identify sites of gene expression. While immunohistochemistry (IHC) shows protein localization in cells and tissue samples, ISH can help identify the cell of origin. In order to achieve successful results, we used AMPIVIEW™ ISH probes, which combines the precision of targeted, sequence-specific RNA probes with a superior sensitivity of loopRNA™ technology, making them compatible with nanopolymer detection systems used in IHC. This powerful tool can be designed to detect the nucleic acid expression patterns and spatial localization of individual targets or DNA-RNA, RNA-RNA interactions. In addition, RNA-protein interactions in tissues can be studied when combined ISH and IHC. This study explains how these probes are used not only for the detection of viruses such as SARS-CoV-2 and human papillomavirus (HPV), but also the expression of endogenous biomarkers such as HER2/neu in FFPE tissue samples.

An Expandable FLP-ON::TIR1 System for Precise Spatiotemporal Protein Degradation in *C. elegans*

Y. Xiao[1], C. Yee[2], M. A. Q. Martinez[1], C. Zhao[1], W. Zhang[1], D. Q. Matus[3], C. Hammell[4]; [1]Stony Brook University, Stony Brook, NY, [2]Stanford University/HHMI, Stanford, CA, [3]Arcadia Science, Berkeley, CA, [4]Cold Spring Harbor Laboratory, Cold Spring Harbor, NY

Organismal development relies on the proper spatial and temporal control of gene expression. The auxin-inducible degradation system has been widely adopted in *C. elegans* for its ability to control the spatiotemporal patterns of target protein expression. While the AID system has provided a key step forward in controlling endogenous protein activity, it still needs further optimization, especially for cell-

type-specific protein degradation. Previous studies reported insufficient depletion of multiple AID*-tagged proteins using tissue or cell type specific promoters which fails to recapitulate the genetic null phenotype, leaving only hypomorphic defects to be detected. Given the modular nature of the AID system we hypothesize that one of the potential limiting factors in these experiments is insufficient expression of TIR1 when driven via spatially restricted promoters with dynamic activity. Here, we aim to boost TIR1 level using a FLP/FRT based recombination binary system. In this study, we engineered a hybrid transgenic system that programs cell type specific FLP activity to animate a dormant, high-powered promoter to drive optimized $_{At}$TIR1(F79G) expression in a cell type specific fashion. This composite system enables high activity TIR1-dependent degradation to be achieved in specific cell types without a dependency on cell-type specific promoter strength. We benchmark the utility of this system by generating a number of tissue specific FLP-ON::TIR1 drivers to reveal genetically separable cell-type specific phenotypes for a variety of proteins expressed in multiple tissues during *C. elegans* post-embryonic reproductive development. We also demonstrate that the FLP-ON::TIR1 system is compatible with other AID degron sequences, like mIAA7, which is optimized for faster degradation kinetics. Finally, we generate an expandable toolkit utilizing the basic FLP-ON::TIR1 system that can be adapted to drive optimized $_{At}$TIR1(F79G) expression in any tissue or cell type of interest for targeted protein degradation. We concluded that our FLP-ON::TIR1 system could further facilitate the expansion of the genetic toolbox for *C. elegans*, enabling more sophisticated temporal studies of cell and developmental processes to be addressed.

Automated Tissue Culture Workflow for Plating, Maintenance, and Differentiation of hiPSCs on Glass Bottom Plates for 3D Live Cell Microscopy, and their Cryovial Banking for Freezing and Distribution

B. Gregor, A. AICS, N. Gaudreault; Allen Institute for Cell Science, Seattle, WA

Title: Automated Tissue Culture Workflow for Plating, Maintenance, and Differentiation of hiPSCs on Glass Bottom Plates for 3D Live Cell Microscopy, and their Cryovial Banking for Freezing and Distribution

Authors:Benjamin Gregor, Allen Institute for Cell Science, Nathalie Gaudreault

Abstract:

The Allen Institute for Cell Science aims to understand the principles by which human induced pluripotent stem cells (hiPSCs) establish and maintain robust dynamic localization of cellular structures, and how they transition between states during differentiation and disease. We do this by visualizing hiPSC lines expressing fluorescently tagged proteins that represent a specific cellular structure or organelle using 3D live cell microscopy. These gene-edited hiPSCs and all our other openly available scientific resources can be found at allencell.org.. To produce a large number of standardized cell images for analysis, we have developed a fully automated workflow on a Hamilton Star. This robotic liquid-handling platform can perform hiPSC culture and cryovial banking seamlessly. We have also automated the seeding, maintenance, passage, and differentiation of edited hiPSCs at timed intervals, on 6-well plastic plates for propagation, and 96-well glass bottom plates conducive to high-resolution 3D microscopy. Here, we describe this automated workflow that has been instrumental in the successful scale-up and optimization of our work, along with details such as aspiration and dispense speeds, movements of plates, and seeding strategies. Upon validating our methods through a side-by-side comparison of quality control results obtained from manual and automated modes, we found that automation considerably improved our pipeline by providing more uniformity, reproducibility, and overall cell quality while eliminating operator-to-operator variability and the need for weekend

maintenance of cell lines. We have also developed an automated image-based colony segmentation and feature extraction pipeline to streamline the process of predicting cell count and selecting wells with consistent morphology for high-resolution 3D microscopy. Overall, the automation of our cell culture platform with robotic equipment and the use of image processing algorithms not only increased consistency and reproducibility, but also ensured standardization and scalability. We found that our method considerably decreased error and variability introduced by manual repetitive handling of cultures and reduced the need for stringent training standards.

Simplified, open-source analysis of DNA-binding proteins

M. Dilsaver; Lumicks B.V., Waltham, MA

The structure, regulation, and maintenance of DNA is critical to cellular function. Errors in these underlying mechanisms play a major role in diseases such as cancer. As a result, insights into the molecular details are needed to further our understanding, improve biological models, and develop novel therapeutics. Single-molecule techniques have emerged as useful tools for uncovering the activity and function of DNA-binding proteins in real time. Furthermore, the data from single-molecule techniques allows for an accurate quantification of many molecular properties, such as binding location, kinetics, etc. For many researchers, however, developing an analysis pipeline to quantify single-molecule data is challenging due to the required time, resources, and expertise. To address these obstacles, we developed an automated, open-source image processing and data quantification toolbox. We show that our toolbox allows for easy, rapid, and intuitive processing of single-molecule data. Using systems like the gene editing CRISPR/Cas9 system, we demonstrate that our toolbox 1) reports DNA binding specificity at the base-pair level, 2) measures binding constants (kon/koff) from the direct visualization of individual complexes interacting with DNA, and 3) allows for the accurate quantification of enzymatic processivity and protein diffusion. Overall, we show that our simplified, open-source data analysis platform allows for automated processing of single-molecule data and rapid characterization of virtually any DNA-binding protein or polymerase. This toolbox is accessible to all researchers and will enhance efforts to understand a wide range of normal and pathological DNA processes.

Survey of Cell Line Compatibility with Cells-to-C_T™ for Direct RT-qPCR Analysis of Gene Expression

E. Quandt, J. Bhandari, L. Chapman; Thermo Fisher Scientific, Austin, TX

Cells-to-C_T™ is a direct lysis method that accelerates and simplifies gene expression analysis by real-time reverse transcription quantitation PCR (RT-qPCR) by eliminating the need for traditional RNA purification, instead a cell lysate is used directly as a template for RT-qPCR. This method has been shown to be compatible with many, but not all, commonly used cell types. For this reason, it is recommended that each new cell type be evaluated for compatibility before proceeding with experimentation. In order to expand the utility of Cells-to-C_T as well as to determine the underlying reasons why some cells lines are incompatible, we evaluated the performance of Cells-to-C_T on a panel of previously untested cell lines. We find that the majority of cell lines tested are compatible with Cells-to-C_T, but that a subset, primarily enriched with immune cell types, were incompatible with the method. The expanded list of cell lines that are compatible with Cells-to-C_T will enable researchers to better determine if Cells-to-C_T is suitable for their cell line of interest.

FluidFM technology: a technology to revolutionize precision CRISPR editing, cell-based *in vitro* models, single cell adhesion and Live-seq transcriptomics.

T. Gerecsei, A. Kerjouan, A. Migenda Herranz, S. Mailand, M. Milla, K. Keevend, T. Pekeč, D. Ossola, T. A. Beyer; Cytosurge AG, Zürich, Switzerland

Objectives: Single-cell technologies have greatly impacted our understanding of population heterogeneity and cellular mechanisms. Our FluidFM technology addresses many hurdles in single cell research linked to CRISPR genome engineering, adhesion behavior and repetitive sampling of single cells for transcriptomics. Our objective was to use FluidFM to develop novel approaches for these applications.
Methods: The FluidFM technology is integrating atomic force microscopy with microfluidic probes, creating the world smallest syringe. Here, we present our FluidFM OMNIUM system enabling precise injection, extraction, and relocation of single cells. The technology can be used for diverse applications including precision CRISPR mediated gene engineering, semi-automated single cell adhesion measurements, and the recently published Live-seq approach1. The latter allows serial RNA extraction from single cells without impairing their viability enabling tracking of temporal trajectories.
Results: Direct intranuclear injection of CRISPR RNPs into a single cell circumvents harsh transfection methods and permits gene editing in hard-to-transfect and sensitive cells. Fine-tuning of the injection parameters enables to minimize the amount of CRISPR RNPs and deliver optimized amounts of HDR-templates. This enhances homologous recombination and minimize off-target editing effects. To illustrate the power of FluidFM mediated genome engineering we show deletion of SOX17 in hiPSCs. Further, we will present our effort to semi-automated single-cell force spectroscopy though reversable attachment of cells to the FluidFM cantilever. We show how we can measure adhesion forces up to 3 µN- in HeLa and CHO cells, with an unprecedented throughout of 50 cells/2h. Lastly, we will introduce our newest feature for serial RNA extractions (biopsies) from a single cell to support Live-seq workflows.
Conclusion: The FluidFM OMNIUM platform will improve the quality and ease in which single cell level projects in biomedical research are conducted. Intranuclear injection, enables precision gene editing, even in hard-to-transfect and sensitive cells. Semi-automated adhesion workflows enable measurements of cell-cell and cell-matrix interactions with high accuracy and unprecedented throughput. The single cell biopsy workflow allows the serial and non-destructive extraction of cellular material, conserving the physiological context.

Illuminating dynamic structural states in hiPSCs through endogenous gene tagging

B. Roberts, R. N. Gunawardane; Allen Institute for Cell Science, Seattle, WA

The Allen Institute for Cell Science aims to understand the principles by which human induced pluripotent stem cells (hiPSCs) establish and maintain robust dynamic localization of cellular structures, and how they transition between states during differentiation and disease. As a first step, we have created a collection of endogenously tagged hiPSC lines to illuminate cell organization. The tagged proteins include notable membrane-bound and membrane-less cellular organelles, signaling complexes, phase transition markers, transcription factors, and structural markers specific to differentiated cells. To date, the Allen Cell Collection consists of 54 single- or dual-edited lines that have undergone extensive

quality control testing to ensure genomic, cell biological, and stem cell integrity. Here, we highlight our gene-editing and quality control workflow for mono- and biallelic editing of expressed or silent genes that are expressed specifically during differentiation and function as reporters of cellular state. Furthermore, we underscore our efforts to increase efficiency of the current workflow by utilizing Adeno-Associated Virus (AAV) to deliver donor DNAs and multiplexing transfection strategies for gene tagging at multiple loci. Our most recently released lines are CTCF-mEGFP and PCNA-mEGFP, for dynamic visualization of chromatin domains and replication foci, G3BP1-mEGFP to label stress granules, mono- and bi-allelic E-cadherin-mEGFP to visualize adherens junctions and DCP1a-mEGFP for P-bodies. Currently, we are working on getting gene-edited cell populations for N-and VE-cadherin ready for single cell sorting. Our overarching goal is to make these tools openly available to the cell biology community to help accelerate biomedical research. In addition to our cell lines, the donor plasmids, segmented 3D images of about 200,000 cells from our lines, image analysis, visualization tools, integrated cell models and biological findings are all openly available to the research community (www.allencell.org).

B23/P2422

A critical comparison of bulk and single-cell manipulation technologies for genome editing

S. Patange, S. Maragh; National Institute of Standards and Technology, Gaithersburg, MD

The NIST Genome Editing Program within the U.S. Department of Commerce leads international efforts with academia, industry, and government stakeholders to identify and address existing gaps in the standards and measurement needs of the genome editing field. One major project area is to evaluate the performance of technologies that deliver genome editing reagents to human cells. Here, we present our evaluation using HEK293 cells to compare a traditional bulk delivery technology (Nucleofection) with an emerging single-cell manipulation technology (FluidFM). We use several metrics including fluorescence quantification and genomic sequencing to assess the efficiency of reagent delivery and genome editing at the on-target locus These results provide guidance for research applications where it is advantageous to have controlled dose delivery of a reagent or high-resolution data on the distribution of genomic and phenotypic outcomes of a small population of cells. The outcome of this study is a critical step towards addressing future needs and technological advancements that would allow precision manipulation to be coupled with precision measurement for applications in human genome editing.

Diazaborine-based bioconjugation: A uniquely versatile bioorthogonal reaction for biochemistry and cell biology

S. Ghosh, S. C. Mallojjala, J. Hirschi, **S. L. Bane**; Binghamton University, Binghamton, NY

With an abundance of functional groups and reactive species present in biological systems, precise site-specific chemical bond formation is an ongoing challenge. Biorthogonal chemical reactions meet this challenge by incorporating exogenous reaction functional groups into a target biomolecule of interest. Great success has been achieved with the popular “click” reactions, particularly the strain-promoted azide-alkyne conjugation (SPAAC) and the tetrazine-based inverse electron demand Diels-Alder reaction (IEDDA). A common feature of these reactions is that the conjugation products contain large, hydrophobic moieties, which is undesirable for in vivo applications such as drug delivery. A recently uncovered bioorthogonal reaction has potential for broad applications in biochemistry and cell biology.

The diazaborine (DAB) reaction occurs between a hydrazine derivative and an ortho-carbonyl substituted phenylboronic acid. The boronic acid moiety accelerates the usually sluggish hydrazone-forming reaction by several orders of magnitude and yields various forms of a boron-nitrogen heterocycle as the product. Many of these products are zwitterionic; thus, unwanted hydrophobicity is not conveyed into the product. Importantly, the reaction is orthogonal to the SPAAC and IEDDA processes, allowing for its simultaneous deployment for multiple site-specific conjugation applications. The accessibility of hydrazine derivatives from commercial sources coupled with the availability of chemical and enzymatic methods for incorporating these functional groups into biomolecules makes this bioconjugation reaction quite accessible to biological researchers. Our group is investigating the mechanism of formation of this highly unusual heterocycle as well as the stability and reversibility of the various forms of the DAB, with a goal of deploying the optimal reactive pairs for the desired application. We will present results of chemical and computational studies that define the mechanism of this process and biochemical studies that inform the suitability of this chemistry for cellular applications.

New Generation of Fluorescent probes for cell-based measurements of Caspase Activation and Mitochondrial Superoxide

B. S. Mandavilli, D. Beacham, Y. Hu, A. Chen; Thermo Fisher Scientific, Eugene, OR

Neural cell health and stress readouts are critical indicators of altered or impaired function in normal and diseased states of excitable cells, and work has been underway to develop improved small molecule sensor dyes compatible with traditional imaging and High Content Analysis (HCA) interrogation of apoptotic and mitochondrial stress pathways.
The CellEvent™ Caspase Green dye effectively reports caspase activation, but suffers complications in assay configuration when attempting to multiplex with the Green Fluorescent Protein (GFP), calcein, or other 488 laser line tools in fluorescence microscopy. Here, we describe the testing and functional characterization of a new candidate molecule for measuring apoptosis in living cells. Our sensor is comprised of a fluorogenic reporter dye that is liberated from a DEVD peptide substrate by caspase activation, but operates in the Texas Red, 590nm excitation band, with an emission peak near 610 nm, permitting easy multiplex with GFP or calcein stained neurons in both traditional and HCA microscopy configurations. Similarly, mitochondrial superoxide accompanying cell stress is probed in microscopy with the MitoSOX™ Red Mitochondrial Superoxide Indicator dye, which localizes to mitochondria and reports superoxide generation, ignoring other Reactive Oxygen Species (ROS) and Reactive Nitrogen Species (RNS). This dye has an unusually long Stokes' shift, requiring specialized microscopy and HCA filters that excite at 405nm, and capture emission at 610nm for specific superoxide detection. This unconventional spectroscopic profile prevents the dye's use on many imaging platforms and promotes phototoxicity. To this end, our team has produced a dye with the same level of specificity for superoxide that will operate in one of the traditional fluorescence microscopy channels. Our candidate dye, here named MitoSOX™ Green Mitochondrial Superoxide Indicator also localizes to mitochondria of live cells and selectively reports superoxide generation, while ignoring other ROS and RNS species in ex vivo testing. With an Excitation/Emission profile in the GFP/FITC microscopy channel, a series of comparative studies in immortalized and neural cells are shown, highlighting photostability, specificity and signal amplitude from the dye.

New Approaches Towards Targeted Protein Degradation

J. Yang, A. Ting, C. Bertozzi; Stanford University, Stanford, CA

Our lab has pioneered extra cellular approaches towards degrading protein via an approach called Lysosomal Targeting Chimeras (LYTACs). These molecules have worked very well in the lab, but have a long and complex chemical synthesis. In this new work we have made a new version that also traffics and degrades proteins in the lysosome, but can be readily made in e. Coli in one step. We demonstrate the efficacy of this biologic as an extra culler protein degrader.

B27/P2426

Development and application of the ratiometric calcium indicator specific to an inter-organelle communication

Y. Woo, E. Cho, Y. Suh, B. Suh, S. Kim, T. Nhung, T. Nghi, S. Lee, D. Mun, S. Park; Pohang University of Science and Technology, Pohang, Korea, Republic of

Mitochondria-associated ER membrane (MAM) is the structure where these two major calcium-regulating organelles form the close contact site, so it provides physical site for efficient Ca^{2+} crosstalk between them. Due to the technical limitation, it was hard to directly and specifically measure Ca^{2+} concentrations inside the MAM with a poor/limited understanding about MAM Ca^{2+} dynamics. Here, we developed an MAM-specific BRET-based Ca^{2+} indicator, MAM-Calflux, to visualize Ca^{2+} dynamics at this inter-organellar compartment. Application of the bimolecular fluorescence complementation (BiFC) concept in the fluorescent domain successfully spotlighted Ca^{2+}-responsible BRET signals in MAM. Taking advantage of the ratiometric Ca^{2+} indicator, MAM-Calflux could estimate steady-state Ca^{2+} level inside MAM. Also, it achieved the dual functionality as the MAM Ca^{2+} sensor and the MAM structure marker and could visualize the uneven intracellular distribution of MAM Ca^{2+}. Eventually, it unveiled abnormal MAM calcium cross-talk in neurons of neurodegenerative disease model mice. Thereby, we propose a new sensor ratiometrically and specifically indicating the Ca^{2+} concentration in an inter-organelle communication.

Exploring the perspectives of using the D-lldR protein from *Pseudomonas fluorescens* as a biosensor for D-lactic acid *in vitro*

E. Indosova, E. Zolotovskaya, A. Saranchina, P. Drozdova; Institute of Biology At Irkutsk State University, Irkutsk, Russian Federation

Background. Lactic acid (LA) is a common substance widely found in nature and used in industry. It has a chiral carbon atom and thus occurs as two enantiomers. While L(+)-LA acid is common in all living cells, D(—)-LA is a specific metabolite of some bacteria. In human or farmed animals, blood accumulation of D-LA is a marker of bacterial infection. However, a simple, inexpensive and effective chiral-specific method of D-lactic acid detection and quantification is still lacking. Recently, Singh *et al.* (2019; doi: 10.1016/j.synbio.2019.08.004) have discovered and characterized D-lldR, a D-LA-responsive transcription factor from *Pseudomonas fluorescens*. The genetic construct encoding this factor under a constitutive promoter and GFP under the D-lldR-driven promoter proved to be a working biosensor in *P. denitrificans*. However, its dynamic range was 35-100 mM (Singh *et al.*, 2019), which is much higher

than even the 3 mM concentration threshold for D-lactic acidosis, a serious neurological condition (Petersen, 2005; doi: 10.1177/0115426505020006634). In this work, we aimed at determining whether D-lldR can be used to construct a more sensitive system *in vitro*. Methods and Results. To do so, we recloned the sequence encoding D-lldR from the pUCPK'-D-lldR-P_{lldP}-gfp vector (Singh *et al*., 2019) to the pET20b(+) vector, obtaining the expression construct for production of D-lldR with a C-terminal His6 tag. This construct was used to transform *Escherichia coli* strains BL21(DE3)pLysS, C41(DE3) or C43(DE3). In C41(DE3) or C43(DE3) strains, the protein was successfully produced. These cells were used to extract protein and then purify D-lldR with Ni-NTA agarose resin (Thermo). Both crude extract and purified protein were used to check for D-lactic acid-dependent DNA-binding activity with electrophoretic mobility shift assay in a native 5% TBE polyacrilamide gel (Hsieh *et al.*, 2016; doi: 10.3791/54863) with the ROX-labeled oligonucleotide corresponding to the predicted binding site (Singh *et al.*, 2019). However, so far we have not observed the expected shift of the DNA band. This may mean that other cofactors are needed for DNA binding in the *Pseudomonas* cells. This research was funded by the Russian Science Foundation; grant number 20-64-47011 for interdisciplinary project performed in association with the Petrozavodsk State University.

3D print your own lab - 3D printers in service of biological laboratories

Z. Baster; National Heart, Lung, and Blood Institute, NIH, Bethesda, MD

Within the past 10 years 3D printing gain in popularity, due to expiration of several key patents. The main application for 3D printing is in different branches of Engineering and manufacturing prostheses and customized surgical tools. Interestingly, specialized 3D printers can be used in almost any field of life, from printing buildings to printing biocompatible scaffolds designed for seeding cells. Currently more and more research groups use 3D printers to design unique parts of instruments to use in their projects. One of the main advantages of current 3D printers is their availability, both in the case of number of 3D printers in the community, as well as in the cost of the printer, which is less than $1000 for high quality entry level printer, and the printing material.

Many labs struggle with acquiring small lab equipment, like shakers or sample holders, due to their high cost. The solution to that problem, that I would like introduce, is using 3D printers to make such equipment. With basic knowledge in 3D printing and electronics, this approach can reduce the cost of small laboratory devices 10-fold and more.

Nonetheless, the main problem behind 3D printing is a need to provide a 3D model to the printer. Such a design usually requires good background in 3D computer-aided design software. There are many services allowing to share design files between people, yet they are usually low specialized and not popular in biological science community.

The goal of this work is to reach out to our community, both to makers and people in need. Firstly, to popularize the use of 3D printers in making every-day small lab equipment, allowing to reduce the cost of running the lab. Secondly, to assess the need for a such solution in our community. Finally, to connect scientist interested in exchanging knowledge and 3D print designs.

B30/P2429

Development of a new All-In-One inducible lentiviral shRNA/gRNA Vector

L. Wu, H. Su, J. Fellows, M. Fu, J. Heller, B. Park, D. Yin; Origene, Rockville, MD

Tet-On is a powerful inducible system and a classical tool to regulate gene expression in mammalian cells. It has also been applied to regulate Pol III-driven transcription, such as shRNA or gRNA driven by a U6 or H1 promoter. However, all of the [JF1] current versions of Tet-On shRNA vectors are based on H1-2O2 or U6-2O2 promoters, which are only compatible with first-generation tetracycline repressor TetR.[JF2] In addition, these promoters have the problem of driving downstream transcription without the binding of the Tet regulatory protein. Here, we developed a new system that is built upon tetracycline activator protein, Tet-On 3G, combined with a new structure of Tet responsive promoter H1-4O4, which tightly regulates [JF3] the downstream transcription of gRNA or shRNA. The responsiveness of our system to Doxycycline regulation is dramatically improved compared with the current versions. The new Tet-On system is further optimized into a compact structure to be compatible with the lentivirus package (All-In-One Lenti-Tet-On system), which still keeps the leaky expression at an undetectable level. Combined with all these features, the new generation of the Tet-On system offers broad applications in gene knocking down and genomic editing.

B31/P2430

Improved design of kinase translocation reporters allows simultaneous measurement of cAMP-dependent kinase (PKA) and extracellular signal-regulated protein kinases (ERK) activities

S.-J. Tsai[1], Y. Gong[2], J. Xu[2], F. Zahra[1], M. J. Caterina[1,1,1,1], S. J. Gould[1]; [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD

Signal transduction through protein kinases mediates a vast array of physiological processes and disease pathologies. Live-cell biosensors for protein kinase activities have led to significant advances in our understanding of human health and disease. Of these, kinase translocation reporters (KTRs) are among the most useful, as they allow for facile monitoring of kinase activity based on movement of a fluorescent protein (FP) between the nucleus and the cytoplasm. A working KTR relies on phosphorylatable sites within a vicinal pair of strong bipartite nuclear localization signal (bNLS) and weak nuclear export signal (NES). When the sites are phosphorylated, the added negative charges inhibit bNLS activity and stimulate NES activity, reversing the net strength and triggering movement of the KTR from nucleus to cytoplasm. While many of the original KTRs are useful, some are less so, suggesting room for improvements. Here we describe principles to redesign KTRs that yielded enhanced performance characteristics. First we increased KTR size, thereby minimizing their back-diffusion through the nuclear pore complex. Another improvement was to restructure the bNLS to render tuning to various levels of kinase activity. Third, we found that marking the nucleus/cytoplasm boundary with endoplasmic reticulum-localized FPs greatly eliminated image analysis and biological artifacts caused by other commonly used marker proteins. Importantly, integration of these design principles allowed us to develop a PKA-sensitive KTR (PKA-KTR) with greatly enhanced sensitivity and response amplitude to forskolin and other PKA stimuli, that was functional in multiple cell lines and primary cells. We applied the same principles to optimize an existing KTR for ERK (ERK-KTR) and derived a set of new sensors with tunable sensitivity for different cultured and primary cell types. We also showed that our improved PKA-KTR and ERK-KTR can be used to simultaneously record both signaling pathways. Importantly, these sensors are designed such that they can be multiplexed with other indicators to achieve even higher-

dimensional, real-time monitoring of diverse signaling pathways. In summary, we demonstrated a set of generalizable principles to optimize and improve KTR sensors for higher sensitivity, enhanced response amplitude, and expanded versatility in cellular contexts and applications.

Regulation of Actin Dynamics 2

Dissecting the role of cortical actomyosin dynamics during Wnt-dependent asymmetric cell division

M. Taher[1,2], V. Juciute[1,2], D. Qi[1,2], E. Wang[1,2], K. Sugioka[1,2]; [1]Department of Zoology, University of British Columbia, Vancouver, BC, CANADA, [2]Life Sciences Institute, University of British Columbia, Vancouver, BC, CANADA.

Asymmetric cell division plays a crucial role in controlling cell type diversification during metazoan development by producing two daughter cells with different fates, shapes, and sizes. In *Caenorhabditis elegans* embryo, asymmetric cell division of endomesodermal precursor EMS requires a Wnt ligand expressed from the posteriorly located P_2 cell. Although previous studies report that Wnt signalling pathway components localize asymmetrically in a dividing cell and specify mitotic spindle orientation, microtubule organization asymmetry, and cell fate, the precise mechanism underlying the Wnt-dependent asymmetric cell division remains elusive. Here, we investigated the role of cortical actomyosin in the EMS asymmetric cell division. We quantitatively analyzed the cortical actomyosin dynamics by visualizing non-muscle myosin II/NMY-2::GFP and lifeact::mKate2 (F-actin marker) using a spinning disk confocal microscope. We observed the polarized cortical flow from the posterior cell cortex toward the cleavage furrow during cytokinesis, as we reported previously (Sugioka and Bowerman 2018). On the other hand, the anterior cell cortex did not exhibit the pronounced furrow-directed cortical flow. Moreover, we found that the dividing EMS cell exhibits asymmetric actin orientation during cytokinesis: actin filaments were randomly oriented throughout the cortex at anaphase onset, then over time, actin filaments oriented as mesh-like at the anterior, mostly vertical at the cleavage furrow, and they tend to be horizontal at posterior. Interestingly, these asymmetries of cortical flow and actin orientation are lost in *wnt/mom*-2 and *frizzled/mom*-5 mutants, suggesting the Wnt-dependent regulation of cortical actomyosin dynamics. We are currently investigating a potential actomyosin regulator downstream of the Wnt pathway. We are also investigating how the loss of asymmetric cortical flow affects asymmetric cell division by introducing actin and myosin inhibitors. Our study should reveal new mechanisms underlying the Wnt-dependent regulation of asymmetric cell division.

B34/P2432

Exploring SLK effects on adhesion cytoskeletons

Y. Lin[1], H. Lin[2], Y. Jo[1], C. Fan[1], F. Tsai[1,3]; [1]Department of Pharmacology, National Taiwan University College of Medicine, Taipei, TAIWAN, [2]Department of Immunology, National Taiwan University College of Medicine, Taipei, TAIWAN, [3]Department of Internal Medicine, National Taiwan University Hospital, Taipei, TAIWAN.

SLK(Ste20-like kinase) is a serine/threonine protein kinase involved in many biological processes including cell migration, apoptosis and cell proliferation. It was identified as one of the candidates from our recent screen of synthetic dysmobility, as collective cell migration could be synergistically increased

by simultaneous suppression of myosin activator ROCK and actin modulator SLK. Although previous research suggested that SLK might directly suppress RhoA-ROCK activities in cardiomyocytes, our results did not reveal direct signaling interactions between SLK and ROCK during cell migration. Interestingly, recent reports revealed that SLK activated ERM to regulate apical-basal polarity in epithelial cell sheets. Our preliminary data also showed that knockdown of SLK improved cell alignment in head and neck cancer SAS cells, and cell sheets with SLK knockdown persisted to grow in single layer rather than multiple layers. Therefore, we hypothesized that by activating ERM, SLK regulates actin cytoskeletons to remodel cell-cell and cell-matrix adhesion, both of which are critical for cell sheet integrity and collective cell migration. We are now elucidating whether and how SLK regulates adhesion cytoskeletons, with the ultimate goal of understanding its mode of synergistic collaboration with ROCK during collective cell migration.

B35/P2433

Anillin Regulates Rho Activity during Cell-Cell Junction Remodeling

Z. Craig, A. Walkon, R. Stephenson, T. Arnold, A. L. Miller; University of Michigan, Ann Arbor, MI.

Epithelial tissues require apical cell-cell junctions to adhere cells to one another and generate specialized barriers that are essential for homeostasis, while disrupted barrier function is linked to disease pathogenesis. As cells change shape and tissues experience mechanical forces, cell-cell junctions must be continually remodeled while maintaining a functional barrier. However, the mechanisms underlying junction maintenance, repair, and remodeling are not well understood. Using *Xenopus* embryonic epithelial cells as a model epithelium, our lab has shown that tight junction repair following local leaks in the barrier following cell shape change involves Rho flares, short-lived local accumulations of active RhoA, which trigger actomyosin contractility to restore barrier function. Anillin is a scaffolding protein that is known to regulate RhoA during cytokinesis, where it forms a tension-dependent complex with p190RhoGAP (p190) to terminate Rho contractility after cytokinetic furrow ingression is complete (Manukyan et al. 2014, J. Cell Sci.). We and others have shown that Anillin is also present at cell-cell junctions, where it regulates junction integrity, organizes junctional actomyosin, and perpetuates Rho activity by increasing Rho's membrane retention time and thus its availability to downstream effector proteins (Arnold et al. 2019, eLife; Budnar et al. 2019, Dev. Cell; Reyes et al. 2014, Curr. Biol.). Here, we demonstrate that Anillin and p190 both localize to Rho flares. We hypothesize that Anillin coordinates contractility at Rho flares by first promoting membrane retention of active Rho and then recruiting p190 to terminate contractility. Recent data shows that Anillin knockdown enhances the intensity of Rho flares, which suggests that Anillin is involved in negative regulation of Rho. Interestingly, Anillin knockdown also reduces tight junction reinforcement following tight junction breaks. Ongoing work is focused on investigating the mechanism of p190's recruitment to Rho flares, and whether Anillin binding is required for p190 localization at Rho flares. Additionally, we are investigating the function of p190 at Rho flares by knocking down p190 or disrupting p190's GAP activity and measuring effects on local Rho activation and tight junction remodeling. Together, this work will reveal how Anillin and p190 coordinate contractility during RhoA-dependent tight junction repair in polarized epithelia.

B36/P2434

Shaping the presynaptic compartment and cytoskeleton via Tropomyosin

B. Ermanoska, A. A. Rodal; Brandeis University, Waltham, Massachusetts, MA.

Meter-long axons of human peripheral nerves endure the mechanical strain of a lifetime of muscle contraction. A submembranous cytoskeleton, composed of periodic repeats of spectrin and actin rings and non-muscle myosin II (NMMII), is suggested to provide a mechanical scaffold for axons. The organization and composition of the presynaptic actin cytoskeleton remain largely unknown due to the small size of the presynaptic compartment and the numerous membrane specializations and actin structures it contains. To address this question, we examined the presynaptic actin cytoskeleton at the *Drosophila* larval neuromuscular junction (NMJ) - a model synapse with presynaptic boutons having multiple active zones that innervate the mechanically active postsynaptic muscle. We identified different actin subpopulations, including an actin core traversing the NMJ, cable-like structures, and persistent patches, in addition to the previously characterized endocytic actin patches. We assessed the organization of the presynaptic actin upon neuronal down-regulation of non-muscle Tropomyosin (Tm1), a key actin regulator which we found to localize along the NMJ, partially overlapping with the presynaptic actin core. The coil-coiled tropomyosin dimer binds along actin filaments and acts as an inhibitor of Arp2/3 nucleation. In line with this function, neuronal decrease of Tm1 levels induced up-regulation of presynaptic actin assemblies, which correlated with increased levels of the Arp2/3 nucleation complex. Tropomyosin is also crucial for the recruitment of NMMII to actin filaments, and upon neuronal Tm1 down-regulation we found a correlating decrease of NMMII not only in the presynaptic compartment but also in the postsynaptic muscle proximal to boutons. This finding suggests that neuronal actomyosin rearrangements could propagate transsynaptically, and possibly tune synaptic function. In addition, we mimicked the presynaptic actin disorganization observed upon neuronal down-regulation of Tm1 by performing axotomy, which indicates that both physical and genetic defects could lead to similar disruptions of the neuronal mechanical continuum. Finally, we demonstrate that Tm1 regulates synaptic morphology as its neuronal down-regulation induces ectopic growth of synaptic protrusions. Thus, our study provides unique insight of the role of Tropomyosin in shaping the presynaptic compartment and regulating of F-actin and contractile apparatus organization, addressed in their *in vivo* context in the animal.

B37/P2435

Positive Feedback is Essential for Rho Amplification in Cortical Excitability

D. Chomchai, W. Bement; Cellular and Molecular Biology, University of Wisconsin - Madison, Madison, WI.

Recent studies have revealed that the cell cortex - the plasma membrane and the cytoskeleton-rich layer of cytoplasm just beneath it - behaves as an excitable medium. Specifically, during cytokinesis propagating waves of Rho GTPase activity and F-actin assembly and disassembly are concentrated in the equatorial cortex, where they direct the formation of the contractile ring. Rho wave propagation is proposed to be the result of an excitable circuit: interdependent positive and negative feedback loops. Positive feedback is suggested to depend on the Rho Guanine nucleotide exchange factor (GEF) Ect2, and negative feedback depends on the Rho GTPase activating protein (GAP) RGA-3/4. Similar dynamics have been observed with other GTPases, such as Cdc42 during cell locomotion and cell polarization. Collectively, these dynamics are termed cortical excitability.

Modeling of cortical excitability predicts that positive feedback is essential for Rho wave generation, but this has yet to be directly tested *in vivo*. We have previously shown that cortical excitability can be induced in immature Xenopus laevis (frog) oocytes by co-expressing mutant Ect2 and RGA-3/4. Using this system as an *in vivo* model for cortical excitability, I found that two Rho GEFs capable of positive feedback, GEF-H1 and Net1, can support cortical excitability in the place of Ect2 whereas two others that are not capable of positive feedback, Abr and ArhGEF10, did not support cortical excitability. Additionally, I also found that Ect2 modified to lack the capacity to participate in positive feedback did not support cortical excitability.
Another model prediction that has yet to be tested *in vivo* is that Rho wave generation is all-or-none. To test this, I held RGA-3/4 levels constant while titrating Ect2. I found that cells with low expression of Ect2 generated Rho waves with characteristics (amplitude, period, width) identical to those with high expression of Ect2, suggesting that Rho wave generation is indeed all-or-none. I also found that there is a threshold of ~50ng/uL Ect2 expression necessary to produce Rho waves. Just beyond the threshold, the likelihood of a cell to exhibit cortical excitability increases sharply, as predicted by the model. Together, these data provide direct *in vivo* evidence that Rho amplification by positive feedback is a feature of cortical excitability.

Spatiotemporally Precise Optogenetics Reveal Ras/mTorC2/Akt Pathway Tune Polarity and Organize Protrusions in Human Neutrophil Migration

D. S. Pal, P. N. Devreotes; Department of Cell Biology and Center for Cell Dynamics, School of Medicine, Johns Hopkins University, Baltimore, MD.

In the last several decades, biochemical and genetic investigations have revealed that Ras GTPases promote cell growth, energy metabolism, and innate immunity functions of neutrophils. However, their role in cell motility is still unexplored. Although Ras mediates multiple signaling pathways which control neutrophil chemotaxis, there is no conclusive evidence to show Ras activity on the plasma membrane directly regulates immune cell migration. To prove that activation of Ras could generate cellular protrusions, we employed a spatiotemporally precise, cryptochrome-based optogenetic system in migratory HL-60 human neutrophils. We recruited GTP-bound or constitutively active Ras to the cell membrane. K- or H-Ras recruitment during global illumination experiments promoted actin polymerization at the ‘front’ or leading edge resulting in sustained protrusions and increased random motility in neutrophils. These findings were corroborated by transient recruitment of GTP-bound Ras to ‘back’ or inactive regions of the cell membrane which led to polarity breaking and localized protrusion generation. Furthermore, activating endogenous Ras by recruiting RasGRP4, a physiologically relevant RasGEF in neutrophils, was very effective in generating protrusions. Pharmacological inhibition studies suggested that these cytoskeletal effects of Ras activation are predominantly mediated through mTorC2 pathway. These findings led us to investigate a crucial downstream Ras-mTORC2 effector, Akt1, whose role in cell migration is still unidentified. Global or localized activation of Akt1 on the membrane showed that it is a positive regulator of F-actin polymerization, protrusive activity, and migration. Interestingly, we also discovered that Akt1 activation occurs via a yet uncharacterized PI3K-independent mechanism in neutrophils. Altogether, this study is the first of its kind in human neutrophils where we dynamically perturbed activities of established players of classical growth control pathways, on a sub-cellular level, and visualized their direct involvement on actin assembly, cell shape, and migration modes.

Cell metabolism regulates contractility

L. D. Troughton, J. R. Beach, P. W. Oakes; Loyola University Chicago, Chicago, IL

Cell migration is a dynamic process that requires extensive protein turnover, extracellular-matrix interaction and remodeling, and a dynamic actomyosin cytoskeleton. The actomyosin motor is vital for the force generation required to initiate and maintain motile behaviour. Interestingly, different cell types utilize this machinery in different ways to promote either mesenchymal or amoeboid-like migration. Regardless, these processes rely heavily on ATP hydrolysis, and availability of ATP is thus likely to tune both the mode of migration and the underlying mechanical interactions. Moreover, migration mode plasticity often accompanies pathological states such as cancer, where a dysregulated metabolism is often a defining feature. Surprisingly, how metabolic activities affect the cellular contractile machinery and the rest of the cytoskeleton remains unclear. Here we investigate how small-scale changes to cellular metabolism (and ultimately ATP:ADP ratios) alter the contractile behaviour of fibroblasts and immune cells. Using traction force microscopy to measure the contractile energy the cells exert on their substrate while simultaneously imaging intracellular ATP, we find that contractile energy tracks with rapidly fluctuating ATP levels. We observe a near instantaneous decrease in contractile energy when intracellular ATP is reduced by perturbing glycolysis with 2-deoxy-D-glucose or by reducing culture supplement concentrations (glucose, sodium pyruvate, and L-glutamine). Moreover, we observe reduced actin retrograde flow rates, cell spreading and membrane protrusion dynamics during the reduced intracellular ATP phase, which can be rescued by increasing supplement concentrations. Surprisingly, increasing the availability of the metabolites has no effect. This suggests that cellular contractile energy is tightly coupled to the availability of ATP. Furthermore, we demonstrate that the actin dynamics that drive cell membrane/ blebbing activity consume more ATP than the myosin motors. This suggests amoeboid-like migration has a higher bioenergetic demand than mesenchymal migration. Taken together, these observations demonstrate that cell migration is intricately regulated via the metabolic demand of the cytoskeletal components.

Contractility patterns in actomyosin networks with turnover are controlled by system geometry

M. Savinov[1], A. Krishna[2], N. Ierushalmi[2], A. Mogilner[1], K. Keren[2]; [1]Courant Institute of Mathematical Sciences, New York University, New York, NY, [2]Department of Physics, Technion--Israel Institute of Technology, Haifa, ISRAEL.

Actomyosin network contraction plays an essential role in many cellular processes including motility, division, and intracellular transport. How cells regulate their actomyosin cytoskeleton to generate distinct architectures and contractile dynamics from the same underlying molecular components is still not well understood. Here we tackle this challenging question using a combined experimental and modeling approach.

Our experimental efforts employed a reconstituted actomyosin system, in which cell extracts are encapsulated in water-in-oil droplets. Without any upstream regulation, this system spontaneously self-organizes and generates stable contractile patterns, with flow persisting for hours. Interestingly, we found the contractile behavior was strongly dependent on droplet size. In small droplets, these systems exhibit a dynamic steady-state characterized by radially symmetric inward flow. As the droplet size increases, the networks transition to a state of contractile waves or spirals.

In order to determine the mechanism underlying this size-dependent transition, we developed a mathematical model of the actomyosin network as a compressible, viscous fluid with active stresses representing the local network contraction due to myosin. Whether the network flows due to contraction or experiences viscous drag due to filament linkage is density-dependent; thus, the model considers the coexistence of different local mechanical states with distinct rheological properties. Analysis and numerical simulation demonstrate that our model successfully reproduces key experimental results, most notably that the transition between continuous and periodic contraction occurs at a characteristic length scale that is inversely dependent on the network contraction rate. This model shows how large-scale contractile behaviors emerge from the interplay of network connectivity, essential for long-range force transmission, with motor activity and turnover, which continually rearrange the network.
In conclusion, we demonstrate how varied contraction patterns can arise from the same microscopic constituents, without invoking specific biochemical regulation, merely by a change in the system's geometry. This work has broad implications for how contractile actin networks might behave in different parts of the cell, different stages of the cell cycle, or in cells of different size.

Non-degradative ubiquitination of VASP regulates actin dynamics

L. E. McCormick[1], L. Herring[2], N. G. Brown[2], S. L. Gupton[1]; [1]Cell Biology and Physiology, University of North Carolina At Chapel Hill, Chapel Hill, NC, [2]Pharmacology, University of North Carolina At Chapel Hill, Chapel Hill, NC.

Filopodia are dynamic, actin-rich structures that extend outward from the cell to explore and respond to cues in the local environment. The actin polymerase VASP is a component of the filopodial tip complex, where it regulates actin polymerization and filopodial dynamics. Previously, we showed that VASP transiently co-localizes with the brain-enriched E3 ubiquitin ligase TRIM9 at the tips of neuronal filopodia. TRIM9 was required for the reversible, non-degradative ubiquitination of VASP and this modification was associated with decreased filopodia number and stability. Furthermore, the axon guidance cue netrin promoted deubiquitination of VASP. We hypothesize VASP ubiquitination is a mechanism to negatively regulate actin dynamics by blocking VASP and actin interactions. Through mass spectrometry, we identified numerous lysine residues that are ubiquitinated in VASP. We selected several of these residues for follow-up investigation. Using chemical ubiquitination, we created purified, ubiquitinated VASP to evaluate its activity through in vitro assays. We observe no changes in the tetramerization of ubiquitinated VASP through mass photometry. In preliminary assays, we do not see any changes in the bundling or binding of ubiquitinated VASP to actin filaments through cosedimentation assays. Currently, we are testing the ability of ubiquitinated VASP to accelerate the elongation of actin filaments through actin pyrene polymerization assays. Future work will visualize actin polymerization in the presence of ubiquitinated VASP through TIRF microscopy assays.

B42/P2440

Mechanochemical simulation of stress fiber

H. Ni[1], Q. Ni[2], G. A. Papoian[3], Y. Jiang[4], A. Trache[5]; [1]Institute for Physical Science and Technology, University of Maryland, College Park, College Park, MD, [2]Institute for NanoBioTechnology, John Hopkins University, Baltimore, MD, [3]Department of Chemistry and Biochemistry, University of Maryland, College Park, College Park, MD, [4]Department of Mathematics and Statistics, Georgia State University, Atlanta, GA, [5]Department of Medical Physiology, Texas A&M University Health Science Center, Bryan, TX.

Stress fibers are contractile actomyosin bundles that sense and transduce mechanical force by connecting to extracellular matrix through focal adhesions. Under external mechanical stimuli, stress fibers actively remodel and display properties of viscoelastic materials. For example, experiments show that mechanical stretching immediately increases the contractile force generated by stress fibers, which slowly drops afterwards. The molecular origin for such behavior is not well understood. In this work, we simulated mechanochemical dynamics and force generation of stress fibers using molecular simulation platform MEDYAN. We model the stress fiber as two connecting bipolar bundles attaching to focal adhesions. In the presence of myosin motors and alpha-actinin crosslinkers, the simulated stress fiber is able to generate contractile force that resembles its biomechanical functions. When the stress fiber is extended by tensile pulling, we found instant increase of the contractile force which slowly decreases until reaching a new steady state, in close agreement with experiments. We further show that the characterized timescale of contractile force relaxation is not determined by the external stimuli, instead, is determined by the intrinsic property of the stress fiber: the degree of crosslinking as well as the dynamics of the actomyosin network. Our results provide a molecular explanation on how actomyosin networks respond to mechanical stimuli and have strong implications in understanding the mechanobiology of cells.

B43/P2441

CAP1 and cofilin1: an intimate duet that governs neuronal actin dynamics

M. Rust[1], A. Heinze[1], F. Schneider[1], C. Schuldt[1], S. Khudayberdiev[1], T. Duong[1], R. Stringhi[2], E. Marcello[2]; [1]Institute of Physiological Chemistry, Philipps-University of Marburg, Marburg, GERMANY, [2]University of Milan, Milan, ITALY.

Cyclase-associated proteins (CAP) are evolutionary conserved actin-binding proteins (ABP). *In vitro* studies of the past few years unraveled important functions for CAP in actin treadmilling, as they demonstrated that it accelerates both dissociation of actin subunits from filamentous actin (F-actin) and nucleotide exchange on actin monomers. Mammals express to CAP family members, namely CAP1 and CAP2. Analyses of systemic knockout (KO) mice by us and others unraveled important functions for CAP2 in heart physiology and myofibril differentiation during skeletal muscle development. Instead, due to the lack of appropriate mouse models, the physiological functions of CAP1 in mammals largely remained unknown. We have generated a conditional KO mouse model for CAP1 to study its function in the brain. Brain-specific CAP1-KO mice displayed a defect in neuron connectivity, while other important aspects of brain development were not affected. Impaired neuron connectivity was caused by delayed neuron differentiation, which we demonstrated for hippocampal neurons isolated from CAP1-KO mice. Mechanistically, we found that CAP1 controlled actin turnover and F-actin dynamics during neuron differentiation and that it cooperated with the key actin regulator cofilin1. Moreover, rescue experiments in double KO neurons lacking CAP1 and cofilin1 revealed mutual functional dependence of

both ABP in neuronal actin dynamics and neuron differentiation. Further, we found that CAP1 was relevant for actin regulation not only during neuron differentiation, but also in dendritic spines, the postsynaptic compartment of most excitatory synapses in the vertebrate brain. Consequently, CAP1 inactivation altered dendritic spine density and morphology as well as synaptic function in hippocampal neurons. We showed that CAP1 cooperated with cofilin1 in actin regulation in dendritic spines and that both ABP were functionally dependent on each other at synapses. Together, we identified CAP1 as a crucial regulator for neuron differentiation and synaptic function, and we provide strong evidence for the conclusion that CAP1 and cofilin1 form an intimate duet that governs neuronal actin dynamics.

B44/P2442

Simultaneous Inhibition of the Arp2/3 Complex & Formins Enhances *de novo* Actin Filament Nucleation in *Arabidopsis thaliana*

L. Xu[1], L. Cao[1], J. Li[1], C. J. Staiger[1,2,3]; [1]Department of Biological Sciences, Purdue University, West Lafayette, IN, [2]Department of Botany and Plant Pathology, Purdue University, West Lafayette, IN, [3]EMBRIO Institute, Purdue University, West Lafayette, IN.

Precise control over when, where, and how actin filaments are created in eukaryotic cells leads to the construction of unique cytoskeletal arrays with specific functions within a common cytoplasm. Actin filament nucleators are key players in this activity, which include the conserved Actin-Related Protein 2/3 (Arp2/3) complex that creates dendritic networks of branched filaments as well as a large family of formins that typically generate long, unbranched filaments and bundles. In some eukaryotic cells, these nucleators compete for a common pool of actin monomers and loss of one favors the activity of the other. However, it remains unclear whether this is a common mechanism across kingdoms. In plant epidermal cells, the cortical actin array plays a key role in cell morphology establisment, response to pathogens, and supporting symbiotic microbe interactions; however, the exact role of filament nucleation and the function of different nucleators in coordinating actin filament dynamics in the plant cortical actin is still poorly understood. Here, we combined the ability to image single filament dynamics in living plant epidermal cells with genetic and/or small molecule inhibitor approaches to stably or acutely disrupt nucleator activity. We found that Arp2/3 mutants, *arp2-1* and *arpc2*, or acute CK-666 treatment resulted in a marked reduction of actin filament abundance as well as significantly decreased side-branched nucleation frequency. We also confirmed that both plant Arp2/3 complex and formins were capable of generating side-branched filaments *in vivo*, but Arp2/3-nucleated filaments grew slower and were shorter than formin-nucleated ones. Surprisingly, simultaneous inhibition of both nucleators increased the overall actin filament abundance and enhanced the frequency of *de novo* nucleation events. Collectively, these observations suggest that plant cells have a unique actin filament nucleation mechanism to maintain the dynamic behavior of the homeostatic network of actin filaments in the cortical cytoskeleton.

B45/P2443

Augmented Actin Cable Fragmentation and Slow Turnover Rate of Abp1-GFP with Core-Shelled Quantum dots.

N. Le, J. Routh, C. Kirk, K. Kim; Biology, Missouri State University, Springfield, MO.

Quantum dots (QDs) are nano-semiconductor crystals that emit a broad range of tunable fluorescence. Due to its unique characteristics, QDs have shown vast potential for various industrial and biomedical

applications. However, the lack of knowledge in QDs and its toxicity mechanism has been a great concern for large scale adoption. The goal of our research is to investigate the toxicity of QDs and uncover the mechanism of its toxicity using budding yeast, Saccharomyces cerevisiae, as a model organism. We first tracked quantum dots intracellular trafficking and found that post-internalized QDs are distributed at the early endosome and the late Golgi/ trans Golgi network. Our RNA sequence data revealed a downregulation of AP2, a gene that is important for the initiation of clathrin-coated pit. Consistently, QDs exposure resulted in a longer lifespan of Abp1-GFP patches at the membrane and a slower Abp1-GFP turnover rate after internalization as well as altered polarization of GFP-Snc1. Furthermore, markedly increased levels of fragmented actin cables were observed upon QD treatment for 6 hours. We then tested whether QDs alter Cof1 activity. Using a temperature sensitive mutant strain cof1-22, we found that at permissive temperature, QDs exposure rescued the depolarization of actin patches caused by cof1-22 mutation. We, therefore, came to the conclusion that QDs may directly or indirectly regulate Cof1-mediated actin severing activity. The possibility of QD interaction with Cof1 and QD-mediated elevation of Cof1 expression via protein shotgun identification and iTRAQ-based proteome analysis, respectively, is currently being investigated.

Regulation of Actin Organization by Clathrin Light Chains in Mouse Embryonic Stem Cells

M. Tiwari[1], M. Dingankar[2], A. Solanki[1], D. Subramanyam[1]; [1]National Centre for Cell Science, Pune, INDIA, [2]Indian Institute of Science Education and Research, Pune, Pune, INDIA.

Clathrin mediated endocytosis (CME) is a major studied endocytic pathway for the internalization of macromolecules, proteins and lipids from the plasma membrane. It is implicated in various cellular and biological processes including cellular signaling, motility and polarity. Recent studies demonstrate the importance of CME in the maintenance of mouse embryonic stem cell (mESC) pluripotency. ESCs are derived from the early pre-implantation embryo and are a valuable system to study early developmental cell fate decisions. The major component of CME is the clathrin triskelion, which is composed of three molecules of the clathrin heavy chain (CHC), each of which is associated with the smaller clathrin light chain (CLC). In mammals, there are two clathrin light chains, CLCa and CLCb whose individual physiological roles are poorly understand. CLCs have been shown to help recruit and organize actin to sites of endocytosis in differentiated cells, especially under conditions of high membrane tension. However, their role in mESCs remains unknown. Using the CRISPR-Cas9 genome editing system, we have generated CLC knock out mESC lines. We show that in the absence of only CLCa, or both light chains, actin is disorganized, forming patches in mESCs. Quantitative analysis of actin structures in Clta^{KO} mESCs show lower actin mesh density, increased actin patches, and lower actin branch points compared to WT mESCs. We also observe an enrichment of actin binding proteins Arp3 and cortactin in the patches, suggesting altered actin organization in the absence of clathrin light chains in mESCs. Our results demonstrate a unique role for CLCa in the organization of the actin cytoskeleton in the context of mESCs, and are critical for providing insight into early developmental processes.

F-actin processive polymerization at the minus end

E. Kudryashova[1], A. Ankita[2], H. Ulrichs[2], S. Shekhar[2], D. S. Kudryashov[1]; [1]Chemistry and Biochemistry, The Ohio State University, Columbus, OH, [2]Emory University, Atlanta, GA.

Polarity is a key property of filamentous actin required for its barrier functions, cell migration, and cargo transport. It underlies the ability of the actin cytoskeleton to do productive work either via directional polymerization or the activity of myosin motors. At the functional level, the polarity-dependent filament dynamics are enhanced by actin-binding proteins, whose combined effects favor elongation from the barbed (plus) ends and shortening at the pointed (minus) ends. Pointed-end elongation is disfavored by the logic of cellular organization, the abundance of profilin, and the structural properties of the minus end. Accordingly, all the proteins currently known to promote F-actin polymerization do so at the filament barbed ends. Bacterial and viral pathogens that hijack the actin machinery for self-propelling in the cell cytoplasm also promote actin polymerization at the barbed ends. In striking exception, we found that VopF and VopL bacterial toxins produced by pathogenic *Vibrio* species promote unconventional minus-end F-actin elongation and, therefore, are the first *bona fide* pointed-end processive polymerases. Upon nucleation, the toxins remain associated with the filament pointed end, promoting its elongation even in the presence of profilin, as revealed by single-molecule live-cell and *in vitro* reconstituted TIRFM analyses. The VopF/L-induced nucleation and filament elongation at both ends disrupt cell polarity, undermining the defensive functions of the actin cytoskeleton. Beyond the role in the pathogenesis, the paradigm-shifting discovery of the pointed-end actin processive elongation expands the current view on the functional possibilities achievable with the actin cytoskeleton design.

B48/P2446

Unraveling the effects of Mical-induced oxidation on actin isoforms

E. E. Grintsevich, J. L. Martin; California State University, Long Beach, Long Beach, CA.

The Mical family of enzymes are unusual actin regulators that prime filaments (F-actin) for disassembly via site-specific oxidation of M44/M47. Filamentous actin acts as a substrate of Mical enzymes as well as an activator of their NADPH oxidase activity which leads to hydrogen peroxide generation. Mical enzymes are required for cytokinesis, muscle and heart development, dendritic pruning, and axonal guidance among other processes. Thus, it is critical to understand how this family of actin regulators functions in different cells and tissues. Humans express multiple actin isoforms in cell-specific manner but Mical's impact on their intrinsic properties was never systematically investigated. Our data reveal the differences in intrinsic stability of Mical-oxidized actin isoforms. Furthermore, our results establish a link between actin stability and its activation of NADPH oxidase activity of Mical. Our data suggest that differential properties of actin isoforms translate into the distinct patterns of hydrogen peroxide generation in Mical/NADPH-containing systems. Altogether our results suggest that Mical activities (posttranslational modification of actin and its NADPH-oxidase activity) may have different functional outputs in different cells and tissues depending on the isoform-related identities of local actin networks.

B49/P2447

Cytotoxic T Lymphocyte Activation Signals Modulate Cytoskeletal Dynamics and Mechanical Forces

A. Pathni, A. Özçelikkale, I. Rey-Suarez, S. Davis, N. Rogers, L. Li, Z. Xiao, A. Upadhyaya; University of Maryland, College Park, MD.

CD8+ cytotoxic T lymphocytes (CTLs) play a vital role in the adaptive immune response by killing tumor cells and cells infected with pathogens. During infection, the first signal for naïve CD8+ T cell activation is provided by antigen presenting cells which present pathogenic peptides to the T cell receptor (TCR). Complete activation requires a second signal, provided by the binding of co-stimulatory proteins to the CD28 receptor on the CTL membrane. Inflammatory cytokines, such as interleukin-12 (IL-12), have recently been characterized as a third signal for CTL activation, enhancing proliferation and effector function. Activated CTLs secrete lytic granules containing perforin and granzymes at the CTL-target synapse or the immune synapse (IS), triggering target cell death. The CTL cytoskeleton is instrumental in aiding the killing of target cells: within minutes of contact, the microtubule cytoskeleton reorganizes to allow centrosome translocation to the IS. Lytic granules are transported along microtubules to the IS where granule secretion is regulated by actin depletion and recovery. The cytoskeleton further promotes target killing by mediating mechanical force exertion at the IS. In this study, we hypothesize that the third signal for CTL activation, IL-12, modulates cytoskeletal dynamics and force exertion at the IS, thus potentiating effector function. We use total internal reflection fluorescence (TIRF) microscopy to study actomyosin flows and microtubule tip speeds at the IS of murine CTLs activated with TCR engagement and co-stimulation alone (two signals, 2SI), or additionally with IL-12 (three signals, 3SI). We find that 3SI CTLs have enhanced actin depletion, altered actomyosin dynamics and microtubule growth rates as compared to 2SI CTLs. Rapid TIRF imaging of lytic granules in activated CTLs revealed that granules in 3SI CTLs have altered accumulation patterns and lower velocities than in 2SI CTLs. We further characterize and compare centrosome polarization in 2SI and 3SI CTLs using confocal microscopy. Finally, we use traction force microscopy to show that 3SI CTLs exert greater forces than 2SI CTLs. Our results demonstrate that activation of CTLs in the presence of IL-12 results in differential modulation of the cytoskeleton, thus indicating a potential mechanism via which the third signal can augment the T lymphocyte biophysical response.

PIKfyve regulates lamellipodia dynamics via Rac1 GTPase activation and Kindlin-2 recruitment

G. Luo[1], **H. Karaburk**[1], R. Benyair[1], G. Kreider-Letterman[2], R. Garcia-Mata[2], L. Weisman[1]; [1]University of Michigan, Ann Arbor, MI, [2]The University of Toledo, Toledo, OH.

Cell migration is an essential phenomenon in diverse biological processes including embryonicdevelopment, immune responses, and tissue repair. This directed movement of cells is controlledby chemical cues and signaling pathways. The force generated by actin polymerization within thecells drives cell migration by projecting membrane protrusions at the leading edge of cells. Amongthose protrusions, lamellipodia are the major driver of cell migration and are controlled by actindynamics. There are multiple signaling pathways that drive actin polymerization in lamelloipodiaduring cell migration. One key signaling pathway is based on phosphorylated inositol lipids whichact by interacting with various effector proteins, which in turn organize protein complexes atspecific membrane subdomains. To date, Class I phosphoinositide 3-kinases (PI3Ks), have beenshown to regulate actin polymerization to control cell migration. Importantly, new preliminarydata from our lab

suggests that another lipid signaling pathway may also regulate cell migrationvia actin polymerization at the plasma membrane. Our data show that PIKfyve, a PI3P 5-kinase,which has key roles at the lysosome, additionally localizes to the cell leading edge. Moreover, weobserve that an acute 5-10 minute chemical inhibition of PIKfyve reduces actin levels at cellprotrusions; and impairs lamellipodia dynamics in living cells. Using live-cell imaging, we alsodetect that acute inhibition of PIKfyve results in the concomitant impairment of actin dynamics aswell as loss of Rac1 GTPase activation in lamellipodia. Furthermore, we observe that acuteinhibition of PIKfyve impairs the localization of Kindlin-2, which regulates actin dynamics via atleast two mechanisms. We also observe that Arp2/3 complex recruitment to the plasma membranerequires PIKfyve activity. Together, these findings suggest that PIKfyve regulates lamellipodiadynamics via direct regulation of actin dynamics, and that this occurs in part by activation of Rac1and the recruitment of Kindlin2 to plasma membrane.

Actin Dynamics in Development

B51/P2449

Evolutionary diversification of Arp2 separated somatic versus germline roles

K. A. Stromberg[1], T. Spain[1], S. A. Tomlin[2,3], C. M. Schroeder[1]; [1]Department of Pharmacology, University of Texas Southwestern Medical Center, Dallas, TX, [2]Division of Basic Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, [3]Howard Hughes Medical Institute, Seattle, WA.

The actin cytoskeleton often forms branched networks that are critical in many fundamental cellular processes, including cell motility and division. The Arp2/3 complex, a 7-membered protein complex including actin-related proteins (Arps) 2 and 3, is responsible for generating branched actin. Arp2 is evolutionarily ancient among eukaryotes and under stringent sequence conservation, yet we surprisingly discovered two clade-specific gene duplications of *Arp2* in *Drosophila*: *Arp2D* in the *obscura* clade and *Arp2D2* in the *montium* clade. Our targeted sequencing and phylogenetic analyses show these duplicates evolved independently about 14 million years ago and were retained throughout speciation within their respective clades. The two duplicates exhibit distinct sequence diversification from canonical Arp2 with Arp2D being the most divergent. Because Arp2 is normally conserved, we investigated the gene duplications to determine how evolution can diversify Arp2 structure and function. We first replaced canonical *Arp2* in *D. melanogaster* with *Arp2D* or *Arp2D2* to test whether both duplicates can polymerize branched actin networks similar to their parental gene. Surprisingly, we found both rescue the *Arp2* knockout lethality phenotype despite their sequence divergence. However, *Arp2D*-expressing males were subfertile and had lower sperm production. Cytological analyses revealed defects in the early stages of sperm development. We identified two structural regions in Arp2D that differ from canonical Arp2 and found one novel domain is critical for rescuing lethality, whereas a divergent loop contributes to the testis defects observed in *Arp2D*-expressing males. Based on our findings, we hypothesize that evolutionary diversification of Arp2 led to separation of function between somatic and germline cells, and specific structural elements in Arp2 tune actin branching for these different contexts.

B52/P2450

Dual control of formin-nucleated actin assembly by the chromatin and ER in mouse oocytes

H. Wang[1], **J. HU**[1], K. Yi[2], Z. Ma[3], X. Song[1], Y. Lee[1], P. Kalab[4], A. Bershadsky[1], Y. Miao[3], R. Li[1]; [1]Mechanobiology Institute, National University of Singapore, Singapre, SINGAPORE, [2]Stowers Institute for Medical Research, Kansas, MO, [3]School of Biological Sciences, Nanyang Technological University, Singapre, SINGAPORE, [4]Johns Hopkins University, Baltimore, MD.

The first asymmetric meiotic cell divisions in mouse oocytes are driven by formin 2 (FMN2)-nucleated actin polymerization around the spindle. In this study, we investigated how FMN2 is recruited to the spindle peripheral ER and how its activity is regulated in mouse meiosis I (MI) oocytes. FMN2 contains a nuclear localization sequence (NLS) within an N-terminal spindle localization domain (SLD) previously shown to be required for FMN localization to the spindle periphery. Combining mass spectrometry from oocyte extract and pulldown assay using recombinant proteins, we confirmed FMN2 NLS is bound to the importin α1/β complex. Furthermore, disruption of FMN2-importin interaction in oocytes revealed that RanGTP is required for FMN2 accumulation proximal to the chromatin and the MI spindle. Revisiting FMN2 SLD interactome, along with in vitro pulldown, in vivo Co-IP, and Fluoppi experiments, we confirmed the physical interaction between FMN2 SLD and an ER membrane protein VAPA. Thus, after being recruited and unloaded at the spindle periphery, the importin-free FMN2 is then anchored to the surface of ER around the spindle through SLD-VAPA interaction. Taking advantage of actin polymerization assays (pyrene and TIRF), we also show that FMN2 is autoinhibited through an intramolecular interaction between the N-terminal SLD with the C-terminal formin homology 2 (FH2) domain, which nucleates actin filaments. Surprisingly, we found VAPA binding to SLD relieves the autoinhibition of FMN2, leading to increased actin polymerization. This dual control of formin-mediated actin assembly allows actin polymerization to initiate the movement of the meiotic spindle toward the cortex, an essential step in the maturation of the mammalian female gamete.

B53/P2451

The prophase oocyte nucleus is a homeostatic G-actin buffer

K. Scheffler[1], **F. Giannini**[1,2], T. Lemonnier[1], B. Mogessie[1]; [1]MCDB, Yale University, New Haven, CT, [2]School of Biochemistry, University of Bristol, Bristol, UNITED KINGDOM.

Formation of healthy mammalian eggs from oocytes requires specialised F-actin structures. F-actin disruption produces aneuploid eggs, which are a leading cause of human embryo deaths, genetic disorders, and infertility. We found that oocytes contain prominent nuclear F-actin structures that are correlated with meiotic developmental capacity. We demonstrate that nuclear F-actin is a conserved feature of healthy mammalian oocytes and declines significantly with female reproductive ageing. Actin monomers used for nuclear F-actin assembly are sourced from an excess pool in the oocyte cytoplasm. Increasing monomeric G-actin transfer from the cytoplasm to the nucleus or directly enriching the nucleus with monomers led to assembly of stable nuclear F-actin bundles that significantly restrict chromatin mobility. By contrast, reducing G-actin monomer transfer by blocking nuclear import triggered assembly of a dense cytoplasmic F-actin network that is incompatible with healthy oocyte development. Overall, our data suggest that the large oocyte nucleus helps to maintain cytoplasmic F-actin organisation and that defects in this function are linked with reproductive age-related female infertility.

B54/P2452

The role of nuclear F-actin in oocyte genomic integrity

S. Ghadaouia, F. Giannini, K. Scheffler, B. Mogessie; Yale University, New Haven, CT.

Efficient DNA repair is critical for animal development. Mammalian oocytes are remarkably susceptible to DNA damage and accumulate DNA lesions with advancing maternal age, a phenomenon whose molecular basis remain unknown. The actin cytoskeleton has recently emerged as a protector of oocytes against chromosomal abnormalities. We recently discovered that mammalian oocyte nuclei contain prominent actin filaments that are significantly reduced in reproductively older females. Our new preliminary data show that oocyte genome damage causes excessive assembly and bundling of nuclear F-actin cables. Based on these observations, we hypothesize that nuclear F-actin structures promote DNA repair and that their disruption underlies reproductive aging-related accumulation of DNA damage in oocytes. We will test this exciting hypothesis using a combination of advanced microscopy, localized nuclear F-actin degradation, and DNA damage induction assays. We are combining pharmacological approaches of generating moderate levels of DNA damage with high-resolution live and immunofluorescence microscopy assays to analyze DNA damage repair. These integrated approaches could reveal new actin-based mechanisms of genomic integrity and provide new insights into the causes of reproductive age-related female infertility.

B55/P2453

Investigating mechanisms regulating actin in the early *Drosophila* embryo

A. R. Yeh, A. C. Martin; Biology, MIT, Cambridge, MA.

Actin networks undergo dynamic rearrangements that promote cell and tissue morphogenesis during development. The range of mechanisms that control actin network organization during development is still not fully understood. The *Drosophila* Synaptotagmin-like protein, Bitesize (Btsz), has been shown to organize actin at epithelial cell apical junctions in a manner that depends on its interaction with the actin-binding protein, Moesin. Here, we discovered that Btsz also functions at earlier, syncytial stages of development. In the syncytial embryo, actin organization changes in a cell cycle-regulated manner. In interphase, actin forms structures called caps, which are located above syncytial nuclei. These actin caps grow and collide such that pseudocleavage furrows form between mitotic nuclei and prevent spindles from colliding during the synchronous mitotic divisions. Btsz-RNAi disrupts these pseudocleavage furrows, leading to spindle collisions and other nuclear division defects. Previous studies have focused on how Btsz regulates actin through Moesin. However, there are multiple Btsz isoforms, only some of which contain the Moesin Binding Domain (MBD). Mulitple isoforms are transcriptionally upregulated at the maternal-zygotic transition. We used existing *btsz* alleles and CRISPR/Cas9 to engineer new *btsz* alleles to test the requirement of different Btsz isoforms during syncytial divisions. Our data suggest that non-MBD isoforms are important for proper syncytial development and preventing spindle collisions. We found that the C-terminal half of the Btsz1 isoform can bind F-actin with micromolar affinity which suggests that Btsz can regulate actin directly. This work suggests a novel mechanism for a Synaptotagmin-like protein regulating actin organization during animal development.

Localization Mechanism of The Arf-GEF Steppke During Initial Junction Formation in the Drosophila Embryo

L. Xu, T. Harris; Department of Cell and Systems Biology, University of Toronto-47731885, Toronto, ON, CANADA.

Cytohesins are a class of Arf guanine nucleotide exchange factors (Arf GEFs) that can regulate actin networks and membrane trafficking in several contexts. Steppke (Step) is the sole Drosophila cytohesin, and it has been shown to negatively regulate myosin in several Drosophila developmental processes. Step and its two candidate adaptor proteins, Stepping Stone (Sstn) and Ajuba (Jub), have been shown to be enriched at myosin-rich adherens junctions (AJs), and depend on the actomyosin network for their localization. However, it is unknown when Step is first recruited to AJs or whether Step has the same degree of association with Sstn and Jub. Thus, analyzing embryos from cellularization, where myosin is minimally associated with AJs, to full extension of the germband, where myosin is highly enriched at AJs, we investigated the localization of Step, Sstn and Jub using spinning disk confocal microscopy of fluorescently tagged proteins expressed by endogenous promoters. During cellularization, all three proteins are evenly distributed along the plasma membrane. They first become enriched at tricellular junctions as junctions gain more actomyosin network during Drosophila embryogenesis stage six. All three proteins become gradually more enriched at tricellular junctions as the embryo develops. Other myosin-rich regions that Step, Sstn and Jub are enriched at include apical regions of invaginating tissues such as the ventral furrow and posterior midgut, and the ventral midline. In the amnioserosa, where myosin is gradually lost as the embryo develops, Step, Sstn, and Jub follows a similar pattern, losing junctional signal as time goes on. In addition to having similar localization patterns, we show that Sstn is required specifically for Step enrichment to tricellular junctions during gastrulation, but with Sstn RNAi depletion, Step is still seen evenly distributed along bicellular junctions. Furthermore, we show that Sstn depletion leads to distorted cell-cell interactions across the ectoderm. We are currently investigating the role of Jub in Step localization at these stages. Thus far, our results show that Step and its adaptor proteins are first enriched at AJs as they associate with actomyosin networks, exhibit very similar localization patterns, and that Sstn is required for Step's enrichment to these junctions.

Adipose triglyceride lipase promotes prostaglandin-dependent actin remodeling by regulating substrate release from lipid droplets

M. Giedt[1], J. Thomalla[2], M. Johnson[2], Z. Lai[3], **T. Tootle**[1], M. Welte[2]; [1]Anatomy and Cell Biology, University of Iowa-Carver College Med, Iowa City, IA, [2]Biology, University of Rochester, Rochester, NY, [3]Harvard T.H. Chan Advanced Multi-omics Platform, Harvard T.H. Chan School of Public Health, Boston, MA.

A key factor controlling oocyte quality and fertility is lipids. Even though lipid droplets (LDs) are crucial regulators of lipid metabolism, their roles in fertility are poorly understood. During *Drosophila* oogenesis, LD accumulation in nurse cells coincides with dynamic actin remodeling necessary for late-stage follicle morphogenesis and fertility. Loss of the LD-associated Adipose Triglyceride Lipase (ATGL) disrupts both actin bundle formation and cortical actin integrity, an unusual phenotype also seen when Pxt, the enzyme responsible for prostaglandin (PG) synthesis, is missing. Dominant genetic interactions and PG treatment of follicles *in vitro* reveal that ATGL and Pxt act in the same pathway to regulate actin remodeling, with ATGL upstream of Pxt. Further, lipidomic analysis detects arachidonic acid (AA)

containing triglycerides in ovaries. Because AA is the substrate for Pxt, we propose that ATGL releases AA from LDs to drive PG synthesis necessary for follicle development. We also find that exogenous AA is toxic to follicles *in vitro*, and LDs modulate this toxicity. This leads to the model that LDs both sequester AA to limit toxicity, and release AA via ATGL to drive PG production. We speculate that the same pathways are conserved across organisms to regulate oocyte development and promote fertility.

E-cadherin dependent molecular and biophysical mechanism of epithelial phagocytic clearance in the early vertebrate embryo

H. M. Häkkinen[1], E. Hoijman[2], M. Batet Palau[1,3], L. Bianchi[1,2], S. Wieser[4], V. Ruprecht[1]; [1]Cell and Developmental Biology, Centre for Genomic Regulation (CRG), Barcelona, SPAIN, [2]Universitat de Barcelona (UB), Barcelona, SPAIN, [3]Universitat Pompeu Fabra, Barcelona, SPAIN, [4]The Institute of Photonic Sciences (ICFO), Barcelona, SPAIN.

Cellular errors can lead to spontaneous cell death in the earliest stages of development. We identified that the embryonic surface epithelium mediates efficient phagocytic clearance of apoptotic cells in the early blastula-gastrula embryo and that this mechanism is conserved between zebrafish and mouse (Hoijman *et al.* Nature 2021). We found that epithelial cells form two types of actin-based protrusions during target interactions: 1) phagocytic cups responsible for apoptotic target uptake and 2) “epithelial arms” that are able to exert mechanical pushing forces on targets. Combining experiments and mathematical modeling we showed that both types of protrusions are required for phagocytic clearance by non-motile epithelial cells. We here address the role of cell-cell adhesion in phagocytic clearance by the embryonic epithelium. Using high-resolution quantitative live imaging and genetic tools we identified that E-cadherin, a central regulator of epithelial tissue connectivity, also controls phagocytic tissue clearance. Our results suggest that E-cadherin is required for both phagocytic cup and epithelial arm formation. We further show that E-cadherin is not required for a direct *trans*-binding at the target-epithelial cell interface, but is rather acting upstream of actin polymerization upon target interaction. Pharmacological interference with actin polymerization regulators reveals that Arp2/3 is essential for both phagocytic cup and epithelial arm formation, while Formins are dispensable from epithelial arms. Our data suggest that a lack of Formin prevents the final closure of the phagocytic cup, while a lack of Arp2/3 inhibits its entire formation. These findings reveal distinct functions of actin regulators in controlling epithelial protrusions plasticity and establish a new function of E-cadherin mediated tissue connectivity that controls efficient phagocytic tissue clearance.

The F-actin disassembly factors, Capulet and Flare, regulate distinct pools of actomyosin dynamics to promote epithelial remodeling during *Drosophila* gastrulation

M. A. Collins, A. C. Martin; Department of Biology, Massachusetts Institute of Technology, Cambridge, MA.

During development, epithelial tissues undergo extensive remodeling events that transform an embryo from a simple sheet of cells to a complex three-dimensional organism. Such morphogenetic changes are driven by the intrinsic mechanical properties of individual cells within the tissue as well as the forces these cells actively generate, both of which are regulated by the contractile actomyosin cytoskeleton. While the spatial and temporal coordination of actomyosin assembly and force generation has been

extensively studied in morphogenesis, regulation of actomyosin disassembly, and its impact on cellular mechanics, is less well understood. Using *Drosophila* gastrulation as a model, we found that two different mediators of actin disassembly, Capulet and Flare, have strikingly distinct localization patterns during mesoderm invagination. Capulet and Flare are both implicated in modulating Cofilin's activity to sever and disassemble actin filaments (F-actin), suggesting they have pivotal roles in controlling where F-actin is disassembled. Mesoderm invagination involves the inward folding and internalization of a subset of cells along the ventral surface of the embryo. Before invagination onset, Capulet protein is confined to dense patches on the medioapical surface of cells throughout the epithelium. Furthermore, Capulet patch size scales with apical surface area; Capulet accumulations shrink in constricting cells (mesoderm) while those in non-constricting cells (ectoderm) do not change in size. In contrast to Capulet, Flare is only recruited to the cell cortex as the mesodermal cells (*Twist*-expressing) begin to fold inward. Once the mesoderm is internalized, Flare becomes enriched along the closure seam and junctional in the neighboring ectoderm tissue (*Twist*-negative). Pharmacological inhibition of Rho-kinase results in diffuse Flare, suggesting that Flare recruitment to junctions within the ectoderm may depend on intercellular forces. Finally, depletion of Capulet or Flare disrupted closure of the folding mesoderm, highlighting a key role for actin disassembly during this process. Together, these data suggest that Capulet and Flare spatially regulate the dynamics of distinct apical and junctional F-actin pools to promote mesoderm invagination.

AID-ing our understanding of the *Drosophila* actin mesh

H. M. Bailey, M. E. Quinlan; Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, CA.

The process of egg development, oogenesis, is highly conserved and crucial for producing offspring. *Drosophila melanogaster* have long served as a model system to understand aspects of egg development including stem cell and germ cell development, meiosis, cell migration, intercellular signaling and mRNA localization. An essential component of oogenesis in *Drosophila* is the presence of a cytoplasmic actin meshwork that spans the oocyte and persists during mid-oogenesis. This complex actin network is built by the collaboration of actin nucleators, Spire and Cappuccino (Spir and Capu). The composition, organization, stabilization, and removal of the mesh remain unknown. This is, in part, due to the requirement for actin binding proteins in early oogenesis and our inability to visualize removal of the actin mesh because egg chambers expire *ex vivo* just prior to this transition. To overcome these obstacles, I am developing methods to directly observe this meshwork and study the underlying regulatory mechanisms of the mid to late oogenesis transition. I am utilizing the Auxin Inducible Degradation (AID) system to test the requirement of candidates in mesh regulation. AID is composed of three components; a protein tagged with the AID motif (candidate), Tir1 (a transgenic auxin receptor), and the plant hormone auxin. When cells have all three components, the candidate is ubiquitinated on the AID motif and sent to the proteasome for degradation. Using this system in mid-oogenesis will allow for temporal control and removal of the candidate proteins and determining their role in mesh stabilization, maintenance, organization, and removal. Thus, far I have endogenously tagged Spir, Capu, and Myosin V (didum) with the AID degron. I have been working to optimize conditions for removal of the candidates on a biologically meaningful timescale. I am taking multiple approaches to visualize the effects of candidate removal on the mesh in real time. These include using flow chambers for drug treatment and using an adapted Windowmount (O'Brien lab) method to visualize oogenesis. Altogether,

my work will facilitate a detailed characterization of the actin mesh that can translate to studies in other organisms and provide a powerful tool to the *Drosophila* research community.

The cortical actomyosin cytoskeleton is spatiotemporally dynamic in the C. elegans oogenic germline syncytium over short and developmental time scales

J. Linehan, M. Werner, D. Lee, S. Marron, A. Maddox; University of North Carolina, Chapel Hill, NC.

The production of a female gamete with sufficient cytoplasmic volume to support embryogenesis involves the spatial-temporal coordination of intercellular signaling, cell architecture, differentiation, and cell cycle progression. Oocytes are produced by syncytia, tissue-like cells consisting of many partially compartmentalized nuclei connected to a common cytoplasm by stable actomyosin rings. In *C. elegans*, oogenesis is carried out in a U-shaped germline. Mitotic germline stem cell compartments divide at one end of the syncytium, and compartments are gradually displaced along the length of the syncytium as they proceed through stages of prophase of meiosis I, over the course of 40+ hours. Cytoplasm flows into the syncytial central core from nurse cell-like compartments and apoptotic compartments, and into rapidly growing presumptive oocytes proceeding around the bend. It remains unknown how cortical contractility and the size of compartments and their actomyosin rings are differentially regulated in enlarging, cellularizing and apoptotic germ cells. Here we report that distribution of actomyosin is highly variable throughout the germline and that levels of actomyosin on intercellular bridge rings are not sufficient to explain ring size dynamics during oogenesis, suggesting that this process is regulated by a balance of mechanical forces. While the actomyosin rings rimming cytoplasmic bridges are relatively stable, actomyosin rings close in several contexts: when stem cells divide mitotically, when compartments undergo apoptosis, and when presumptive oocytes cellularize. To analyze actomyosin ring dynamics in the germline, we developed a method of mounting *C. elegans* that sustains reproductive health for multiple hours. Using this technique, we collected multi-hour time-lapse fluorescence image series of ring closure during stem cell cytokinesis, compartment apoptosis, and cellularization. Closure speed does not scale with initial ring size for these three different kinds of rings, as we and others have shown occurs in other *C. elegans* cell types. This indicated that germline rings ingress via distinct and novel mechanisms. The density dynamics of the scaffolding protein anillin (ANI-1) and of non-muscle myosin II (NMY-2) throughout ingression are also distinct among germline ring types. Using a theoretical framework, we found that fitting ring protein density dynamics depended on a unique combination of parameter values (cortical contributions, positive and negative feedback loops, and ring size) for each ring type. Together, our findings support the conclusion that the mechanisms of ring intrinsic contractility are distinct among the three contexts of ring closure in the shared cytoplasm of the *C. elegans* oogenic germline syncytium.

RhoA regulator-mediated control of cortical actomyosin patterning in the *Drosophila* egg chamber and embryo

J. A. Jackson[1], M. Denk-Lobnig[2], A. C. Martin[1]; [1]Biology, Massachusetts Institute of Technology, Cambridge, MA, [2]Department of Biopyhsics, University of Michigan – Ann Arbor, Ann Arbor, MI.

Spatiotemporal regulation and polarization of force generation within cells by cortical actomyosin is critical to development. As a result, actomyosin contractility is subject to multiple layers of regulation

and feedback, notably through the RhoA GTPase/Rho kinase pathway. We discovered traveling waves of actomyosin in nurse cells in late-stage *Drosophila* egg chambers, during which these fifteen support cells rapidly transfer their contents to the growing oocyte. These cell-scale waves lead to heavy shape deformation and initiate after each cell has shrunk to 25% its original volume. We show that actomyosin waves are regulated by the GTPase-activating protein (GAP) RhoGAP15B and the guanine nucleotide exchange factor (GEF) Pbl/Ect2. Both RhoGAP15B and Ect2 localize to the nucleus in the earlier stages of oogenesis and become cytoplasmic prior to wave onset, suggesting that release of GAP and GEF is responsible for wave onset. Furthermore, we found that we could induce similar actomyosin waves in the embryo during gastrulation, in which actomyosin behavior is normally pulsatile, by simultaneously overexpressing a GEF (RhoGEF2) and GAP (RhoGAP71E/C-GAP). Overall, these results suggest that transitions between cortical actomyosin patterns are controlled through dynamic activation and inactivation of RhoA and its effectors rather than by overall RhoA activity levels. We are continuing to investigate how systematic perturbation of GAP and GEF levels affects spatiotemporal actomyosin behavior in different developmental contexts.

Growth of a *Drosophila* embryo actin cap begins with apparent coupling of Arp2/3 network induction and exocytosis at plasma membrane infolds organized by centrosomes

R. Tam, N. Vergara Ruiz, T. Harris; Cell and Systems Biology, University of Toronto-47731885, Toronto, ON, CANADA.

Centrosomes spatially organize the actin cortex and membrane secretion in various cellular processes, but the coupling of these effects is incompletely understood. In the syncytial *Drosophila* embryo, nucleus-associated centrosomes induce cortical actin caps which grow into dome-like compartments to house each mitotic apparatus. The actin cap grows to meet an actomyosin border which exerts tension on the actin cap. Compartment formation requires Arp2/3 actin networks and membrane exocytosis, and early caps have a folded topography. Thus, we hypothesized that plasma membrane infolding is coupled with the earliest stages of Arp2/3 network induction and membrane secretion organized by the centrosome. Live imaging the nascent cap revealed plasma membrane folds and tubules in proximity to centrosomal microtubules. As the cap grew, the folds and tubules shifted to its periphery and apparently joined the sides of the forming dome while the dome surface flattened. Centrosome disruption by centrosomin RNAi reduced the initial plasma membrane folds and tubules, suggesting they are pulled inward by centrosomal microtubules. This local infolding seems to overcome a general cortical tension, since weakening the actomyosin cortex by myosin depletion resulted in ectopic folding between centrosomes. The tubules extended from the base of folds and colocalized with Rab8-positive membranes, suggesting sites of exocytosis. Moreover, an Arp2/3 induction pathway (the Rac-GEF Sponge, Rac-GTP, and SCAR), Arp3, and F-actin were enriched at the centrosome-proximal folds and tubules relative to non-centrosomal-associated natural and ectopically-induced folds. Depletion of Arp3 resulted in abnormal aggregation of the centrosome-associated plasma membrane folds, indicating that local induction Arp2/3 networks normally separates the folds and tubules. We propose that centrosome microtubules pull the plasma membrane inward to couple exocytosis and Arp2/3-induction pathways, and that local Arp2/3-based actin polymerization may push the membrane structures apart to optimize exocytosis and promote subsequent expansion of the cap.

Plasma membrane organization and dynamics in relation to the actomyosin network of the early syncytial Drosophila embryo cortex

R. K. Naidoo, T. J. C. Harris; University of Toronto, Toronto, ON, CANADA.

The cell cortex is a thin layer of actin cytoskeleton that associates with the inner leaflet of the plasma membrane (PM). The primary functions of the cell cortex are to provide structure and force generation, giving the cell highly polymorphic and dynamic remodelling properties essential for processes such as cell division, migration, and cell-cell adhesion. Studying how materials organize at the cortex and how they interact as a composite during dynamic events provides holistic understanding of cortical remodelling processes. The syncytial preblastoderm stage of Drosophila embryogenesis provides a system to study the structure of the PM and actomyosin across a large and relatively uniform cortex, and additionally how the structure behaves during actomyosin assembly/disassembly cycles. Here, using a combination of spinning disk confocal microscopy, 3D reconstruction soft- ware, and genetic perturbation we have characterized structural interaction between the PM, actomyosin network, and endoplasmic reticulum (ER) membrane during cyclic preblastodermal contraction. We dual-imaged the PM and myosin and observed that the PM structure is organized into three distinct layers which fold above and below the actomyosin cortex. The continuity of this membrane was verified using 3D reconstruction analyses. The folded structure, identity of the three structural layers, and positioning of the myosin network within the middle PM layer, were supported with additional probes. We then asked if the two materials were interacting with each other during myosin contractile activity and observed that myosin recruitment to the cortex correlated with condensation of PM undulation in XY and Z. Next we asked if the intertwined recruitment of myosin with the PM played a role in PM structure by disrupting heavy chain myosin using shRNA. Myosin perturbation resulted in abnormal structure of the PM where the size of undulation and the thickness and depth of the membrane significantly increased. Together, these results show that the myosin network affects the folded structure of the PM, indicating that they are an integrated material. We then investigated the bottom layer of the PM structure below the actomyosin cortex by dual-imaging the PM with the ER membrane. We found that the bottom layer of the PM overlaps with ER membrane tubules and together they follow contractile dynamics of the cortex. We propose a model of the cell cortex in which the PM undulates above and below the actomyosin cortex and its bottom layer folds meet with ER membranes. We hypothesize that the intertwined relationship between the PM and myosin network, and contact between the PM and ER regulate myosin network translocation during graded cortical contractility.

B65/P2463

Interrogating Differential Contributions of Adhesion Proteins BOC and CDON to Sonic Hedgehog Cytoneme Formation

C. A. Daly, E. Hall, D. Stewart, S. Ogden; Cell and Molecular Biology, St Jude Children's Research Hospital, Memphis, TN.

Proper physiological development relies on cell-to-cell communication via secreted morphogens. These signaling molecules facilitate long distance cellular communication in temporal- and tissue-specific manners to instruct cell fate and pattern tissues. Sonic Hedgehog (SHH) morphogens play integral roles in a variety of developmental processes including neural tube patterning and limb development. SHH-producing cells extend thin, actin-based projections termed “cytonemes” that facilitate direct transport

of ligand to signal-receiving cells. To permit mechanistic studies on cytonemes in mammalian systems, our lab developed protocols that allow preservation of cytonemes for confocal analysis in cultured cells and murine embryos. Using these techniques, we found that expression of SHH promotes cytoneme initiation in cultured murine fibroblasts. We determined that while Dispatched (DISP) deployment receptor is largely dispensable for cytoneme formation, it is critical for efficient loading of SHH into cytonemes both *in vitro* and *in vivo*. Notably, the structurally related SHH coreceptors CDON (Cell adhesion-associated Down-regulated by Oncogenes) and BOC (Brother of CDON) mediate SHH-induced cytoneme formation and stability. Further study of these three receptors led to identification of an interaction between DISP and BOC that occurs independent of SHH ligand status. Conversely, DISP and CDON interact in the absence of SHH and disengage upon SHH binding to DISP. These results, along with the different expression domains of BOC and CDON in the developing embryo, point towards distinct roles of the coreceptors in signal relay from the SHH-producing tissue. Since loss of both BOC and CDON ablates SHH-induced cytonemes, one of these functions appears to be activation of cytoneme-initiating signaling occurring downstream of SHH-coreceptor engagement. However, the specific interactions and intracellular signaling pathways that result in cytoneme initiation have yet to be identified. My focus is to clarify the SHH-activated signals occurring in response to its association with CDON, BOC, and/or DISP that drive cytoneme-mediated transport of SHH during embryonic development.

B66/P2464

Investigating tropomyosin isoform localization and function during sea star development

V. Montenegro, C. B. Shuster; Department of Biology, New Mexico State University, Las Cruces, NM.

Spatial segregation of viscoelastic and contractile actin networks helps drive critical cell shape changes such as polarized cell migration and cytokinesis. Tropomyosin (Tpm) represents an actin-binding protein whose differential effects on filament branching, actin depolymerization and myosin contractility may help define these different cytoskeletal networks. In vertebrates, four genes are alternatively spliced to generate 28 different isoforms, which display different effects on actin organization, diverse expression patterns and differing levels functional redundancy. However, the isoform-specific roles of Tpm splice forms in regulating cellular mechanics during cell division and early development remain unclear. In the sea star Patiria miniata, a single Tpm gene gives rise to three long and two short isoforms, and in oocytes, mRNA for one long (X3) and both short isoforms (X4 and X5) were detected. To explore the spatial dynamics of these proteins, fluorescent fusions for Tpm X3 and X4 were expressed in Patiria oocytes and embryos. Both isoforms localized to the cortex prior to meiosis I and were recruited to actin flares upon hormone addition. Upon germinal vesicle breakdown, both isoforms were largely cleared from the cortex, tracking with previously described decreases in cortical actin. Surprisingly, neither isoform was enriched in the polar body contractile ring, where it has been long assumed to be essential, but both isoforms were enriched in the polar body. Throughout early embryogenesis, X3 and X4 became increasingly restricted to the apical cortex and adherent junctions, but could also be detected on the mitotic spindle and at the nuclear envelop just prior to NEB. During mitosis, X3 and X4 remained largely cortical, and neither isoform could be detected in the contractile ring. To determine the specific functions of the three expressed Tpm isoforms during meiosis and early development, morpholinos against X3-X5 were designed. Oocyte maturation, fertilization and early cleavage were normal in morphants, but depletion of either long or short Tpm isoforms failed to form a midgut, which normally expands dramatically during late gastrulation. While these results support a role for Tpm in ensuring the integrity of the apical actin cytoskeleton in epithelia, current efforts are focused on achieving

phenotypes earlier in development to better understand the role of these proteins in determining the cellular mechanics of meiosis and early embryonic cleavages.

B67/P2465

Transgelin as a Regulator of Myofibroblast Differentiation in Epithelial to Mesenchymal Transition

G. Emin; University of Delaware, Newark, DE.

Cellular differentiation into highly contractile myofibroblasts can be a major underlying cause of morbidity and mortality in a large number of fibrotic diseases. Filamentous (F-)actin reorganization into stress fibers and the incorporation of alpha smooth muscle actin (αSMA) into these stress fibers play a critical role in myofibroblast differentiation. An understanding on the regulation of F-actin reorganization could lead to the development of therapeutic interventions against fibrosis. Transgelin (TAGLN), is an actin associated molecule that is upregulated early during fibrotic EMT. It is speculated that TAGLN is required to cross-link F-actin for stress fibers formation, but this remains unclear. In addition, it is not certain if TAGLN regulates the incorporation of αSMA. This led us to test the hypotheses that Tagln is required for the differentiation of epithelial cells to myofibroblasts by promoting (1) stress fiber formation and (2) the incorporation of αsma into the stress fibers.
We developed an ex vivo whole organ model of fibrosis by placing isolated mouse ocular lenses in culture. In this model we saw F-actin reorganization into stress fibers within 1 hour. This also resulted in an increase in αsma and Tagln mRNA levels, demonstrating co-regulation. Next we used an in vitro model of fibrosis to determine the association of Tagln with stress fibers and asma. Exposure of cultured immortalized mouse lens epithelial cells (imLECs) to TGFβ2 resulted in co-upregulation of Tagln and αsma mRNA and protein levels. Using fluorescence confocal microscopy, we find that of the cells that organized F-actin into stress fibers, 40% do not express TAGLN. Intriguingly we found that all the cells that incorporated αSMA express TAGLN. Exposure of imLECs to TGFβ2 increases the proportion of cells, from 17% to 26%, that have αSMA and TAGLN in stress fibers.
Our data thus far suggests that stress fiber formation is not necessarily dependent on TAGLN, but that αSMA incorporation may be dependent on TAGLN. Ongoing TAGLN knockdown/knockout studies will determine if TAGLN binding to F-actin is required for αSMA incorporation. Understanding the role of TAGLN in myofibroblast differentiation and the generation of contractile forces will provide insight into whether targeting TAGLN could be a means of preventing the transition of cells into myofibroblasts during fibrosis.

B68/P2466

Comprehensive analysis of actin binding proteins and actin nucleation factors in erythropoiesis reveals Tensin1 as a novel actin regulator in erythroid terminal differentiation

A. Ghosh[1,2], S. Barndt[3], M. Coffin[4], J. Mason[4], V. Fowler[4], S. Lo[5]; [1]Biological Sciences, University of Delaware, Newark, DE, [2]Delaware Biotechnology Insititute, Newark, DE, [3]Medical and Molecular Sciences, University of Delaware, Newark, DE, [4]University of Delaware, Newark, DE, [5]School of Medicine, University of California, Davis, CA.

Mammalian red blood cells (RBCs) are generated in a terminal erythroid differentiation pathway culminating in cell polarization and expulsion of the nucleus (enucleation). Actin filament polymerization is critical for enucleation, but the molecular mechanisms for either are not well understood. We utilized publicly available RNA-seq and proteomics datasets to analyze actin-binding proteins and actin

nucleation factors differentially expressed during erythroid terminal differentiation. We discovered that the focal adhesion protein, Tensin1 (TNS1), shows a dramatic increase in expression during terminal erythroid differentiation at both transcriptional and translational levels. This contrasts with other actin-binding proteins that either decreased or showed a minor increase in expression during erythroid differentiation when compared to TNS1. Tensins are a family of proteins typically found at specialized cell-matrix focal adhesions. TNS1 is the largest of the four proteins in this group with a predicted molecular weight of ~185 kDa, containing N-terminal and internal actin-binding domains, and C-terminal SH2 and PTB domains. We found that human CD34+ cells differentiated to erythroid cells express a novel truncated form of TNS1 (e-TNS1) (predicted MW ~125 kDa) missing the N-terminal actin-binding domain, likely due to an internal TNS1 mRNA translation start site. We performed CRISPR/Cas9 gene editing of the e- TNS1 gene in CD34+ cells prior to differentiation and examined the effects of loss of e-TNS1 in terminally differentiated erythroid cells via a combination of cellular and biochemical analyses. In cells with TNS1, confocal microscopy revealed that e-TNS1 is localized in the cytoplasm during terminal erythroid differentiation, with no apparent membrane association or focal adhesion formation. Similar to our previous studies, we observed distinct foci of F-actin in differentiated cells with a polarized nucleus, and in enucleating cells. By contrast, cells lacking e-TNS1 post-Cas9-mediated gene editing were found to have greatly reduced F-actin foci. Interestingly, we also observed that the Glycophorin-positive erythroblasts lacking TNS1 were significantly larger than cells with TNS1, suggesting a role for TNS1-regulated F-actin polymerization in cell size reduction late in terminal differentiation. In conclusion, our study shows that e-TNS1 is a novel regulator of erythropoiesis with a critical role in terminal erythroid differentiation of human CD34+ hematopoietic stem cells via regulating F-actin polymerization as well as cellular size reduction. We speculate that e-TNS1 signaling pathways enable the F-actin reorganization necessary for enucleation and formation of mature RBCs.

B69/P2467

Myo1c regulates neurite formation in mouse cortical neuron through regulating F-actin aggregation and actin-membrane interplay

X. Liu, S. Bennison, K. Toyooka; Drexel University School of Medicine, Philadelphia, PA.

Myosins are actin-binding proteins that are most notable for functioning as actin motor proteins. MYO1C belongs to the class 1 myosin, and it is encoded in the Miller-Dieker syndrome critical region on human chromosome 17p13.3. Neurodevelopmental defects including impaired neurite formation are common in MDS patients, however, MYO1C's roles in neurons and neurodevelopment are unclear. We found mouse Myo1c is expressed in the cerebral cortex from embryonic to neonatal stages. To study Myo1c functions, we knocked down Myo1c in layer 2/3 cortical pyramidal neurons using *in utero* electroporation and discovered defects in neuronal morphogenesis in Myo1c-depleted neurons, including shorter apical dendrites at P3 and decreased neurite number at P12. *Ex vivo* live imaging reveals that Myo1c KD neurons in layer2/3 grow neurites faster than the control, suggesting a disruption in the polarity due to lack of Myo1c. In *in vitro* mouse cortical neurons, besides a reduced number of neurites, Myo1c KD also causes a shorter axon. These together suggest that Myo1c plays essential roles in neurite outgrowth. In neuromorphogenesis research, an ongoing question is how actin and cell membrane cooperate to extend protrusions and neurites. Immunocytochemical analysis shows Myo1c is highly expressed at the filopodial and lamellipodial region in stages 1 and 2 of neurite outgrowth colocalizing with F-actin aggregation, which is an essential step in neurite outgrowth. This indicates the association of Myo1c with F-actin organization during the early stages of neurite formation. Myo1c KD in

cortical neurons in DIV0 shows a reduction of F-actin aggregates in the soma area, suggesting a role of Myo1c in promoting F-actin aggregation. On the other hand, Myo1c can link to the lipid rafts in the cell membrane through interaction with phosphoinositide PIP2. Lipid raft isolation followed by western blot shows that Myo1c level in lipid raft is high during neurite initiation. The treatment of neurons with MBCD, a lipid raft disruptor, shows similar phenotypes as seen in Myo1c KD neurons. These include the disrupted Myo1c localization as well as F-actin localization.To identify the molecular signaling pathway, we performed the co-immunoprecipitation analysis and we identified Myo1c bound to ADNP, a strong autism risk protein as well as a responsible gene for ADNP syndrome. This further indicates the importance of Myo1c in neurodevelopment and neurodevelopmental disorders. Together, these shed light on Myo1c's novel role in the regulation of actin and potentially serve as a promoter in the membrane-actin coupling during neurite initiation.

The Roles and Regulation of Capping Protein in Cortical F-actin Network Organization in the *C. elegans* Zygote

S. E. Yde[1], R. S. Kadzik[1], E. Munro[1,2,3], D. R. Kovar[1,2,3,4]; [1]Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, [2]Committee on Development, Regeneration, and Stem Cell Biology, University of Chicago, Chicago, IL, [3]Institute for Biophysical Dynamics, University of Chicago, Chicago, IL, [4]Department of Biochemistry and Molecular Biology, University of Chicago, Chicago, IL.

The actin cytoskeleton is highly dynamic and continually remodeled during organism development in order to accomplish many fundamental tasks, including polarity establishment, cell division, morphogenesis, and endocytosis. To perform these functions, architecturally distinct filamentous (F-) actin networks must coexist within a cell. Thus, how cells assemble, maintain, and disassemble functionally diverse F-actin networks from a common pool of actin and actin-binding proteins (ABPs) in a shared cytoplasm is an important question. A key determinant of a specific network's architecture and dynamics is the length of actin filaments within the network. Capping protein (CP) acts as an important regulator of actin filament length, by binding the fast-growing barbed ends of actin filaments to prevent further assembly or disassembly.We are combining *in vitro* reconstitution with *in vivo* analysis to investigate the mechanistic role(s) that *C. elegans* CP (*Ce*CP) plays in actin cytoskeleton self-organization in the one-cell *C. elegans* embryo (zygote). In polarized zygotes, two distinct F-actin structures assemble at the anterior cortex, both of which contain *Ce*CP. Filopodia assemble during early mitosis, and mini-comets assemble during late mitosis. In zygotes depleted of *Ce*CP via RNAi, the size and number of filopodia is significantly increased, the time period of filopodia appearance is extended, and there is a corresponding decrease in the assembly of mini-comets. This suggests that in addition to maintaining the architecture, abundance, and timing of the assembly of individual networks, *Ce*CP also plays an important role in controlling the balance of actin incorporation into competing structures.In addition to *Ce*CP's distinct roles in different F-actin networks, we have determined drastic differences in the lifetimes of *Ce*CP-actin barbed end-binding events *in vitro* (t_{half}=~650 s) and *in vivo* (~8 s). These data suggest that there are additional factors that regulate the association of *Ce*CP with actin filaments *in vivo*. We are currently investigating the role of multiple putative CP regulators in the *C. elegans* zygote. We hypothesize that these regulators are differentially active in different networks in order to assemble filaments of varying lengths. Interestingly, we have observed that CARMIL, a canonical CP regulator, localizes preferentially to the shafts of the filopodia. We are currently investigating the differential

regulation of CP within different F-actin networks using *in vivo* imaging of endogenously tagged proteins, RNAi knockdowns, and *in vitro* reconstitution with purified proteins.

Actin-Membrane Interactions

Phase separation properties determine the*in vivo*function of adaptor proteins in myoblast fusion.

R. Zhang, **D. Tong**, P. Pandey, Z. Ruan, D. Lee, E. Chen; Univeristy of Texas Southwestern Medical Center, Dallas, TX.

Cell surface transmembrane receptors often form nanometer- to micrometer-scale clusters to initiate signal transduction in response to environmental cues. At the sites of Drosophila myoblast fusion known as the fusogenic synapse, Ig domain-containing cell adhesion molecules (CAMs) accumulate in clusters and recruit over a dozen additional proteins to facilitate cell membrane fusion. These proteins are enriched in a “focus” to promote actin polymerization and invasive membrane protrusions. The SH2 and SH3 domain-containing adaptor proteins, Crk, Drk, and Dock, are known to link CAMs and the actin cytoskeleton. However, which adaptor protein replays the cell fusion signal from the CAM, Sticks and stones (Sns), to the actin cytoskeleton remains a longstanding question. Using an *in vitro* phase separation assay, we found that the cytodomain of Sns phase separated by itself and that Crk, but not Drk or Dock, partitioned into the Sns condensates. Correspondingly, Crk was recruited to the liquid droplets formed by Sns cytodomain in cultured S2R+ cells. Moreover, *crk*, but not *drk* and *dock*, mutant embryos exhibited a severe myoblast fusion defect, despite the accumulation of Sns and F-actin at the fusogenic synapse. EM analysis showed that in *crk* mutant, the invasive protrusions were abnormally wider, indicating disorganized actin filaments within these protrusions. We further show that the actin-binding WASP-interacting protein Solitary (Sltr) was no longer recruited to the fusogenic synapse in crk mutant embryos. Taken together, our study demonstrates that the distinct phase separation properties of the small adaptor proteins determine their *in vivo* function in myoblast fusion, and suggests that Sltr is recruited to the Sns-Crk condensate at the fusogenic synapse to increase the mechanical strength of the actin cytoskeleton, allowing the formation of narrow invasive protrusions to promote cell membrane fusion.

Self-organized Rho and F-actin patterning in an artificial cortex

J. Landino[1], M. Leda[2], A. Michaud[3], Z. T. Swider[3], M. Prom[3], C. M. Field[4], W. M. Bement[3], A. G. Vecchiarelli[1], A. B. Goryachev[2], A. L. Miller[1]; [1]University of Michigan, Ann Arbor, MI, [2]University of Ediburgh, Edinburgh, UNITED KINGDOM, [3]University of Wisconsin, Madison, WI, [4]Harvard Medical School, Boston, MA.

The cell cortex, comprised of the plasma membrane and an underlying meshwork of filamentous actin (F-actin), is remodeled during a variety of essential biological processes including cell adhesion, cell migration, and cell division. Previous work has shown that prior to large-scale remodeling, the cell cortex is dynamically patterned with subcellular waves of F-actin assembly and disassembly, a phenomenon termed “cortical excitability”. In developing embryos, cortical excitability is generated through coupled positive and negative feedback, with rapid activation of F-actin assembly driven by the small GTPase Rho, followed in space and time by inhibition of Rho activity Investigating the mechanisms that support

and regulate cortical patterning is currently limited by a lack of technical approaches that can bridge our understanding of biochemical feedback signaling and cortical pattern formation, including the molecular regulation of signaling molecules, membrane dynamics, and cytoskeletal remodeling. A breakthrough in this gap in knowledge has been the development of an “artificial cortex”, made from supported lipid bilayers (SLBs) and *Xenopus* egg extract, which successfully reconstitutes active Rho and F-actin dynamics in a cell-free system. This reconstituted system spontaneously develops two distinct types of self-organized cortical dynamics: singular excitable Rho and F-actin waves, and non-traveling oscillatory Rho and F-actin patches. Like *in vivo* cortical excitability, patterning in the artificial cortex depends on Rho activity and F-actin polymerization. We also find that SLB fluidity directly influences the propensity for pattern formation in the artificial cortex, which suggests dynamic membranes support cortical patterning. These findings reveal that the cell cortex is a self-organizing structure and present a novel approach for investigating mechanisms of Rho-GTPase-mediated cortical dynamics.

Actin cortex drives membrane tension propagation in cells

H. De Belly[1], S. Yan[2], H. Borja da Rocha[3], S. Ichbiah[3], J. Town[1], H. Turlier[3], C. Bustamante[2], O. Weiner[1]; [1]UCSF, San Francisco, CA, [2]UC Berkeley, Berkeley, CA, [3]College de France, Paris, France

For proper regulation of physiology, cells need a way to bridge local biochemical signalling events to cell-wide responses. Membrane tension has been proposed serve this integrative role for cell migration, cell cycle, and cell fate. How far membrane tension propagates in cells is not well understood, with conflicting data in the field, some indicating that membrane tension rapidly propagates across the entire cell and other studies indicating that membrane tension is locally constrained. We hypothesized that some of these discrepancies could be due to methodological differences, such as exogenous force application that may not accurately mimic endogenous forces. To help resolve this controversy, we are using surgical optogenetic tools to trigger focal endogenous mechanical perturbations (such as cell protrusion) in combination with precise multipoint force measurements using a dual optical tweezer setup. Our work reveals that actin driven mechanical perturbations, like those occurring during cell protrusion, lead to rapid membrane tension propagation across the cell with little to no attenuation. In stark contrast, exogenous mechanical perturbations including pulling on the membrane only (such as tether pulling) are locally constrained and do not propagate across the cell. We develop a simple mathematical mechanical model of the cell that captures these key observations and suggests that the cortex and membrane act as an integrated system for propagating mechanical forces across the cell. Our work reveals that the plasma membrane is indeed a long-range integrator of mechanical information across the cell, but only when engaged in a context where forces are applied to both the membrane and cortex, as in a cellular protrusion.

B74/P2472

Wiskott-Aldrich Syndrome protein promotes antigen-specific selection of germinal center B-cells by modulating antigen presentation and mitochondrial function

Y. Li[1], R. Dai[1], J. van Haaren[2], A. Bhanja[2], X. Zhao[1], **W. Song**[3]; [1]Chongqing Key Laboratory of Child Infection and Immunity, Children's Hospital of Chongqing Medical University, Chongqing, CHINA, [2]Cell Biology and Molecular Genetics, University of Maryland, College Park, MD, [3]Chongqing Key Laboratory of Child Infection and Immunity, University of Maryland, College Park, MD.

Wiskott-Aldrich Syndrome protein (WASp)-deficiency causes severe immune disorders, characterized by poor antibody responses to infections and elevated autoantibodies. However, the cellular mechanisms by which WASp regulates antigen affinity-dependent selection of B-cells in germinal centers remain elusive. Using WASp knockout (WKO) and bone marrow chimeric mice, we demonstrated germinal center B-cell (GCB)-intrinsic roles for WASp in selecting high-affinity antigen-specific GCBs. Antigen-specific IgG in the serum, their relative affinity, and the percentages of antigen-specific GCBs were all drastically reduced in WKO and WKO chimeric mice, compared to WT and WT chimeric mice. While the B-cell receptor internalized antigen at a similar rate in WKO and WT GCBs, the ability of WKO GCBs to present antigen and interact with cognate T-cells was defective. Surprisingly, WKO GCBs displayed a higher survival and a lower apoptosis rate than WT GCBs in the absence of antigenic stimulation and T-cells. This increased survival rate was associated with reduced ROS and mitochondrial superoxide production in WKO GCBs compared to WT GCBs. Mitochondria in WKO GCBs exhibited lower levels of dysfunction indicators, higher membrane potential, larger volumes, and longer shapes than those in WT GCBs. WKO significantly reduced the cellular level of F-actin and the recruitment of Drp1, a dynamin-related protein required for mitochondrial fission, to mitochondria. Our data demonstrate essential and B-cell-intrinsic roles for WASp in interacting with T-cells to activate antigen-specific GCB and in promoting the apoptosis of non-specific GCBs through mitochondrial stress.

B75/P2473

Pivotal roles of branched actin in promoting B-cell receptor signaling attenuation

A. Bhanja[1], M. Lazzaro[1], I. Rey-Suarez[2], A. Upadhyaya[2], **W. Song**[1]; [1]Cell Biology and Molecular Genetics, University of Maryland, College Park, MD, [2]Physics, University of Maryland, College Park, MD.

B-cell receptor (BCR) signaling in response to antigenic stimulation is a critical initiation and regulatory step for B-cell activation and differentiation. The actin cytoskeleton plays essential roles in modulating BCR signaling. When encountering cell-surface antigens, actin-driven B-cell spreading on the antigen-presenting surface amplifies signaling by promoting surface BCR clustering, while B-cell contraction following the spreading promotes signal attenuation by driving the merger of BCR clusters. This signal attenuation curtails the activation of autoreactive B-cells. However, the mechanism by which the actin cytoskeleton switches BCR signaling from the amplification to attenuation mode was unknown. Here, we show that branched actin polymerized by Arp2/3 is required for B-cell contraction in addition to its role in B-cell spreading. Contracting B-cells exhibit centripetally moving inner actin foci in the B-cell membrane region contacting antigen-presenting surfaces. These inner actin foci are derived from the lamellipodial actin network. N-WASP, but not WASP, activated branched actin polymerization forms these actin foci by sustaining their lifetime and centripetal movement. N-WASP-dependent inner actin foci are necessary for recruiting non-muscle myosin II to create an actomyosin ring-like structure at the periphery of the membrane contact region, driving contraction. B-cell contraction particularly increases

the BCR molecular density of individual clusters, compared to B-cell spreading and post-contraction phases. Increased molecular density in BCR clusters leads to decreases in the phosphorylation of the BCR, the stimulatory kinase Syk, and the inhibitory phosphatase SHIP1. These results suggest that the actin cytoskeleton reorganizes from the lamellipodial branched actin networks to centripetally moving actin foci, enabling actomyosin ring-like structure formation, through N-WASP-activated Arp2/3. Actomyosin-mediated B-cell contraction attenuates BCR signaling by increasing receptor molecular density in individual BCR clusters.

B76/P2474

Epithelial polarity requires WAVE-dependent transport of E-Cadherin/HMR-1

M. Soto[1], L. Cordova Burgos[1], D. Rao[1], J. Egwuonwu[1], S. Borinskaya[2]; [1]Rutgers - Robert Wood Johnson Medical Sch, Piscataway, NJ, [2]Saint Elizabeth University, Morristown, NJ.

Cadherin dynamics drive morphogenesis, while defects in Cadherin polarity contribute to diseases, including cancers. However, the forces polarizing Cadherin membrane distribution are not well understood. We previously showed that WAVE-dependent branched actin polarizes Cadherin distribution in the embryonic and adult *C. elegans* intestine, and suggested one mechanism is protein transport. While previous studies suggested that WAVE is enriched at various endocytic compartments, the role of WAVE in protein traffic is understudied. Here we test the model that WAVE regulates Cadherin by polarizing its transport. In support of this model we show that: 1) endogenously tagged WAVE accumulates in vivo at several endocytic compartments, including recycling endosomes and Golgi; 2) likewise, Cadherin protein accumulates at recycling endosomes and Golgi; 3) loss of WAVE components reduces Cadherin accumulation at apically directed RAB-11-positive recycling endosomes and increases accumulation at Golgi. In addition, live imaging illustrates that dynamics and velocity of recycling endosomes enriched for RAB-11::GFP and RFP::RME-1 are reduced in animals depleted of WAVE components, and their movements are misdirected, suggesting WAVE powers and directs their movements. This *in vivo* study demonstrates the importance of WAVE in promoting polarized transport in epithelia, and supports that WAVE promotes cell-cell adhesion and epithelial polarity by promoting Cadherin transport.

B77/P2475

Mechanisms underlying the slow axonal transport of spectrin and its assembly into the membrane associated peroidic skeleton

O. Glomb[1], G. Swaim[2], S. Yogev[3]; [1]Neuroscience, Yale University, New Haven, CT, [2]Cell Biology, Yale University, New Haven, CT, [3]Neuroscience, Cell Biology, Yale University, New Haven, CT.

How the size of the cytoskeleton is scaled to the size of the cell remains poorly understood, particularly in neurons. In the axon, the delivery of cytoskeletal proteins from the cell body is the main mechanism determining overall cytoskeletal mass. This delivery is believed to consist of fast movements interspersed by long pauses, consistent with the known rates of molecular motors. We developed a probe to visualize the axonal delivery of endogenous spectrin and its assembly into the membrane periodic cytoskeleton (MPS) during axon stretch-growth, when axon size scales with the growing organism. We find that, contrary to current models of axonal delivery of cytoskeletal proteins, spectrin can move processively at rates ~100-fold slower than that of molecular motors. We identified two conserved coiled-coil proteins that link spectrin to kinesin-1 and are required to generate processive

slow movement and to form the MPS. Spectrin was delivered to hotspots along the axon, where it locally incorporated into the MPS lattice to drive its expansion. Interestingly, the rate of spectrin integration into the lattice and hotspot expansion was set by the rate of animal growth and hence axon stretch growth. Thus, slow processive transport and local expansion scale the cytoskeleton to the size of the axon.

INF2 Regulates Organelle Motility via ER-associated Actin

C. R. Schiavon[1], Y. Wang[1], A. Manole[1], T. Sung[1], Y. Dayn[1], P. Latour[2], A. Echaniz-Laguna[3], M. E. Shy[4], B. J. Zuchero[5], G. S. Shadel[1], U. Manor[1]; [1]Salk Institute for Biological Studies, La Jolla, CA, [2]Hospices Civils de Lyon, Bron, FRANCE, [3]Paris-Sud University, Le Kremlin Bicêtre, FRANCE, [4]University of Iowa, Iowa City, IA, [5]Stanford University, Stanford, CA.

Charcot-Marie-Tooth (CMT) disease is the most common inherited neurological disorder, affecting ~1 in 2500 people. It is a peripheral, length-dependent neuropathy defined by progressive degeneration of the nerves in the distal parts of the body. Mutations in a wide variety of proteins cause CMT. Many of these proteins play a direct or indirect role in organelle mobility. Given this fact and the fact that cells affected in CMT (peripheral neurons) are the longest cells in the body, it is hypothesized that CMT is a result of impaired organelle mobility. INF2 is one of the proteins mutated in CMT. It is an ER-anchored formin protein which promotes actin assembly and modulates mitochondrial morphology and motility through this actin polymerizing activity. All CMT-causing INF2 mutations result in a constitutively active form of INF2. We predicted that this aberrant activity causes excess accumulation of ER-associated actin around mitochondria, restricting their mobility. We have demonstrated that mitochondrial mobility is reduced by exogenous expression of two CMT-causing INF2 mutations. We also studied the mobility of other organelles and found that expression of these mutants also reduces the mobility of endosomes and lysosomes, broadening the potential organelles that may play a role in the pathomechanism of CMT. We further validated these results in primary human fibroblasts from two CMT patients harboring endogenous INF2 mutations as well as neurons directly converted from these fibroblasts. Neurons derived from CMT patient fibroblasts also display neuronal swellings, consistent with a neurodegenerative phenotype. The reduction in organelle mobility is reversible by pharmacologically depolymerizing actin, supporting the model of excessive actin polymerization limiting organelle movement. To avoid the toxic side-effects of wholesale actin depolymerization, we developed a novel tool to specifically disrupt ER-associated actin. We found that this tool results in rescue of organelle mobility without causing obvious toxicity and reverses the neuronal swellings observed in derived CMT neurons. These findings demonstrate a potential mechanism by which INF2 mutations lead to excessive ER-associated actin, impaired organellar mobility, and ultimately, peripheral neuron degeneration.

Motors: Kinesins in Neurons

B80/P2477

Selective axonal transport through branch junctions is directed by growth cone signaling and mediated by KIF1/kinesin-3 motors

S. Tymanskyj, L. Ma; Department of Neuroscience, Thomas Jefferson University, Philadelphia, PA.

Development of a functioning nervous system requires the establishment of individual neurons communicating with multiple targets, achieved by a single axon generating multiple branches. These branches differ in lengths and targets, and as such have different metabolic and protein needs. Delivery of proteins from the cell body to the correct targets rely on the orchestration of microtubule-based transport by the motor protein kinesin family, but if and how protein or membrane cargos are regulated along the axon is unknown. Here we demonstrate that cargo delivery is in fact regulated along the axon, specifically through branch junctions where they can target specific branches. We show that anterograde transport of LAMP-1 and synaptic vesicles through axonal branch junctions is highly selective, influenced by branch length and more strongly by growth cone motility. We further show that not all cargos are responsive to the same cues with secretory vesicles such as BDNF being largely unresponsive. We developed an optogenetic tool based on mimicking the guidance receptor activity of positive (TrkA) and negative (PlexinA4) cues and focally activated one specific growth cone. We were able to demonstrate that signaling from the growth cone can rapidly direct transport through branch junctions located a distance away from the site of activation. We further demonstrate that such transport selectivity is differentially regulated and mediated by the KIF1/kinesin-3 family motors. We propose that this transport regulation through branch junctions could broadly impact neuronal development, function, and regeneration.

B81/P2478

Differential regulation of kinesin and dynein motility by microtubule-associated septin complexes

Y. Suber, K. Nakos, E. Spiliotis; Drexel University, Philadelphia, PA.

Septins are a large family of GTP-binding proteins that oligomerize into higher order complexes, which associate with microtubules (MTs). Microtubule motors kinesin and dynein mediate plus-end and minus-end directed intracellular transport respectively, and their activity and directionality are regulated by several different factors including microtubule-associated proteins (MAPs). In previous work (Karasmanis et al, Dev Cell 46:204, 2018), we found that the MT-associated septin 9 (SEPT9) impedes the motility of kinesin-1/KIF5C and enhances kinesin-3/KIF1A, and through this differential regulation promotes neuronal axon-dendrite membrane polarity. Here, we explored the hypothesis that different septin complexes exert different effects on kinesin and dynein motors. Using in vitro single molecule motility assays, we compared the effects of the MT-associated SEPT2/6/7, SEPT5/7/11 and SEPT2/6/7/9 on the motility of kinesin-1/KIF5C, kinesin-3/KIF1A and the dynein-dynactin-BicD2 (DDB) motor complex. MT-associated SEPT2/SEPT6/SEPT7 and SEPT5/SEPT7/SEPT11 impeded the motility of kinesin-1/KIF5C in a similar manner to SEPT9. Strikingly, we found that the motility of kinesin-1/KIF1A is differentially modulated by SEPT9, SEPT2/6/7 and SEPT5/7/11. MT-associated SEPT2/6/7 decreased the binding, velocity and run-lengths of kinesin-3/KIF1A, which are all enhanced by SEPT9. In contrast, SEPT5/7/11 did not affect the binding and run-lengths of kinesin-3/KIF1A, but had a mild impact on velocity and pausing. DDB velocity and run lengths were significantly reduced by MT-associated SEPT2/6/7/9,

SEPT2/6/7 and SEPT5/7/11. Although SEPT2/6/7/9, SEPT2/6/7 and SEPT5/7/11 inhibited the MT landing rates of DDB, we found that only SEPT2/6/7/9 and SEPT5/7/11 enhanced the number of immotile DDB particles, which was indicative of a decrease in DDB detachment. SEPT5/7/11 was similarly unique in impeding the detachment of immotile kinesin-1/KIF5 and kinesin-3/KIF1A motors. Taken together, these data demonstrate that MT-associated septins fine tune motor motility by modulating individual parameters such as motor detachment in a septin paralog and complex-specific manner.

B82/P2479

Kinesin-1, -2 and -3 motors use family-specific mechanochemical strategies to effectively compete with dynein during bidirectional transport

W. O. Hancock[1], A. M. Gicking[1], T. Ma[1], Q. Feng[2], R. Jiang[3], S. Badieyan[4], M. A. Cianfrocco[4]; [1]Biomedical Engineering, Penn State University, University Park, PA, [2]Cell Biology, Yale University, New Haven, CT, [3]Molecular & Cell Biology, UC Berkeley, Berkeley, CA, [4]Biological Chemistry, University of Michigan, Ann Arbor, MI.

Bidirectional cargo transport in neurons requires competing activity of motors from the kinesin-1, -2 and -3 superfamilies against cytoplasmic dynein-1. Previous studies demonstrated that when kinesin-1 attached to dynein-dynactin-BicD2 (DDB) complex, the tethered motors move slowly with a slight plus-end bias, suggesting kinesin-1 overpowers DDB but DDB generates a substantial hindering load. Compared to kinesin-1, motors from the kinesin-2 and -3 families display a higher sensitivity to load in single-molecule assays and are thus predicted to be overpowered by dynein complexes in cargo transport. To test this prediction, we used a DNA scaffold to pair DDB with members of the kinesin-1, -2 and -3 families to recreate bidirectional transport in vitro, and tracked the motor pairs using two-channel TIRF microscopy. Unexpectedly, we find that when both kinesin and dynein are engaged and stepping on the microtubule, kinesin-1, -2, and -3 motors are able to effectively withstand hindering loads generated by DDB. Stochastic stepping simulations reveal that kinesin-2 and -3 motors compensate for their faster detachment rates under load with faster reattachment kinetics. The similar performance between the three kinesin transport families highlights how motor kinetics play critical roles in balancing forces between kinesin and dynein, and emphasizes the importance of motor regulation by cargo adaptors, regulatory proteins, and the microtubule track for tuning the speed and directionality of cargo transport in cells.

B83/P2480

The CFEOM-causing β-tubulin-R380C mutation activates kinesin motor activity

P. Sinha Roy[1], A. Luchniak[1], A. Kumar[1], I. Schneider[1], V. Gelfand[2], R. Jernigan[1], **M. Gupta, Jr**[1]; [1]Iowa State University, Ames, IA, [2]Northwestern University, Chicago, IL.

Kinesin-mediated transport on microtubules is critical for axon development and health. Mutations in the kinesin Kif21a, or the microtubule subunit β-tubulin, inhibit axon growth and/or maintenance producing the eye-movement disorder congenital fibrosis of the extraocular muscles (CFEOM). While most CFEOM-causing β-tubulin mutations examined inhibit kinesin-microtubule interactions, Kif21a mutations hyperactivate the motor. These contrasting observations led to opposed models of inhibited or hyperactive Kif21a in CFEOM. We show that, contrary to other CFEOM-causing β-tubulin mutations, R380C enhances kinesin activity. β-tubulin-R380C expression increases kinesin-mediated peroxisome transport in S2 cells. The binding frequency, percent motile engagements, run length and plus-end dwell

time of Kif21a are higher on β-tubulin-R380C than wildtype microtubules reconstituted in vitro. This conserved effect persists across tubulins from multiple species. Using molecular dynamics, we visualize how β-tubulin-R380C allosterically alters structural elements within kinesin that underlie processive motility. These findings resolve the disparate models and confirm both inhibited or hyperactive kinesins are involved in CFEOM. They also demonstrate the microtubule's role in regulating kinesin and highlight the importance of balanced transport for cellular and organismal health.

Entering the primary cilia of sensory neurons in *C. elegans*: A single-molecule perspective

A. Mitra, E. Loseva, E. J. G. Peterman; Department of Physics and Astronomy, Vrije Universiteit Amsterdam, Amsterdam, NETHERLANDS.

Intraflagellar transport (IFT) along a microtubule-based axoneme orchestrates the growth and maintenance of primary cilia, elongated signalling hubs protruding out of eukaryotic cells. Kinesin-2 motors drive anterograde IFT trains, assembled at the cilia base, into the cilium, importing cargo proteins hitchhiking on the trains. In this study, we employ a single-molecule fluorescence microscopy approach involving localized illumination, to visualize and quantify the entry of individual anterograde kinesin-2 motors, kinesin-II and OSM-3, and cargo proteins associated with anterograde IFT trains, IFT dynein and tubulin, into cilia located at the tip of dendrites of chemosensory neurons in *C. elegans*. Single-molecule tracking reveals docking of the different proteins to IFT trains, as well as pausing and the entry into the cilium. At the ciliary base, where the transition zone acts as a diffusion barrier for larger proteins, IFT dynein docks on to assembling IFT trains, which appear stuck for a significant duration. Trains are picked up at the base by Kinesin-II, transporting them through the transition zone, into the cilium. The other kinesin motor, OSM-3, hops, just like the cargo protein, tubulin, onto these moving IFT trains throughout the transition zone. Pooling the localization information of many single molecules allows mapping of the 3D ultrastructure of the axoneme with a precision of several tens of nanometers, in wild-type *C. elegans* as well as mutant strains lacking kinesin-2 motor and/or transition zone function. These maps provide new insights in ciliary structure at the base, train-docking dynamics and the interplay of the kinesin-2 motors, kinesin-II and OSM-3. In summary, using single-molecule live-cell imaging in *C. elegans*, we illuminate structural and dynamic features at the base of primary cilia.

B85/P2482

An ALS-associated KIF5A mutant forms oligomers and aggregates and induces neuronal toxicity

K. Chiba, J. Nakano, S. Niwa; Tohoku University, Sendai, Japan

KIF5A is a kinesin superfamily motor protein that transports various cargos in neurons. Mutations in Kif5a cause familial amyotrophic lateral sclerosis (ALS). It has been suggested that ALS is caused by loss of function of KIF5A. However, the precise mechanisms regarding how mutations in KIF5A cause ALS remain unclear. Here, we show that an ALS-associated mutant of KIF5A, KIF5A(Δexon27), is predisposed to form oligomers and aggregates in vivo and in vitro. Moreover, KIF5A(Δexon27)-expressing Caenorhabditis elegans neurons showed morphological defects. These data collectively suggest that ALS-associated mutations of KIF5A are toxic gain-offunction mutations rather than simple loss-of-function mutations.

Motors: Kinesins in Regulation of Microtubule Dynamics

B86/P2483

Understanding the role of the beta tubulin tail as a mechanism to control kinesin-8 activity

K. Alemany, J. Moore; University of Colorado AMC, Aurora, CO.

The microtubule surface is a molecularly complex landscape, decorated by the heterogeneous carboxy-terminal tails (CTTs) of tubulin proteins, which serve as potential sites of regulation. The 'tubulin code' hypothesis proposes that differences in CTTs, such as changes in amino acid sequences that are encoded by different genes called tubulin isotypes and post-translational modifications, present a molecular code for specifying interactions with proteins that regulate microtubules. We previously conducted a genetic interaction screen to identify genes that require CTTs for function. This screen identified Kip3, a kinesin-8 family motor, as potentially requiring the β-tubulin CTT for function. Kinesin-8 members are unique motors that combine two activities to regulate aspects of dynamic instability: processive motility towards the plus end of the microtubule and depolymerizing activity. Here we seek to define the mechanism through which the β-CTT promotes Kip3 function. We address these questions using budding yeast to assess Kip3 function and define the features of β-CTT and Kip3 that are important for this interaction. From our results we draw three major conclusions. First, the β-CTT is not necessary for Kip3 binding and motility along the microtubule. Second, in mutant cells that lack β-CTT there is increased accumulation of Kip3 at the plus end and across the microtubule. Third, the β-CTT is necessary to promote Kip3 mediated catastrophe. Furthermore, we find that high levels of Kip3 induce tubulin accumulations that are unable to form microtubules, and this effect requires β-CTT. Our findings suggest that the β-CTT is important for Kip3 depolymerase activity at the microtubule plus end by supporting a Kip3-tubulin binding state that inhibits the normal tubulin-tubulin interactions that occur in microtubules. To further define this binding state, we mapped and analyzed potential interaction sites on both the β-CTT and Kip3. Our results support a model in which the negatively charged residues of the β-CTT may interact with positively charged residues found in Kip3's Loop12 that are well-conserved across kinesin-8 family members. We further propose that β-CTTs are tunable platforms for regulating kinesin-8 motor's ability to depolymerize microtubules.

B87/P2484

Liquid-liquid phase separation generates KIF1C clusters that drive microtubule sliding, knotting, and breakage in cells

Q. Geng, R. Prasad, K. Verhey; The University of Michigan, Ann Arbor, MI.

Kinesin proteins are exquisite nanomachines that convert chemical energy into mechanical work. Transport kinesins can carry cargoes along microtubule (MT) tracks and can slide anti-parallel microtubules. Here, we find that overexpression of the kinesin-3 family member KIF1C in cells leads to heavily curved, knotted, and fragmented MTs in regions where KIF1C accumulates and forms puncta. Interestingly, the KIF1C puncta display properties of liquid-liquid phase separation (LLPS). A highly disordered proline-rich domain (PRD) in the KIF1C tail is necessary for driving LLPS and for KIF1C's ability to induce MT destruction. Furthermore, a split kinesin assay demonstrates that the PRD is sufficient for LLPS in cells and for MT destruction when combined with a kinesin motor head. Together, these experiments indicate a strong correlation between KIF1C LLPS and MT destruction. Live imaging in cells shows that groups of KIF1C motors in the puncta slide anti-parallel microtubules into dense knots that

break. To further understand how LLPS of KIF1C promotes MT destruction, we substituted the KIF1C tail with constructs that undergo LLPS, clustering, or anchoring to organelle surfaces. All substitutions recapitulate KIF1C-induced MT destruction, supporting our working model that clustered KIF1C motors lead to active sliding and extensive crosslinking of the MT network, eventually causing MT breakage. Overall, our work reveals that the unique LLPS property of the KIF1C PRD clusters multiple motors and affects MT network integrity. These results suggest that clustering of many kinesin motors, including on an organelle, can have deleterious effects on the MT network in cells.

Importin a/β Promote Kif18B Microtubule Association to Spatially Control Microtubule Destabilization Activity

S. C. Ems-McClung[1], S. Shrestha[1], M. A. Hazelbaker[1], S. L. Shaw[2], **C. E. Walczak**[1]; [1]Indiana University School of Medicine-Bloomington, Bloomingrton, IN, [2]Indiana University, Bloomington, IN

Tight regulation of microtubule (MT) dynamics and organization is necessary for proper spindle assembly and chromosome segregation. The microtubule destabilizing Kinesin-8, Kif18B, controls astral MT dynamics and spindle positioning. Kif18B interacts with importin α/β as well as with the plus-tip tracking protein EB1, but how these associations modulate Kif18B *in vivo* is not known. We mapped the key binding sites on Kif18B, made residue-specific mutations, and assessed their impact on Kif18B function. Blocking EB1 interaction disrupted Kif18B MT plus-end accumulation and inhibited its ability to control astral microtubule length in cells. Blocking importin α/β interaction reduced Kif18B plus-end accumulation on astral MTs but did not inhibit its ability to control astral MT length. *In vitro*, importin α/β increased Kif18B binding to the MT lattice by increasing the on-rate and decreasing the off-rate, which stimulated MT destabilization activity. In contrast, EB1 promoted Kif18B-mediated MT destabilization without increasing lattice binding *in vitro*, which suggests that EB1 and importin α/β have distinct roles in the regulation of Kif18B-mediated MT destabilization. We propose that importin α/β-spatially modulate Kif18B association with MTs to facilitate its MT destabilization activity. Our results suggest that Ran-regulation is important not only to control molecular motor function near chromatin but also provides a spatial control mechanism to modulate MT binding of NLS-containing spindle assembly factors.

Motors: Myosins in Contraction

B89/P2486

motile properties of nonmuscle myosin 2c

M. Rahman, J. R. Sellers; NIH, Bethesda, MD.

Nonmuscle myosin 2 (NM2) paralogs are members of actomyosin cytoskeletal complex where they hydrolyze ATP to convert chemical energy into mechanical functions in cells. NM2 are expressed in all mammalian cells where they contribute to many subcellular functions including cell migration, adhesion and cytokinesis. Mutations in NM2 proteins causes cancer, hearing loss, bleeding disorders etc. NM2 has three paralogs, namely NM2A, B and C. Both NM2A and NM2B are well investigated regards to their roles in disease and development with extensive characterization of their biochemical, kinetic and structural properties. NM2C, on the other hand, is the most recently identified isoform and less is known about its roles, biochemical and kinetic properties compared to its other two counterparts.

Recent studies showed the involvement of NM2C in disease and development. For example, NM2C is associated with sensorineural hearing impairment and peripheral neuropathy. Other studies show roles of NM2C in cell dynamics, e.g. formation of sarcomere like architecture in the tricellular apical junction and control of microvilli growth. Such roles of NM2C in cells are critically dependent on NM2C generated motility. However, the motile properties of NM2C are not studied in detail like NM2A or NM2B. Thus, study of the motile properties of NM2C will bring information that will be required to understand its subcellular function in greater detail. Here, we study the motile properties of NM2C e.g. speed at which it translocates actin, processive movement of NM2C filaments on actin and on actin-fascin bundles. We find from the in vitro motility assays that NM2C translocates actin at 46.1±0.4 (mean ± SEM) nm/s which is slowest among all three NM2 paralogues. We also show that GFP attachment at the NM2C regulatory light chain site reduces (~ 15%) actin gliding speed in vitro which is consistent with earlier data of NM2A. From single filament assays, we also show that NM2C filaments move processively on both actin (27.8±0.45 nm/s) and actin-fascin bundles (22.1±0.86 nm/s) in the presence of methyl cellulose. We find that NM2C filaments makes large stacks in vitro which is consistent with recent observation in cells.

B90/P2487

In vitro assembly and tension formation of a synthetic sarcomere

P. Bleicher[1], N. Billington[1], R. G. Hart[2], I. Chandrasekar[2], J. R. Sellers[1]; [1]National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, [2]Enabling Technologies Group, Sanford Research, Sioux Falls, SD.

Myosin 2 is the motor that powers muscle contraction and various cytoskeletal functions such as adhesion, cell motility and cytokinesis. Muscle fibers are arranged into repetitive sarcomeres where bipolar myosin filaments interact with actin filaments to bring about shortening. These systems are amenable for mechanical studies at the level of whole muscle, individual muscle fibers and even as isolated myofibrils. In contrast myosin 2 in nonmuscle cells is localized in many places including just behind the leading edge, in stress fibers and during cytokinesis in the contractile ring. Recently several super resolution light microscopic studies of various cells have shown evidence for a sarcomere-like arrangement of actin and myosin in certain parts of cells. However, even here these structures are not easily amenable to mechanical studies to probe the properties of myosin. To address this in vitro we are using micropatterning to create sarcomeric arrangements of actin and nonmuscle myosin 2 paralogs. These model sarcomeres can self-organize into tense, anti-parallel fibers with the motile nonmuscle myosin 2 filaments in their center as observed by total internal reflection fluorescence microscopy (TIRFM). A fluorescence resonance energy transfer (FRET)-based force sensor is used to quantify the tension formation of the paralogs, revealing the single-molecular force and ratio of active and relaxed myosin heads. Alpha-actinin reduces the contraction velocity without affecting the force during tension formation. Taken together, this minimal system provides a mechanistic foundation for intracellular sarcomere contractility where the effect of accessory proteins can easily be probed.

B91/P2488

Smooth muscle myosin 2 filaments dynamically assemble and activate during induced contractility

M. Bennett[1], S. Sala[1], S. Demeulenaere[2], H. Patel[1], P. Oakes[1], J. Beach[1]; [1]Loyola University, Chicago, IL, [2]Loyola University, Wilmington, IL.

Vascular smooth muscle cells (SMCs) line blood vessels throughout the body, where they dynamically alter vessel diameter to regulate blood pressure, provide structural integrity, and absorb shock on a

beat-to-beat timescale. Interactions between actin and the molecular motor smooth muscle myosin 2 (SM2) drive contractility within the cell and allow smooth muscle to perform these vital functions. As smooth muscle function fails, profound vascular disease can ensue with tragic results- even death. Integral to SM2's ability to function is the formation of SM2 filaments and the interaction with these filaments with actin. Although smooth muscle contraction is integral to health, there are many unknowns about SM2 filament assembly and dynamics and the role these dynamics play in SMC contraction. Our goals were first, to determine equilibrium kinetics between SM2 monomer and filaments, and second, to determine if this equilibrium is shifted during SMC activation to drive contraction. Fluorescence recovery after photobleaching (FRAP) of SM2 in A7R5 (rat aortic smooth muscle cells) shows SM2 in filaments are highly dynamic, with recovery halftimes on the order of 10s of seconds with SMC activation stabilizing filaments. This suggests SM2 filament dynamics are more similar to non-muscle myosin 2 (NM2) than striated myosin 2. Consistently, structured illumination microscopy of SM2 and NM2 suggests that these closely-related myosin 2s can co-assemble into filaments. To further understand SM2 during cell contractility, we analyzed assembly levels. The prevailing model in SMC contraction suggests that activation of existing filaments leads to cell wide contractile forces, as opposed to increased filament assembly. However, our data and recent literature demonstrate a significant steady-state SM2 monomer pool (~25% of total SM2). By using an imaging-based assembly assay, the percent of filamentous and monomeric SM2 can be measured. Our results indicate the monomer pool decreases while filamentous myosin increases upon SMC activation. This indicates the filamentous population is tunable, with additional monomers being assembled into filaments upon activation of SMCs by carbachol. Traction force microscopy in A7R5 cells transfected with a calcium sensor confirms that the increase in SM2 filament formation coincides with both intracellular Ca response to stimulus and increase in contractile force production. This supports a model of SMC contraction in which both existing filaments are activated and new filaments are formed to produce cell level contractile forces.

B92/P2489

Cellular Contractile Structures are Organized by Assembly and Coalescence of Myosin Contractile Units

W.-h. Chou[1,1], M. Molaei[1,1], H. Wu[2], P. Oakes[2], J. Beach[2], M. Gardel[1,1,1,1]; [1]University of Chicago, Chicago, IL, [2]Loyola University Chicago, Chicago, IL

Various cellular processes are powered by mechanical forces, such as cell migration, cell division, and mechanosensing. At the molecular scale, mechanical forces are generated by myosin filaments sliding adjacent actin filaments past each other. Inside cells, the actomyosin cytoskeleton further builds higher-order contractile structures, such as stress fibers, where arrays of myosin contractile units contract crosslinked F-actin bundles to produce contractile forces. While the molecular regulation of myosin is well-understood, much less is known about myosin contractile units. Recent studies have identified that myosin contractile units arise from myosin stacks that nucleate and amplify at the leading edge of the cell. However, the organization and regulation of myosin contractile units across the cell remain poorly understood. In this work, we quantified myosin contractile units across the cell using quantitative microscopy. We label non-muscle myosin IIA in the cell using the CRISPR knock-in approach, which allows us to quantify the number of myosin filaments associated with myosin contractile units at the endogenous level. We find that myosin form contractile units of various sizes, ranging from 5 to 50 myosin filaments per contractile unit. Large contractile units tend to be on large F-actin bundles, such as

on mature transverse arcs or ventral stress fibers. However, F-actin does not play a role in organizing the contractile units. Instead, we show that the sizes of myosin contractile units are regulated by their assembly and coalescence, similar to size control mechanisms of cellular organelles. Combining live cell imaging, pharmacological perturbations, and quantitative analysis, we find that myosin filament assembly is required to assemble myosin contractile units. In addition, myosin motor activity can drive the coalescence between contractile units, which is not required for the assembly of contractile units but is required for the maturation of contractile units. With a simple agent-based simulation, we demonstrate that the assembly and coalescence of myosin contractile units underlie their organization in cells. Together our data provide new insight into myosin regulation in cells, revealing an additional regulatory layer of cellular contractility.

B93/P2490

Robust mechanism of tension production compensates for increasing the dosage of myosin Myp2 in the cytokinetic contractile ring

J. Martinez-Baird, K. Bellingham-Johnstun, C. Laplante; North Carolina State University, Raleigh, NC

Cytokinesis partitions a mother cell into two daughter cells by the constriction of a contractile ring of actin and myosin. In this contractile ring, myosin motor proteins can generate tension by binding to and pulling on actin filaments. Yet, how these myosins drive the production of tension during cytokinesis remains unknown. In fission yeast, two type II myosins cooperate to drive cytokinesis: Myo2 and Myp2. Myp2 contributes to ~50% of the total tension of the constricting contractile ring. Based on this role, we hypothesized that the amount of tension generated by the contractile ring scales up with increasing amounts of Myp2. We tested this hypothesis by measuring the impact of doubling the genetic dosage of *myp2* (2x*myp2*) on cytokinesis. We integrated a second copy of *mEGFP-myp2* into the *leu1* locus of cells expressing *mEGFP-myp2* at their endogenous locus. Fluorescence intensity comparisons showed that adding a second copy of *myp2* increased the amount of fluorescence signal from mEGFP-Myp2p to ~1.27X. Unsurprisingly, this incremental increase in Myp2p had no measurable impact on the constriction rate of rings in 2x*myp2* cells. Furthermore, the comparable constriction rates suggests that the total amount of tension generated by 2x*myp2* rings is comparable to wild types. However, increasing Myp2 by ~25% causes its arrangement around the ring to shift from an uneven crescent shape in wild types to a relatively uniform circle in 2x*myp2*. This organizational re-arrangement suggests an underlying change in the mechanical proprieties of contractile rings in 2x*myp2* cells. We measured the impact of increasing Myp2 on the mechanical properties of the contractile ring using laser ablation. The displacement of the severed tips of ablated constricting contractile rings follows an exponential profile as expected of a viscoelastic material under tension. Our data showed 2x*myp2* rings had a dramatic increase of ~90% in viscous drag, consistent with Myp2 acting as a crosslinker of actin filaments. These results highlight both the strong relationship between Myp2 and viscous drag, such that a 25% increase of Myp2p in the ring resulted in a dramatic increase in viscous drag, and the robust nature of the compensatory mechanisms in the contractile ring that can overcome significant increases in viscous drag to conserve constriction rate.

B94/P2491

Control of actomyosin contractility by spectrin maintains the distribution of axonal microtubules and F-actin

G. L. Swaim, O. Glomb, S. Yogev; Yale University, New Haven, CT

The axonal cytoskeleton is subject to exterior forces acting on the axon itself as well as to interior forces generated by molecular motors. How cytoskeletal organization is maintained despite these forces is poorly understood. From a candidate approach screen for mutants that disrupt cytoskeletal organization, we identified that mutations in *unc-76*/FEZ1 lead to a drastic misdistribution of axonal microtubules (MTs), where the distal axon contains areas with no MT polymers interspersed among accumulations of excessive MT polymers. We determined that this misdistribution is not due aberrant MT dynamics, but rather to uncontrolled movement of whole polymers, which in control animals are static. Using additional screening, single cell knock down approaches, live microscopy, and genome engineering we determined that UNC-76/FEZ1, along with the short coiled coil protein UNC-69/SCOC, act as a kinesin-1 adaptor for spectrin transport. The spectrin cytoskeleton is severely disrupted in either *unc-76* or *unc-69* mutants, and microtubules are misdistributed not only in *unc-76* mutants, but also upon cell-specific knock down of *unc-69* and spectrin. To investigate the mechanisms that lead to microtubule disorganization in the absence of the spectrin cytoskeleton we conducted *in vivo* live imaging of polymer transport in combination with genetic and pharmacological perturbations. Surprisingly, we found only a minor contribution of MT-based motors to MT polymer movement, but an important role for actomyosin contractility: acute inhibition of myosin II with blebbistatin arrested MT movement and long-term treatment rescued the steady-state misdistribution of MTs. Consistent with a role for the spectrin cytoskeleton sequestering actomyosin, we found that upon disruption of the spectrin cytoskeleton ectopic F-actin accumulates around microtubule ends . Taken together, our data suggest a major role for the axonal spectrin cytoskeleton in organizing the distribution of F-actin and MTs, partially by regulating myosin II activity. Myosin II is known to be a part of the spectrin cytoskeleton, where it enables the axon to withstand external forces. We propose that restricting actomyosin contractility to the sub-membranal spectrin lattice allows the axon to counteract external forces without applying uncontrolled forces on its other cytoskeletal elements.

B95/P2492

Reconstitution of the calcium-triggered contractile apparatus of the ciliated protozoa *Spirostomum*

J. Honts[1], T. Bartolome[1], F. Melzl[1], C. O'Shea[1], S. Bhamla[2]; [1]Drake University, Des Moines, IA, [2]Georgia Institute of Technology, Atlanta, GA

Protists, notably ciliated protozoa, exhibit a novel form of contraction that is rapidly triggered by calcium ions but does not require ATP hydrolysis. Ultrafast forms of calcium-triggered contraction have been described for the *Vorticella* stalk and the *Spirostomum* cell body. In heterotrich ciliates *Stentor* and *Spirostomum*, contraction is mediated by branching, spindle-shaped structures called myonemes. The goal of these studies is to reconstitute this novel contractile system in vitro. Through mass spectrometric analysis of *Spirostomum ambiguum* cytoskeletal preparations, a family of EF-hand proteins closely related to the calcium-binding protein centrin have been identified in several *Spirostomum* species. Bioinformatics analysis of published and derived proteome data suggests the existence of a distinct subgroup of centrin-like calcium-binding contractile proteins in a variety of ciliated protozoa. In addition, several candidates for a centrin-binding Sfi1-like scaffold protein have been identified in the

Spirostomum proteome. Synthetic genes encoding *Spirostomum* centrin and Sfi1-like centrin-binding proteins have been engineered for expression in *E. coli.* Expression of the Sfi1-like repeat protein in bacteria yielded little protein, while co-expression of *Spirostomum* centrin and the Sfi1-like repeat protein yielded both proteins in milligram quantities. These proteins have been purified by IMAC and gel filtration chromatography. Gel filtration chromatographic separations revealed a single peak containing the two proteins, with a molecular mass consistent with the formation of a 1:1 complex. Electrophoretic mobility shift experiments showed both centrin and the centrin-Sfi1 complex undergo a conformational change upon the addition of calcium. Microscopic observations revealed that concentrated mixtures of these two proteins assembled to form unusual branching networks when calcium was added. Current efforts are aimed at engineering a self-assembling form of centrin-Sfi1 filament bundles that can be induced to contract in response to calcium ions. Our ultimate goal is to engineer *Spirostomum* contractile proteins to fully reconstitute in vitro the ultrafast form of contraction seen in living *Spirostomum* cells. These studies should yield insight into the structure, mechanism and regulation of these novel contractile systems in living cells.

Defining the functions of myosin 2 isoforms in epithelia using intestinal organoids

M. Yousafzai, K. Remmert, L. Boley, C. Alexander, A. Pedrosa, J. Hammer; National Heart, Lung, and Blood Institute, Bethesda, MD

Mouse intestinal organoids provide a physiological context for the investigation of fundamental aspects of epithelial cell biology (e.g. cell:cell adhesion, maintenance of barrier function, cell division, and extrusion of apoptotic/aneuploid cells) because they retain a folded, crypt-villus topology in the form of a three-dimensional, regenerative, stem cell-driven tissue model. Moreover, they are amenable to structure-function analyses using knockout (KO) and knockin (KI) mice, shRNA-mediated protein knockdown (KD), the expression of fluorescent reporters via lenti and/or Piggybac-mediated recombination, and imaging using several super-resolution modalities. Here we imaged the localization and dynamics of endogenous myosin 2A (M2A) and myosin 2C (M2C) using organoids made from GFP-M2A and GFP-M2C KI mice. M2A localizes along the lateral surface of organoids, consistent with its known roles in supporting cadherin-based cell: cell adhesion at adherent junctions (AJs) and ZO-1-based cell: cell adhesion at tight junctions (TJs). M2A also localizes in stress fibers at the basal surface, consistent with a role in supporting integrin-based cell: ECM adhesion as well. Interestingly, M2A is seen not only in the cleavage furrow of dividing enterocytes, but also in evenly-spaced strings of cortical mini-filaments that span the long axis of the dividing cell. shRNA-mediated knockdown of M2A in GFP-M2A KI organoids leads to the appearance of a multilobed phenotype that scales with the degree of KD (the dimmer the GFP-M2A signal, the more multilobed the organoid appears). Current efforts are directed at understanding the physical basis of this robust phenomenon. Finally, endogenous M2C localizes exclusively at the apex of organoid, where it appears as a belt of mini-filaments that resides directly across from ZO-1 in TJs and is brightest at tricellular junctions. Current efforts are directed at creating confluent 2D organoids from WT and M2C KO mice to assess the role of M2C in maintaining barrier function using a variety of permeability assays.

B97/P2494

Mmsdh as a bridge between metabolic activity and cortical dynamics

M. C. Jacob, D. N. Robinson; Johns Hopkins School of Medicine, Baltimore, MD

The cytoskeleton is an energy intensive system responsible for many cellular processes such as cell motility, morphology, and division. In the case of Dictyostelium discoideum, the cortical cytoskeleton is a highly dynamic network that actively responds to sites of mechanical stress via accumulation and disassembly of prefabricated contractility kits (CKs) at the cortex. These CKs are comprised of cytoskeletal proteins known as non-muscle myosin II (NMII), cortexillin I (cortI), and IQGAP1 and/or IQGAP2. Depending on which IQGAP is bound, these CK proteins can be mechanoresponsive or non-mechanoresponsive. Interestingly, the components of the CKs also interact with proteins outside the traditional cytoskeletal system. In our lab, past genetic selections and proteomic studies done in Dictyostelium discoideum have revealed metabolically related proteins that interact with cytoskeletal proteins like NMII and cortI. An exemplar protein that came about from these studies was the mitochondria-localized ATP/ADP antiporter, ancA. AncA was identified as a genetic suppressor of a cytokinesis-defective phenotype caused by a myosin II phosphomimetic scenario. Interestingly, ANT, the human analogue of ancA, was shown to be a genetic protector against cigarette smoke in the lung tissue of COPD patients when overexpressed - with cigarette smoke exposure known to be a disrupter actin and myosin II organization. In the same vein, methyl-malonate semialdehyde dehydrogenase (mmsdh) was found to be a genetic interactor of NMII and a biochemical interactor of cortI and IQGAP1. Mmsdh is an enzyme downstream of the valine catabolism pathway that is localized in the cytoplasm and mitochondria and that catalyzes the production of propionyl-CoA. Though much is known about mmsdh's function in metabolism, not much is known about its interaction with the cytoskeleton. Here, I am characterizing mmsdh's impact on the cytoskeleton and how these cytoskeletal interactions may contribute to mmsdh's metabolic role. To this end, we are generating an mmsdh knockout in Dictyostelium discoideum and am employing several assays to probe alterations in metabolic activity and/or cytoskeletal dynamics. Collectively, we aim to define how mmsdh contributes to cortical cytoskeleton function and how this activity may contribute to mmsdh's metabolism role.

Motors: Myosins in Cell Migration

B98/P2495

Microtubule-binding Myosin-X (Myo10) is required for efficient dendritic cell migration in complex environments

A. Gasilina, P. Rezvan Sangsari, N. Y. Morgan, J. A. Hammer; National Institutes of Health, Bethesda, MD

Activation of naïve T cells by antigen-presenting dendritic cells is a critical determinant of efficient adaptive immune responses. Following pathogenic antigen capture, dendritic cells use a CCL19/CCL21 chemokine gradient to guide their migration from the primary sampling site to the closest lymph node. During migration dendritic cells must negotiate passage through basement membranes, extracellular matrices, cell junctions, and branched vessel networks, all while maintaining speed, persistence and directionality. Efficient navigation through these complex microenvironments involves coordinated movements of the cell's nucleus, actin-rich extensions, and microtubule cytoskeleton, which together regulate space exploration, path finding, and pore size selection. In this study we are using imaging to define the contribution that the MyTH4/FERM domain-containing molecular motor myosin-X (Myo10)

makes to dendritic cell migration. Using murine bone marrow-derived and splenic dendritic cells, we show that Myo10 is dispensable for dendritic cell differentiation, maturation, and CCL19/CCL21 chemokine sensing, but is essential for efficient directed cell migration in confined and complex environments. Specifically, Myo10-depleted dendritic cells exhibit increased velocity but impaired directionality and persistence during directed migration in both confined 2D environments and complex branched networks. In complex networks especially, Myo10-depleted dendritic cells are ineffective at using their nucleus as the pore size and path selector, and they cannot resolve competing leading edges. These deficiencies result in cell entanglement and fragmentation. Current efforts are directed at determining whether Myo10 requires its microtubule-binding MyTH4 domain to control dendritic cell navigation through complex environments.

B99/P2496

Mechanoresponsive Adaptability in Pancreatic Cancer Cells and Tissue

E. Parajon, D. N. Robinson; Johns Hopkins School of Medicine, Baltimore, MD

Pancreatic ductal adenocarcinoma (PDAC) is an aggressive cancer characterized by early systemic dissemination and poor patient prognosis. Our lab identified a PDAC program of upregulation of key highly mechanoresponsive cytoskeletal proteins that accumulate in response to mechanical stress. Cancer cells are highly adaptive and must continuously adjust to their ever-changing environment, including nutrient and oxygen availability, stiffness of the local matrix, and the neighboring cells. The mechanoresponsive proteins compose an adaptability program that allows cells to respond to alterations in many of these parameters. In humans, this mechanoresponsive machinery encompasses nonmuscle myosin II proteins (NMIIA, NMIIB, and NMIIC), alpha-actinins (ACTN4, but not ACTN1) and filamin (FLNB with FLNA to a much smaller extent). However, it is still unclear how the mechanoresponsive cytoskeletal machinery drives PDAC dissemination and metastasis. NMIIA, NMIIC, ACTN4, and FLNB, are expressed at low levels in normal pancreatic ductal epithelia but become highly expressed in PDAC. We are utilizing a three-dimensional, reconstituted tissue model with engineered cells where we have altered the adaptability program using the CRISPR-Cas9 system. We are also investigating how these engineered cells influence neighboring cell behaviors and tissue mechanics. This study has revealed that knocking out NMIIC and ACTN4 leads to significant changes in cortical tension, cell roundness, and cell motility of metastasis derived pancreatic cancer cells. This effort will decipher how alterations in these proteins impact cell growth, shape, motility, and invasiveness and will guide future strategies for manipulating these proteins towards a therapeutic end.

B100/P2497

Identifying mechanisms of non-muscle myosin II filament assembly and amplification

M. Quintanilla[1], H. Wu[1], K. Sochacki[2], M. Akamatsu[3], J. Rotty[4], F. Korobova[5], J. Bear[6], J. Taraska[2], P. Oakes[1], J. Beach[1]; [1]Loyola University Chicago, Maywood, IL, [2]National Heart, Lung, and Blood Institute, Bethesda, MD, [3]University of Washington, Seattle, WA, [4]Uniformed Services University of the Health Sciences, Bethesda, MD, [5]Northwestern, Evanston, IL, [6]University of North Carolina, Chapel Hill, Chapel Hill, NC.

The majority of contractile forces in non-muscle cells are generated by non-muscle myosin 2-driven contraction of actin networks. Previous high-resolution imaging in the lamella of migrating fibroblasts revealed myosin filaments appear and amplify by an actin-dependent partitioning process, feeding into

larger actomyosin networks. We believe this filament amplification drives requisite physiological levels of contraction in cells and tissues. Our goals were to delineate mechanisms by which new filaments are established in the lamella, and then define, with molecular precision, how filament partitioning enables the formation of contractile networks. We fail to observe calcium- or Rho-mediated activation in the immediate vicinity of a new myosin filament, suggesting monomer activation occurs with low spatial precision. However, consistent with published work, we observe filament appearance following leading edge retraction. Appearance stalls when actin dynamics are pharmacologically halted, but rescued by myosin monomer release from posterior stress fibers via ROCK inhibition. This suggests that filament formation is a low-precision, stochastic event dependent on regional increases in available monomer. Consistently, when local concentrations of myosin monomer were artificially enriched via photo-recruitment to the plasma membrane, we observed de novo filament formation. Interestingly, once the photo-recruitable myosin initiated filament assembly, endogenous myosin also incorporated into expanding filament clusters, suggesting myosin filaments are capable of self-propagation once an initial filament is established. We then used molecular counting to determine that new lamellar filaments are ~100x more likely to form at pre-existing myosin filaments than to form a nascent filament cluster, despite ample actin available in the lamella. Finally, we demonstrate that prior to partitioning into clusters, bipolar myosin structures are already small sub-resolution filament stacks in register. Taken together, we propose a model whereby increased actin network density during retraction events acts as a kinetic trap for myosin monomers, resulting in nascent filament assembly events. Once established, myosin filaments act as a diffusion trap for assembly-competent monomers and possibly other cytoplasmic myosin filaments, resulting in sub-resolution stacks and clusters. These established filaments and filament clusters then mature into a contractile network to enable cell migration. We anticipate similar mechanisms exist in more complex contractile networks throughout cell and tissue biology.

Myosin Waves and a Mechanical Asymmetry Guide the Oscillatory Migration of *Drosophila* Cardiac Progenitors

N. Balaghi[1,2], G. Erdemci-Tandogan[1,2], R. Fernandez-Gonzalez[1,2,3,4]; [1]Institute of Biomedical Engineering, University of Toronto, Toronto, ON, CANADA, [2]Translational Biology and Engineering Program, Ted Rogers Centre for Heart Research, Toronto, ON, CANADA, [3]Department of Cell and Systems Biology, University of Toronto, Toronto, ON, CANADA, [4]Developmental and Stem Cell Biology Program, Hospital for Sick Kids, Toronto, ON, CANADA.

Heart development begins with the formation of a tube, as cardiac progenitors migrate collectively from opposite sides of the embryo and meet medially. Defective cardiac progenitor migration results in congenital heart defects. However, the mechanisms of cardiac progenitor movement and coordination thereof remain largely unknown. In *Drosophila*, the embryonic heart is a linear structure composed of 52 pairs of contralateral cardiac precursors (cardioblasts, CB) that migrate dorsally and medially to form the heart tube. We developed machine learning tools to quantify the dynamics of CB migration from confocal microscopy movies. We found that CB velocities oscillated between positive (forward) and negative (backward) values. The forward steps were greater in both amplitude and duration, resulting in net forward movement of the cells. Using quantitative time-lapse microscopy, we found that the molecular motor non-muscle myosin II displayed an alternating pattern of localization between the leading and trailing ends of migrating CBs, forming oscillatory waves that traversed the cells. Notably,

the cyclic myosin flows were anti-correlated with oscillations in the position of the CB nucleus. Myosin inhibition delayed CB migration and the timely formation of the heart tube. Live imaging of embryos co-expressing fluorescent myosin and CB-CB contact markers revealed that the alternating pattern of myosin polarity in CBs was associated with alternating contraction and relaxation of the leading and trailing edges of the cell, respectively. Mathematical modeling predicted that the forward migration of CBs using alternating contraction and relaxation of both leading and trailing edges requires the presence of a boundary at the trailing edge of the cell that restricts backward movement. Consistent with this, we found a supracellular actin cable at the trailing edge of the CBs. When we used targeted laser ablation to release the tension sustained by the actin cable, we found that the amplitude of the CB backward steps increased significantly, thus reducing the speed of migration. Together, our results indicate that alternative and periodic cell shape changes generated by oscillatory myosin waves coupled with a supracellular actin cable that resists backward movements, result in a rectified form of cell migration that guides cardiac morphogenesis.

Microtubule Networks

A gamma-tubulin complex-dependent pathway suppresses unscheduled ciliogenesis by promoting cilia disassembly

S. Shankar[1], Z. Hsu[2], A. Ezquerra[3], C. Li[2], T. Huang[1], E. Coyaud[4], R. Viais[3], C. Grauffel[1], B. Raught[4], C. Lim[1], J. Lüders[3], S. Tsai[2], **K. Hsia**[1]; [1]Institute of Molecular Biology, Academia Sinica, Taipei, TAIWAN, [2]National Taiwan University, Taipei, TAIWAN, [3]The Barcelona Institute of Science and Technology, Barcelona, SPAIN, [4]University of Toronto, Toronto, ON, CANADA.

The γ-tubulin ring complex (γ-TuRC) serves as a master template for microtubule nucleation, and its activity is canonically associated with the generation of microtubules to build cellular structures such as primary cilia. Here, we report a γ-TuRC-dependent pathway that promotes cilia disassembly, thereby preventing unscheduled cilia formation and ensuring cell cycle progression. Using proteomics-based mass spectrometry and immunofluorescence analyses, we demonstrate that Kif2A—a kinesin motor that bears microtubule-depolymerizing activity—is recruited to the cilium basal body in a γ-TuRC-dependent manner. Our structural and biochemical data uncover how γ-TuRC specifically recruits Kif2A via the GCP2 subunit and its binding partner Mzt2. Hence, γαμμα-TuRC functional heterogeneity at the basal body facilitates both microtubule nucleation and, through recruitment of KIF2A, control of ciliogenesis.

Microtubule Severing Proteins Play Distinct Roles in Drosophila Neurons

Y. Shen, M. M. Rolls; Pennsylvania State University, State College, PA.

Microtubule severing proteins have similar protein architecture and include a microtubule-interacting domain and an AAA (ATPases Associated with diverse cellular Activities) ATPase domain that catalyzes removal of tubulin heterodimers from a microtubule using ATP as an energy source. There are four severing proteins in Drosophila neurons: Katanin, spastin, Kat60L1 and Fidgetin. The specific role of each severing protein in neurons remains unclear. In our previous study we found Fidgetin promotes degeneration of dendrites after injury, but does not seem to function in uninjured neurons. Kat60L1 has

been shown to contribute to microtubule dynamics in Drosophila dendrites, however, whether the remaining two function in dendrites is not clear. Here, we show that Katanin and spastin have distinct roles in controlling microtubule dynamics in Drosophila sensory neuron dendrites. In *Katanin* mutant neurons, very few microtubule plus and minus ends labeled with EB1-GFP are present. We considered that the strong reduction in EB1-GFP-labeled microtubule ends could be due to a deficit in microtubule growth in *Katanin* mutants. To test this hypothesis, we severed dendrites and assayed EB1-GFP in the cut off dendrite. As in control neurons, dendrite severing increased the number of microtubule ends recognized by EB1 suggesting that when ends are present in Katanin mutants they can be detected. When we overexpressed Katanin, we saw strong increases in both plus end and minus end number, suggesting Katanin functions to maintain number of microtubule ends, and thus presumably microtubule length, in neurons. While overexpression of spastin also increased the number of microtubule ends, *spastin* mutant neurons had similar numbers of growing plus ends to control neurons, however, the number of minus ends labeled with EB1-GFP was strongly reduced. We therefore hypothesized that minus ends remain capped by the g-Tubulin ring complex (g-TuRC) at dendrite branch points. To test this hypothesis, we examined the layout of microtubules at dendrite branch points using fluorescently labeled tubulin. In control neurons, microtubules pass through the branch point in a V shape along the outside and leave an empty space in the middle of the branch point. In *spastin* mutant neurons, the space in middle of the branch point was frequently occupied by microtubules, consistent with continued attachment of the minus end to the nucleation site. Together, we show that Katanin and spastin play different roles in neurons, with spastin mediating the release of new microtubules from nucleation sites and Katanin maintaining overall microtubule dynamics

Dissecting the Function of the Microtubule-Associated Protein, Doublecortin

R. L. Agulto, K. Ori-McKenney; Department of Molecular and Cellular Biology, University of California, Davis, Davis, CA.

Cellular function and health rely on the precise arrangement of underlying cytoskeletal networks. Microtubule-associated proteins (MAPs) regulate microtubule dynamics, bundling, and motor transport for specific cellular processes. Doublecortin (DCX) is a MAP implicated in the neurodevelopmental diseases: subcortical laminar heterotopia (SCLH), also called “double cortex syndrome”, in females and lissencephaly in males[1]. With both SCLH and lissencephaly, affected individuals exhibit intellectual disability and epilepsy of varying severity. Though it has been shown that defects in neuronal migration cause SCLH and lissencephaly, the actual function of DCX within neurons, and how disease mutations alter this function are open areas of investigation. Recent studies have shown that the microtubule lattice can exist in an expanded or compacted state, depending on a variety of factors[2]. Certain proteins can alter the lattice as well. Kinesin-1 prefers an expanded lattice and can actively expand the lattice[3]. Other MAPs such as tau and MAP2 prefer a compacted lattice and can actively compact the lattice[4]. Microtubule lattices stabilized in the presence of taxol have been shown to be in an expanded state[5,6]. Utilizing SiR-tubulin, a fluorescent taxol derivative that binds the expanded lattice, we find that DCX binds cooperatively by actively compacting the lattice, displacing SiR-tubulin from the compacted lattice[4]. We have made several DCX constructs to dissect which domains of DCX are responsible for this cooperative binding and lattice compaction and find that the conserved linker region that connects the tandem microtubule-binding domains of DCX is important for this ability. Our experiments with DCX and different kinesin motors show that DCX can indirectly inhibit certain kinesins that prefer an expanded

lattice by compacting the lattice, providing one explanation for why DCX inhibits kinesin-1 processivity even though they have different binding sites[7]. Our observations have led us to hypothesize that compaction of the microtubule lattice by DCX can affect the local microtubule environment. Patient mutations disrupt the cooperative binding behavior of DCX[8]. Consequently, understanding why DCX displays cooperative behavior, the domains responsible for that cooperativity, and its differences on compacted and expanded microtubule lattices will provide significant insight into how DCX behaves on the microtubule to regulate diverse microtubule processes and how its function becomes altered in disease.

The TOG5 domain of XMAP215 facilitates interaction with F-actin and contributes to microtubule advancement in neurons

T. O'Brien[1], G. Cammarata[2], A. Thawani[3], **L. Lowery**[1]; [1]Boston University, Boston, MA, [2]Boston College, Newton, MA, [3]Princeton University, Princeton, NJ.

Microtubule and F-actin cytoskeletal cross talk and reorganization are important aspects of cell migration and axonal guidance, but the mechanisms by which associated proteins facilitate this are still being revealed. While XMAP215 (CKAP5 / ch-TOG) has been best characterized for its microtubule polymerase function, our previous studies have highlighted a novel role for XMAP215 in facilitating interactions between microtubules and F-actin in the embryonic neuronal growth cone, the dynamic structure at the tip of the growing axon. Here, we utilized biochemical assays in combination with high resolution light microscopy, including super resolution imaging, to determine how XMAP215 links microtubules to F-actin in the growth cone. We first established the TOG5 domain as a necessary region that is responsible for direct interactions with F-actin. In addition, we determined that XMAP215 microtubule-lattice-binding activity as well as TOG5-mediated F-actin binding domains are essential for influencing microtubule guidance into the growth cone peripheral domain. Finally, we discovered that these dual cytoskeletal roles of XMAP215 are independent from, and do not require, its classical microtubule polymerase activity. Thus, our work highlights the novel and important role that XMAP215 plays in directing microtubule extension into targeted regions of the growth cone through F-actin interaction, facilitating protrusion and steering of the axon during outgrowth.

B107/P2503

Microtubule remodeling transforms the cell morphology of activated microglia

M. Adrian[1], M. Weber[1], M. Tsai[1], L. Phu[2], T. Cheung[2], W. J. Meilandt[1], C. Rose[2], C. C. Hoogenraad[1]; [1]Neuroscience, Genentech, South San Francisco, CA, [2]Microchemistry, Proteomics & Lipidomics, Genentech, South San Francisco, CA.

Microglial activation is a pathological hallmark in many neurodegenerative diseases. During activation, microglia undergo complex morphological changes, including loss of their characteristic ramified cell morphology, which is routinely used to detect and quantify inflammation in the brain. However, the molecular mechanisms enabling this morphological change and the relation between microglia cell morphology and its pathophysiological function are not understood. Here, proteomic profiling of activated microglia cells identified parallel microtubule remodeling pathways that drive the morphological change and subsequently control cytokine release. We found that activated microglia cell increase their microtubule dynamics to form a stable and centrosomally anchored microtubule array to

facilitate efficient cytokine trafficking. Moreover, we identified cyclin-dependent kinase 1 (Cdk-1) as a critical upstream regulator of microtubule remodeling, cytokine release, and morphological change in vitro and in vivo. These results demonstrate a critical role for microtubule dynamics and reorganization in microglial activation and modulating cytokine-mediated inflammatory responses.

Anoxia-induced Rearrangements of Cellular Networks

J. ZHU, K. YUEN; The University of Hong Kong, Hong Kong, CHINA.

Oxygen plays a crucial role in cellular energy production because it acts as the terminal electron acceptor in mitochondrial oxidative phosphorylation. Acquiring and utilizing oxygen is essential for protozoans and metazoans on earth. In many organisms, including budding yeast, worms, and zebrafish, cells can enter a reversible suspended animation state under anoxia (0-100 ppm O_2), an extreme form of hypoxia, but the specific molecular mechanisms involved are unclear, and the responses appear to be different from hypoxia. Our current research is centred on elucidating cell molecular mechanisms and pathways in the adaptation of cellular organizations in anoxia-induced suspended animation, in which many organelles rearrange to facilitate the arrest. We have performed a genome-wide deletion gene mutant screening in budding yeast and identified 34 AIS (anoxia-induced suspended animation-required) candidate genes that can be grouped into different functional categories, such as cell cycle regulation, nuclear regulation, and chromosome organization. We have observed polarization of spindle pole body, docking of microtubules and nucleolus, changes in nuclear envelope shape and chromosome condensation by time-lapse live-cell imaging. Specifically, we identified a conserved cell division cycle gene *CDC50* that may be involved in cell polarization when entering anoxia-induced arrest and in polarized proliferation during recovery. We will further investigate how such spindle pole polarization affects kinetochore-microtubule attachment and chromosome segregation accuracy after anoxia. In conclusion, anoxia-induced rearrangements of the cellular network are important for cell survival from anoxia and such understanding will provide insights into therapeutic approaches that may prevent the reactivation of proliferation and metastasis of dormant cancer cells due to oxygen availability.

C53 Interacting with UFM1-Protein Ligase 1 Regulates Microtubule Nucleation in Response to ER Stress

V. Sulimenko[1], A. Klebanovych[1], S. Vinopal[1], E. Dráberová[1], V. Sládková[1], T. Sulimenko[1], V. Vosecká[1], L. Macůrek[1], A. Legido[2], P. Dráber[1]; [1]Institute of Molecular Genetics, Prague, CZECH REPUBLIC, [2]Drexel University College of Medicine, Philadelphia, PA.

ER distribution depends on microtubules, and ER homeostasis disturbance activates the unfolded protein response resulting in ER remodeling. CDK5RAP3 (C53) implicated in various signaling pathways interacts with UFM1-protein ligase 1 (UFL1), which mediates the ufmylation of proteins in response to ER stress. Here we find that UFL1 and C53 associate with γ-tubulin ring complex proteins. Knockout of *UFL1* or *C53* in human osteosarcoma cells induces ER stress and boosts centrosomal microtubule nucleation accompanied by γ-tubulin accumulation, microtubule formation, and ER expansion. C53, which is stabilized by UFL1, associates with the centrosome and rescues microtubule nucleation in cells lacking UFL1. Pharmacological induction of ER stress by tunicamycin also leads to increased microtubule nucleation and ER expansion. Furthermore, tunicamycin suppresses the association of C53 with the

centrosome. These findings point to a novel mechanism for the relief of ER stress by stimulation of centrosomal microtubule nucleation.

Marine sponge extract produces unique microtubule-related structural properties in myofibroblasts

M. B. Vaughan[1], S. Ko[1], A. L. Waters[2], D. Hashemi[1]; [1]Biology, University of Central Oklahoma, Edmond, OK, [2]Chemistry, University of Central Oklahoma, Edmond, OK.

Myofibroblasts are present in fibroses and contractures; these diseases are difficult to treat, and new therapies are needed. Marine sponges are known for producing bioactive compounds with therapeutic promise. We tested numerous marine sponge crude extracts for their effects on fibroblast proliferation, migration, and differentiation into myofibroblasts. One extract from a New Guinea sponge inhibited migration, but also truncated the bipolar cells' long axis, leaving cells somewhat cuboidal; this effect was similar in all 6 cell strains tested. We conducted staining to determine whether the cytoskeleton was affected. Microfilaments arranged in stress fibers were grossly unaffected by the treatment, while microtubules were severely disorganized, leaving a characteristic pattern of 4-8 foci of intensely stained microtubule tangles that developed over a period of 24-48 hours. Tubulin expression was largely unaffected. TGF-beta treatment increased alpha-smooth muscle expression by western blot and immunostaining, although the extract slightly reduced the overall effect. Proliferation was decreased, and certain cell strains were apoptotic. Fractionation will be conducted to isolate purified compounds to determine if these effects are due to a single compound or mixtures of compounds.

B111/P2507

Conserved mechanisms of branched cytoskeletal network growth in the Rhizarian amoeba, *Filoreta ramosa*

S. L. Guest, S. C. Dawson; University of California, Davis, Davis, CA.

Multicellularity involving colonial cell organization and differentiation generates emergent morphological complexity though the development of specialized cytoskeletal structures and cell types. Multicellularity has evolved at least five times across eukaryotic supergroups, including members of the SAR (Stramenopiles/Alveolates/Rhizaria). Our Rhizarian isolate *Filoreta ramosa* exhibits "aggregative multicellularity" in which amoebae fuse to form a reticulate network of branching and anastomosing pseudopodia. The resultant syncytium grows to span multiple centimeters in diameter and shares a contiguous cytoplasm, cell membrane, and cytoskeleton components. *Filoreta* uses branching mechanisms reminiscent of neuronal growth cone extension and dendritic arborization, while self-recognition enables continuous fusion events for rapid repair and dynamic morphology.
How and when have the cytoskeletal mechanisms enabling polarized growth cones and arborized morphology evolved in Eukarya? We are using our recently completed genome combined with super-resolution imaging and morphometric analyses to quantify cytoskeletal elements of complex network growth and development. We use antibodies to ɣ-TURC components and EB1 to visualize non-centrosomal MT nucleation and polarity throughout the network. We have also compared morphological perturbations in the network following treatment with various drugs affecting actin and

MT dynamics. As in neuronal growth cones, the branched network is organized with longitudinal MT arrays and actin-rich pseudopodia that initiate branch formation. Cytoskeletal drugs alter syncytial network development, underscoring the critical role of actin and MT dynamics, and actin-MT interactions in generating the branched morphology in Rhizaria and in Metazoa. We predict that the mechanisms governing the intricate cytoskeletal networks in *F. ramosa* are emergent properties of simple branch and anastomosis patterns involving widely conserved cytoskeletal proteins. Thus, the extensions and branching mechanisms typified by neuronal growth cones are conserved in Rhizaria and thus many pre-date the divergence of major eukaryotic lineages.

Septin association with microtubules is regulated by phosphorylation of the microtubule-binding domain of septin9

P. Bhakt[1], I. A. Kesisova[2], E. T. Spiliotis[1]; [1]DREXEL UNIVERSITY, PHILADELPHIA, PA, [2]Massachusetts Institute of Technology, Cambridge, MA.

Septins are a family of GTP-binding proteins, which assemble into higher order oligomers and filamentous polymers, and function in cell morphogenesis, mitosis, cell migration, and host defense against pathogens. Septins are associated with the actin and microtubule (MT) cytoskeleton, and cellular membranes, but the mechanisms and signaling pathways that regulate these interactions are poorly understood. Previous work has identified putative phosphorylation sites on the N-terminal MT-binding domain of septin 9 (SEPT9), which mediates the interaction of septins with MTs. Here, we have focused on the phosphorylation of the SEPT9 residues S82 and S85 by the glycogen synthase kinase-3 beta (GSK3b), and the phosphorylation of residues S80 and S89 by the citron kinase (CK) and protein kinase A/C (PKA/PKC), respectively. S82 and S85 are also putative PKA/PKC sites, and S89 can function as a priming phosphosite for the phosphorylation of S85 by GSK3b. Notably, all serine residues are positioned between MT-binding motifs (K/R-R/x-x-D/E) of SEPT9. To investigate whether phosphorylation of these residues impact septin-MT association, we performed in vitro phosphorylation of purified recombinant Sept9, and generated a Sept9 construct with phosphomimetic mutations in S80/82/85, which were converted to aspartate (D; Sept9-S80/82/85D). We found that phosphorylation of Sept9 by PKA reduced MT-binding in vitro, and Sept9-S80/82/85D exhibited diminished interaction with MTs in vitro and in MDCK cells. Additionally, expression of the constitutively active kinases GSK3b-S9A and PKAcs-GGSD5X altered the localization of Sept9 to MTs and endomembranes. Notably, expression of Sept9-S80/82/85D in Sept7-depleted cells resulted in significant loss of MT mass, indicating that Sept9 association with MTs is critical for MT polymerization and stability. Ongoing work aims at characterizing the phosphorylation effects on SEPT9 dimerization and heteromeric assembly, its physiological significance for MT organization and functions in polarized traffic and cell polarity.

AUG8 function in the *Arabidopsis* interphase cortical microtubule array

N. Chana, T. Cioffi, S. L. Shaw; Indiana University Bloomington, Bloomington, IN

The genetic mechanisms controlling cellular morphogenesis are largely unknown. These mechanisms are of particular importance in plants, which adapt to changing environmental stimuli through irreversible cell growth. Plant cell shape is defined by a semi-rigid cellulosic cell wall. Cellulose deposition is guided by a plasma-membrane associated network of microtubules nucleated by γ-tubulin ring complexes. This

cortical microtubule array organizes into specific patterns in response to developmental and environmental cues that pattern the cellulose deposition, influencing the material properties of the cell wall. Thus, studying the mechanisms regulating cortical array organization are integral to elucidating how cellular morphogenesis occurs.
In animal cells, branching microtubule-dependent microtubule nucleation occurs almost exclusively during mitosis. The hetero-octameric Augmin complex facilitates this nucleation type by connecting γ-tubulin ring complexes to pre-existing microtubules. The Augmin complex and its mitotic function are conserved in vascular plants, which create bipolar mitotic spindles in the absence of centrosomes. Bioinformatic analyses indicate that *Arabidopsis* contains four paralogous genes closely related to human HAUS8, *X. laevis* haus8.L, and *D. melanogaster* Dgt4. *Arabidopsis* EDE1 is most homologous to HAUS8 and is only expressed in mitosis. The three remaining *Arabidopsis* orthologs, SCO3, QWRF4, and QWRF8(AUG8), are expressed during interphase in growing tissues. While all HAUS8 orthologs maintain strong C-terminal conservation, QWRF4 and AUG8 contain an elaborated N-terminal domain going back to liverworts. We hypothesize that QWRF4 and AUG8 function in the organization of the interphase cortical microtubule array and may have specific roles related to the parallel and antiparallel microtubule bundles arising in different cortical array patterns. To test our hypothesis, we have identified mutants for both genes and characterized defects in the axial growth of the seedling hypocotyl. Mutants for both genes are viable and display hypocotyl hyper-elongation when grown in the dark. To characterize the molecular function of these genes, we have generated fluorescent protein fusions and observed puncta localizing along microtubules.

B114/P2510
Elucidating the molecular mechanism of tubulin isotype function
L. Savoy, M. Gupta; GDCB, Iowa State University, AMES, IA.

Microtubules (MTs) are dynamically unstable cytoskeletal filaments, polymerized from tubulin, an obligate heterodimer of α- and β- subunits. They play an essential role in preserving genome stability and cell viability by mediating a multitude of diverse and conserved cellular functions, like cell division, cell migration, force generation and intracellular cargo transport. Naturally, a variety of regulators underlie these precise MT functions, namely, microtubule associated proteins (MAPs), post translational modifications, and relatively understudied, multiple tubulin isotypes. Why multiple tubulin isotypes exist, remains a fundamental and elusive question in cytoskeleton biology. Unfortunately, studying this question in most metazoan models, possessing multiple isotypes, risk introducing masking effects and hence biased observation. However, Saccharomyces cerevisae, harboring only 2 α- and 1 β-tubulin tubulin isotypes, offers a simple, robust, genetically tractable and superior model system. Our recent study demonstrated that each of the two *S. cerevisiae* α-tubulin isotypes (*TUB1* and *TUB3*) distinctly optimizes the overall efficiency of the two mutually redundant, Dynein- and Kar9-dependent mitotic spindle positioning pathways. Additionally, *TUB1* and *TUB3* drive differential recruitment of MAPs involved in these pathways on cytoplasmic MTs. But the underlying molecular mechanism(s) of differential MAP recruitment by distinct α-tubulin isotypes is presently unknown. In this study, by applying yeast CRISPR-Cas9 toolbox, live cell imaging and cell-based assays we aimed to elucidate the specific structure-function effects between tubulin isotypes and their preferred MAPs (Tub1 vs Dynein- and Tub3 vs Kar9-pathway proteins) by interchanging different functional domains of the two α-tubulin isotypes for the first time to elucidate what portion of each produce their specific functions.

Microtubule Dynamics: Modeling and Reconstitution

Building order from disorder: mechanistic and regulatory roles for phase condensation in the assembly of microtubule architectures by Tubulin polymerization-promoting protein

C.-C. CHANG, S. M. Coyle; The University of Wisconsin-madison, Madison, WI

Microtubule filaments (MTs) provide the foundation for many higher-order cytoskeletal structures within the cell, ranging from the mitotic spindle to ciliary axonemes to the axons and dendrites in neuron cells. These structures require the coordinated action of specific microtubule-associated proteins (MAPs) to organize the microtubules in a precise manner across cellular length-scales. In oligodendrocytes, tubulin polymerization promoting protein (TPPP) is a microtubule-associated protein (MAP) and has been proposed to nucleate and stabilize microtubules at Golgi-outpost to promote the elongation, branching, and polarization of myelin sheaths. However, the molecular mechanism of microtubule bundling by TPPP and its regulation has not been defined. Here, we demonstrate that TPPP assembles higher-order microtubule architectures through a multivalent bind-and-condense mechanism. We find that a structured “core” domain of TPPP can bind MTs in vitro, but that bundle-formation requires the presence of flanking intrinsically disordered regions (IDRs) that drive TPPP droplet formation. The combination of MT-binding and condensation activity was sufficient for assembling MT-bundles, as TPPP-core bunding activity could be functionally rescued by fusion with condensate-forming IDRs from unrelated proteins. Electron-microscopy revealed that these MT-bundles are held together by a combination of direct binding to individual MTs and condensate-bridges between adjacent MTs. To test the relevance of this mechanism in living cells, we reconstituted TPPP-bundle formation synthetically in NIH 3T3 cells. We found that optogenetic clustering of full-length TPPP, but not TPPP-core, led to rapid droplet-formation and MT-association. Moreover, we could induce persistent and extensive MT-bundling in the cell by coupling TPPP to other droplet-forming IDRs. Strikingly, the extent of this bundling scaled with the strength of the IDR, suggesting that regulation of TPPP condensation can provide a mechanism for organizing higher-order microtubule architectures in space and time. Our study provides mechanistic evidence that IDRs enable TPPP to form high valency phase-separated liquid droplets that can enhance its ability to bind, coat, and bundle microtubules. This work provides a new perspective on how LLPS cooperates with classic microtubule-directed activities to allow microtubule architectures to be coordinated across cellular length scales.

B116/P2512

Dynamic Instability from Non-equilibrium Structural Transitions on the Energy Landscape of Microtubule

S. F. Stewman, K. Tsui, **A. Ma**; University of Illinois Chicago, Chicago, IL.

Microtubules are the backbone of the cytoskeleton and vital to numerous cellular processes. All the functions of microtubules are driven by dynamic instability, but its mechanism has remained unresolved for over 30 years because of conceptual difficulties inherent in the prevalent GTP-cap framework. We present a physically rigorous structural mechano-chemical model: dynamic instability is driven by non-equilibrium transitions between the bent (B), straight (S), and curved (C) structures of tubulin monomers and longitudinal interfaces in the two-dimensional lattice of microtubule. All the different phenomena (growth, shortening, catastrophe, rescue, and pausing) are controlled by the kinetic pathways for B-to-S

and S-to-C transitions and their corresponding energy landscapes. Different kinetics of dynamic instability at plus and minus ends are due to different B-to-S and S-to-C pathways necessitated by the polarity of microtubule lattice. This model enables us to reproduce all the observed phenomena of dynamic instability of purified tubulins in kinetic simulations and provide the detailed physical mechanisms behind them.

B117/P2513

Investigating the biochemical mechanisms of microtubule depolymerization with simulations and experiments

L. A. McCormick, E. Bonventre, A. Brudnicka, L. M. Rice; UT Southwestern Medical Center, Dallas, TX.

Microtubules are essential polymers of αβ-tubulin that form key components of the eukaryotic cytoskeleton. Despite decades of study, we lack a complete understanding of how microtubules depolymerize, or "shrink". Are shrinking rates driven purely by the one-at-a-time dissociation of αβ-tubulin subunits from the microtubule end, or might other mechanisms play a role? In previous work, we identified a β-tubulin mutation that slows the shrinking rates of yeast and human microtubules without directly altering tubulin polymerization interfaces. The buried, allosteric β:T238A mutation is a unique tool to study how microtubules depolymerize. Here I use Interference Reflection Microscopy (IRM) and recombinant human tubulin to determine how "doses" of the slow-shrinking mutant affect the dynamics of mixed mutant-wild type (WT) microtubules. Microtubules were polymerized from mixtures of 5%, 10% or 20% T238A (95%, 90% or 80% WT, respectively) at 37 °C. To establish a baseline for the dynamics of WT and mutant, I also measured the polymerization dynamics of pure WT and pure mutant microtubules. Relative to WT, substantial changes in growth and shrinking rates were observed for mixed mutant-WT microtubules, and a decrease in catastrophe frequency was observed for both the plus and minus ends. The mutant-correlated decrease in catastrophe frequency was not accompanied by an increase in rescue frequency. In previous work, we developed kinetic Monte Carlo simulations that create a "biochemical movie" of microtubule dynamics with one reaction - association, dissociation, GTPase - per frame. To test mechanistic interpretations of my data, I have extended our plus end code to model the minus end, and have added the capability to model mixed mutant-WT microtubules. Current work is focused on using my experimental data to constrain kinetic simulations of microtubule dynamics. By combining simulations with experiments, I hope to produce new, quantitative insight into the biochemical mechanism of shrinking.

B118/P2514

Self-organization of microtubules through hydrodynamic interactions drives cell-spanning rotational flows

D. B. Stein[1], A. B. Sami[2], G. Kabacaoğlu[3], M. J. Shelley[1], J. C. Gatlin[2]; [1]Center for Computational Biology, Flatiron Institute, New York City, NY, [2]Molecular Biology, University of Wyoming, Laramie, WY, [3]Bilkent University, Ankara, TURKEY.

The piconewton forces generated by molecular motors carrying cargo along microtubules, or by microtubules polymerizing against the cell cortex or artificial boundaries, are sufficient to deform long microtubules. When microtubules are sparse in the cytoplasm, their deformations are disordered, characterized by high-frequency buckling and inducing only localized cytoplasmic flows. When the microtubules are instead arranged in a dense forest, the nature of the microtubule deformations and

induced cytoplasmic flows can change dramatically, giving rise to long-range order and coherent flows. Using a combination of experiments, large-scale simulations of microtubules interacting hydrodynamically through a viscous fluid, and a coarse-grained theory for dense beds of filaments, we elucidate the mechanisms that underlie the self-organization of microtubule ensembles and their subsequent generation of cell-spanning rotation in two examples: cytoplasmic streaming in the Drosophila Melanogaster oocyte, and spontaneous rotation of artificially confined asters in Xenopus Laevis extract.

B119/P2515

A structural mechano-chemical model of microtubule nucleation

K. K. Tsui, S. F. Stewman, A. Ma; Biomedical Engineering, University of Illinois At Chicago, Chicago, IL.

Microtubules (MTs) are the backbone of cytoskeleton and crucial for many essential processes, such as mitosis, morphogenesis and migration. A critical step in the assembly and regulation of cellular MT network is nucleation. There are two types of templates for MT nucleation in cells: existing MT and γ-tubulin ring complex. Both types of nucleations have been reconstituted in vitro, but their mechanisms remain poorly understood. Here, we developed a physically rigorous structure-based mechano-chemical model that provides an unified mechanism for both types of nucleations. For nucleation from seed MTs, the key observations are: 1) the critical tubulin concentration for nucleation is much higher than that for growth, 2) the concentration-dependent time lags. Our model shows that the bottleneck for nucleation is frequent catastrophes (i.e. the switching from MT growth to shortening) that keep removing nascent MTs from the seed, which is reduced as tubulin concentration increases. The observed time lag is due to repeated assembly and removal of nascent MTs, which delay nucleation. For nucleation from γ-tubulin ring, the most intriguing question is the effects of ring closure, a complex-wide conformational change required for the ring complex to match the tube-like geometry of MT. Our model shows that ring closure helps tubulins to first form a sheet, which is then closed into tube with the help of the ring closure process. Because catastrophe cannot develop while sheet is open, MTs more likely grow longer, increasing the chance of nucleation. Thus, ring closure allows more regulated and efficient MT nucleation.

B120/P2516

Mechanism of Microtubule Assembly by CKAP2

T. McAlear, M. Wozny, M. Strauss, **S. Bechstedt**; McGill University, Montreal, QC, CANADA.

Our lab has recently described the mitotic spindle protein CKAP2 (Cytoskeleton-associated protein 2) as a potent microtubule assembly factor.We now investigate, how CKAP2 can increase the nucleation and assembly rate of microtubules.As working hypotheses, we consider that CKAP2 could either activate tubulin, the microtubule end, affect GTP hydrolysis, or concentrate and capture tubulin to achieve the observed effects. Here, we discuss experiments including structure-function studies for the interaction of CKAP2 with microtubules and tubulin in vitro to confirm or exclude working hypotheses.Strikingly, we find that CKAP2 can grow microtubules in the absence of GTP. We present cryo-EM data showing structures assembled in the absence and presence of tubulin.

B121/P2517

The g-tubulin ring complex (g-TuRC) regulates microtubule protofilament number

A. Aher, L. Urnavicius, A. C. Xue, T. M. Kapoor; Laboratory of Chemistry and Cell Biology, The Rockefeller University, New York, NY.

Microtubules are cytoskeletal polymers comprised of α-β tubulin heterodimers. Tubulin dimers associate in a head-to-tail fashion to form protofilaments, several of which interact laterally to assemble the cylindrical microtubule filament. Microtubules nucleated spontaneously *in vitro* can have 9-16 protofilaments, and 14 protofilament microtubules are the most abundant. In contrast, microtubules in many human cell types have been found to have 13 protofilaments. It has been proposed that the γ-tubulin ring complex (γ-TuRC), a ~2.3 MD cone-shaped assembly comprised of γ-tubulins and associated proteins, can template the nucleation of microtubules with 13 protofilaments in cells. However, it is unclear if the γ-TuRC can specify microtubule protofilament number as structural studies have revealed a mismatch between the helical arrangement of γ-tubulins in γ-TuRC and that of tubulin dimers in a 13 protofilament microtubule. To examine the regulation of microtubule architecture by γ-TuRC, we established assays with purified proteins and employed cryo-electron microscopy (cryo-EM). We first optimized conditions for microtubule nucleation by native human γ-TuRC in TIRF microscopy-based assays. We then established conditions to directly nucleate microtubules on EM grids in the presence of γ-TuRC alone or with additional accessory proteins. We used reference-free 2D classification to segregate individual microtubule segments and measure respective widths. In addition, the segments were subjected to 3D classification with alignment to synthetic references of microtubules with differing protofilament numbers. Together, these analyses indicate that γ-TuRC nucleates microtubules with predominantly 13 protofilaments. Our findings suggest that the association of tubulin subunits with the γ-tubulin subunits might induce changes in the γ-TuRC's conformation and regulate the architecture of the microtubule lattice. The methods we have developed, along with recombinant forms of γ-TuRC we have generated, will help further dissect the regulation of microtubule architecture and nucleation.

CLASPs dictate the tubulin off-rate to regulate microtubule dynamics

E. J. Lawrence, M. Zanic; Vanderbilt University, Nashville, TN.

CLASPs constitute a family of conserved TOG-domain proteins that regulate microtubules in many fundamental cellular processes. CLASPs stabilize dynamic microtubules by suppressing catastrophe and promoting rescue, the switch-like transitions between growth and shrinkage. However, the molecular mechanisms underlying CLASPs' activity are not fully understood. Here, we report that human CLASP1 depolymerizes stable microtubules in the absence of tubulin, an activity previously reported for another TOG-domain protein XMAP215. Surprisingly, we find that, unlike XMAP215, CLASP activity is nucleotide-dependent, depolymerizing stable microtubules in the presence of GTP and GDP, but not in the presence of GMPCPP nor in the absence of nucleotide. We demonstrate that other human CLASP family members (CLASP2α and CLASP2γ) also exhibit nucleotide-dependent depolymerase activity on stable microtubules, as does a TOG2-domain construct, the minimal unit required for regulating microtubule dynamics. By investigating CLASP's effects on microtubules grown with GTP, GMPCPP, or a mixture of the two nucleotides, we find that CLASP1 dictates the rate of microtubule depolymerization regardless of microtubule substrate. Therefore, we conclude that CLASP1 regulates the tubulin-off rate at microtubule ends. The unanticipated finding that CLASPs dictate the tubulin-off rate in a nucleotide-

dependent manner underlies CLASPs activity on dynamic microtubules and provides critical mechanistic insights into an important family of microtubule regulatory proteins.

B123/P2519

CLASP2 facilitates dynamic actin filament organization along the microtubule lattice

N. Rodgers, E. Lawrence, N. Efimova, G. Gonzalez-Vasquez, T. Hickman, I. Kaverina, M. Zanic; Vanderbilt University, Nashville, TN.

Coordination between the microtubule and actin networks is essential for cell motility, neuronal growth cone guidance, and wound healing. Members of the CLASP (Cytoplasmic Linker-Associated Protein) family of proteins have been implicated in the cytoskeletal crosstalk between microtubules and actin networks, however, the molecular mechanisms underlying CLASPs role in cytoskeletal coordination are unclear. Here, we investigate CLASP2α's crosslinking function with microtubules and F-actin. Our results demonstrate that CLASP2α crosslinks F-actin to the microtubule lattice in vitro. We find that the crosslinking ability is retained by L-TOG2-S, a minimal construct containing the TOG2 domain and serine-arginine rich region of CLASP2α. Furthermore, CLASP2α promotes the accumulation of multiple actin filaments along the microtubule, supporting up to 11 F-actin landing events on a single microtubule lattice region. CLASP2α also facilitates dynamic organization of polymerizing actin filaments templated by the microtubule network, with F-actin forming bridges between individual microtubules. Finally, we find that depletion of CLASPs in vascular smooth muscle cells results in disorganized actin fibers, suggesting that CLASP and microtubules contribute to higher-order actin structures. Taken together, our results indicate that CLASP2α can directly crosslink F-actin to microtubules, and that this microtubule-CLASP-actin interaction may influence overall cytoskeletal organization in cells.

B124/P2520

A chemical genetics approach to examine cytoskeleton remodeling functions of AAA proteins

N. H. Jones, T. Cupido, M. J. Grasso, R. Pisa, F. Anson, T. M. Kapoor; Laboratory of Chemistry and Cell Biology, The Rockefeller University, New York, NY.

AAA (ATPases associated with diverse cellular activities) proteins such as katanin and spastin can sever microtubules and contribute to cytoskeletal organization and function. Cell-permeable, selective, and potent chemical probes can be useful tools to study the functions of these proteins in dynamic cellular processes including cell division, cell migration, and the assembly/disassembly of the primary cilium. However, structural conservation across the AAA protein family makes designing selective chemical inhibitors challenging. Here, we used a structure-based approach to design ASPIRe-1 (allele-specific, proximity-induced reactivity-based inhibitor-1), a compound that selectively inhibits katanin with an engineered mutation (D210C). Structural studies confirm our model for compound binding at the AAA ATPase site and the proximity-induced reactivity-based inhibition. ASPIRe-1 treatment (1.25 μM, 4 hours) of cells expressing katanin D210C (in addition to the native protein) increases the length of CAMSAP2 'stretches' at microtubule minus ends by ~1.5-fold, consistent with katanin knockdown studies. Importantly, ASPIRe-1 treatment does not result in cell toxicity, nor does it cause elongation of CAMSAP2 stretches in cells expressing WT katanin, indicating inhibitor specificity. Our findings also suggest that the ATPase activity of katanin contributes to its function in CAMSAP2 regulation. Together, our findings introduce a selective tool to decipher the role of katanin in cytoskeletal dynamics in cell division, cell migration, and ciliary biology. Since ASPIRe-1 binds the conserved ATPase site, our

approach can also be used to study the functions of other AAA proteins, such as VSP4, that regulate membrane dynamics.

Regulating Microtubule Severing by Katanin Physically and Chemically

T. M. Finegan, K. A. Lindsay, N. Abdelhamid, K. M. Primeau, J. L. Ross; Department of Physics, Syracuse University, Syracuse, NY.

We are investigating the physical and chemical regulation of the microtubule severing enzyme, katanin. Katanin is a AAA+ enzyme that hexamerizes to build a functional unit that severs tubulin filaments via the removal of tubulin monomers. Unregulated activity of katanin in cells can destroy the entire microtubule network, thus precise spatial and temporal regulation is essential. We present novel data illustrating that the carboxy-terminal tail sequence of tubulin acts as a code to control katanin severing activity. We are also using quantitative fluorescence microscopy to test the hypothesis that oligomerization of katanin at microtubules is the rate-limiting step for tubulin severing. We are utilizing tools that precisely target katanin localization and expression in cells to locally disrupt the microtubule cytoskeleton and investigate the biochemistry of multitude microtubule-regulated processes. We present novel data quantifying katanin concentration and the microtubule filament density as a function of time to elucidate the dynamics of biochemical control of microtubules by katanin in cells for the first time.

B126/P2522

Combinatorial readout of the tubulin code by katanin

E. Szczesna[1], E. A. Zehr[1], S. W. Cummings[1], A. Szyk[1], K. K. Mahalingan[1], Y. Li[2], A. Roll-Mecak[1,3]; [1]Cell Biology and Biophysics Unit, National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD, [2]Proteomic Core Facility, National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD, [3]Biochemistry and Biophysics Center, National Heart, Lung and Blood Institute, NIH, Bethesda, MD.

Cells functionalize microtubules with spatiotemporally complex patterns of posttranslational modifications. How effectors interpret this tubulin modification code is largely unknown. Here, we show that katanin, a microtubule severing AAA ATPase mutated in microcephaly and critical for cell division, axonal elongation and cilia biogenesis, responds precisely, differentially and combinatorially to three chemically distinct modifications: glycylation, glutamylation, and tyrosination, but is insensitive to tubulin acetylation. Glutamylation and glycylation act as antagonistic rheostats with glycylation being protective of microtubules. Katanin exhibits graded and divergent responses to glutamylation on the α- and β-tubulin tails, and these act combinatorially. The structure of the katanin hexamer central pore constrains the polyglutamate chain patterns on β-tails that can productively be recognized. In contrast, elements distal to the katanin AAA core sense α-tubulin tyrosination, and detyrosination downregulates severing. The multivalent microtubule recognition that enables katanin to read multiple tubulin modification inputs explains *in vivo* observations and illustrates how effectors can integrate tubulin code signals to produce diverse functional outcomes. A.R.M is supported by the intramural programs of the National Institute of Neurological Disorders and Stroke (NINDS) and the National Heart, Heart and Blood Institute (NHLBI).

B127/P2523

Ultrasensitivity of microtubule severing rate on the concentration of free tubulin

C. E. Shiff[1], J. Kondev[2], **L. Mohapatra**[3]; [1]Stanford University, Stanford, CA, [2]Brandeis University, Waltham, MA, [3]Rochester Institute of Technology, Rochester, NY

Cytoskeletal structures aid in cell polarization, motility, and intracellular transport. Their functions are predicated on the rapid turnover of cytoskeleton proteins, which is achieved by the coordinated effort of multiple regulatory proteins whose dynamics are not well understood. In-vitro experiments have shown that free tubulin can repair nanoscale damages of microtubules created by severing proteins. Based on this observation, we propose a model for microtubule severing as a competition between the processes of damage spreading and tubulin-induced repair. Using theory and simulations, we demonstrate that this model is in quantitative agreement with in vitro experiments. We predict the existence of a critical tubulin concentration above which severing becomes rare but fast, and hypersensitive to the concentration of free tubulin. Further we show that this hypersensitivity leads to a dramatic increase in the dynamic range of steady-state microtubule lengths, when lengths are controlled by severing. Our work demonstrates how synergy between tubulin and severing proteins can lead to novel dynamical properties of microtubules.

B128/P2524

Making a microtubule: structural analysis of microtubule nucleation by the gamma-tubulin ring complex (γTuRC)

B. Romer[1], B. Mahon[1], M. Rale[1], N. Coudray[2], G. Bhabha[2], S. Petry[1]; [1]Princeton University, Princeton, NJ, [2]New York University, New York, NY

Microtubules (MTs) are dynamic cylindrical polymers made of α/β-tubulin dimers that function in many diverse and essential cellular processes such as cell division, intracellular transport, and organelle positioning. Because of their importance, it is imperative that microtubules are nucleated at the correct time and place. A protein known to be essential for MT nucleation is γ-tubulin, which together with other proteins in the cell, forms a ring-like template called the γ-tubulin ring complex (γTuRC). Despite its importance, little is known about how the γTuRC nucleates MTs. To address this open question, our work is aimed at determining the structure of the γTuRC in its activated, nucleation-prone state. Using single-particle cryo-EM of γTuRC bound to a known activating factor, we will uncover if structural changes occur in the complex to facilitate MT nucleation. Altogether, these studies will further our understanding of how the universal MT nucleator functions to regulate the production of MTs.

B129/P2525

Acentrosomal spindles assemble from branching microtubule nucleation near chromosomes in *Xenopus laevis* egg extract

B. Gouveia, S. U. Setru, M. R. King, A. Hamlin, H. A. Stone, J. W. Shaevitz, S. Petry; Princeton University, Princeton, NJ

Microtubules are generated at centrosomes, chromosomes, and within spindles during cell division. Whereas microtubule nucleation at the centrosome is well characterized, much remains unknown about where, when, and how microtubules are nucleated at chromosomes. To address these questions, we reconstituted microtubule nucleation from purified chromosomes in meiotic *Xenopus* egg extract and

found that chromosomes alone can form spindles. We visualized microtubule nucleation near chromosomes using total internal reflection fluorescence microscopy to find that this occurs through branching microtubule nucleation. The initial branches nucleate near and towards chromosomes, helping explain how kinetochores might be efficiently captured. By inhibiting molecular motors, we find that the organization of the resultant polar branched networks is consistent with a theoretical model where the effectors for branching nucleation are released by chromosomes, forming a concentration gradient that spatially biases branching nucleation. In the presence of motors, these branched networks are ultimately organized into spindles.

B130/P2526

The role of microtubule severing protein UNC-45A in microtubule curvature

A. Hoshino, V. Clemente, M. Shetty, M. Bazzaro; Masonic Cancer Center and Department of Obstetrics, Gynecology and Women's Health, University of Minnesota, Minneapolis, MN.

Microtubules (MTs) are the least flexible of the cytoskeletal filaments. In cells MTs frequently curve and break (*1*). We have recently identified UNC-45A as novel ATP-independent MT severing protein (***2-5***). Here we wanted to study the contribution of UNC-45A to MT curvature. We used total internal reflection fluorescence (TIRF) and live cell imaging to examine the localization and effect of UNC-45A on MT curvature. We found that UNC-45A preferentially binds the curved regions of the MTs. Furthermore, UNC-45A increased MTs curvature independent of actomyosin. This is consistent with the fact that MT severing by UNC-45A is preceded by MT "kinks" (***3***). In conclusion, UNC-45A preferentially binds to curved MTs and causes exacerbation of this curvature leading to severing. Curved MTs are known to have lattice defects (*6*). Our result suggests that UNC-45A may bind to MT defects. The implication is that UNC-45A may also selectively affect MTs in paclitaxel and oxidative exposed cells (*7, 8*). Thus, UNC-45A may be particularly relevant in human diseases.

Integrated model of the vertebrate augmin complex

S. M. Travis[1], B. P. Mahon[1], W. Huang[2], M. Ma[3], M. J. Rale[1], J. S. Kraus[1], D. J. Taylor[2], R. Zhang[3], S. Petry[1]; [1]Department of Molecular Biology, Princeton University, Princeton, NJ, [2]Department of Pharmacology, Case Western Reserve University, Cleveland, OH, [3]Department of Biochemistry and Molecular Biophysics, Washington University in St. Louis, School of Medicine, St. Louis, MO.

Accurate segregation of chromosomes is required to maintain genome integrity during cell division. This feat is accomplished by the microtubule-based spindle. To build a spindle rapidly and with high fidelity, cells take advantage of branching microtubule nucleation, which exponentially amplifies microtubules during cell division. Branching microtubule nucleation relies on the hetero-octameric augmin complex, but understanding how augmin promotes branching has been hindered by a lack of structural information about the complex. Here, we report an integrated model of vertebrate augmin, combining cryo-electron microscopy, advanced protein structural prediction, and the visualization of fused bulky tags via negative stain electron microscopy. This strategy allowed us to identify the location and orientation of each subunit within the structure. Evolutionary analysis of augmin's structure reveals that it is highly conserved across diverse eukaryotes, and that augmin contains a previously-unidentified microtubule binding site. Moreover, we identify homology with the kinetochore-localized NDC80 complex. This new model of the augmin complex provides insight towards the mechanism and evolution of branching microtubule nucleation.

B132/P2528

The Augmin Complex is Regulated by RanGTP via its Microtubule Binding Domain

J. Kraus[1], S. Travis[1], M. King[2], S. Petry[1]; [1]Princeton University, Princeton, NJ, [2]Washington University in St. Louis, St. Louis, MO

The metaphase spindle is composed from microtubules (MT) that must be nucleated at exactly the right place and time for mitosis to occur efficiently without errors. The chromosome-localized RanGTP controls MT nucleation by sequestering spindle assembly factors (SAFs) via its effectors, importin-α and importin-β. Branching MT nucleation is a primary source of spindle MTs, and is dependent on the proteins augmin and TPX2, which recruit the universal nucleator, the γ-tubulin ring complex (γ-TuRC), to the sides of pre-existing MTs. While TPX2 is a Ran-regulated SAF, it is not required in all species, which leaves the regulation of branching MT nucleation an open question. Here, we use *in-vitro* pulldowns and TIRF microscopy assays to show that augmin is a bona-fide SAF. Augmin directly interacts with both importin-α and importin-β through two unique nuclear localization sequences (NLS) on augmin. Moreover, the localization of augmin to MTs in both *Xenopus* egg extract and *in-vitro* is dependent on the presence of RanGTP. Our work shows that augmin function is directly regulated by Ran, independently of TPX2, pointing to a conserved role for Ran in controlling branching MT nucleation during spindle assembly and beyond.

B133/P2529

Using the tubulin-like phage protein PhuZ to study the fundamental properties of biological energy utilizing polymers

Y. A. P. Huang, H. V. Goodson; University of Notre Dame, Notre Dame, IN

Microtubules (MTs) are energy utilizing polymers of α&β tubulins that form part of the cytoskeleton. A character of MTs is that individual MTs in the same cell constantly change randomly between phases of growth and shortening, a behavior known as Dynamic Instability (DI). Understanding the mechanism of DI and its regulation is essential to understand the role of MTs in cell organization, but DI is still poorly understood. Our lab is working to develop mathematical models (i.e., equations) that quantitatively connect the biochemical characteristics of subunits to the observed dynamic instability behaviors. Traditionally, the critical concentration (CC) is defined to be the lowest concentration of free subunits required to obtain polymer filaments. However, the traditional theory is based on equilibrium polymers and fails to incorporate energy utilization or the DI displayed by dynamically unstable polymers like MTs. Our previous studies based on computational MTs model indicated that MTs have (at least) two experimentally relevant CCs: $CC_{Elongation,}$ above which growth phases of individual filaments can occur transiently. $CC_{NetAssembly}$, above which the population's polymer mass will increase persistently. Here, we use a tubulin-like bacteriophage protein called PhuZ to establish a simplified experimental system to test the predictions of our computational models. Because PhuZ has sufficiently similar characteristics to MTs, studying $CC_{Elongation}$ and $CC_{NetAssembly}$ of wild-type and mutant PhuZs will experimentally contribute to establish a predictive understanding of the relationship between the characteristics of the subunits, the behaviors of the filaments and the attributes of the dynamically unstable biological polymer systems.

Sensory and Signaling Functions of Cilia

B135/P2530

Kinesin-2 motors differentially impact biogenesis of distinct extracellular vesicle subpopulations shed from *C. elegans* sensory cilia

M. Clupper, R. Gill, M. Elsayyid, D. Touroutine, J. Caplan, **J. Tanis**; Department of Biological Sciences, University of Delaware, Newark, DE.

Secreted extracellular vesicles (EVs) play a critical role in communication between cells during physiological processes and under pathological conditions. A single cell can release multiple distinct EV subpopulations, each with different cargo enrichment and functionalities. How an individual cell packages and sheds distinct populations of EVs is unclear. In *C. elegans*, EVs bud from male sensory neuron cilia and then are either up-taken by surrounding glia or discharged into the environment where they play a role in animal-to-animal communication. We developed a model to interrogate EV cargo enrichment mechanisms by expressing different fluorescently-labeled EV cargoes in *C. elegans* at single copy and imaging with total internal reflection fluorescence (TIRF) microscopy. We discovered the ion channel CLHM-1 as a cargo in EVs released from the ciliary base into the environment. tdTomato-tagged CLHM-1 and GFP-tagged PKD-2 TRPP channel, a well described EV cargo, colocalize in the ciliary base and middle segment of the cilium proper. However, we found that these proteins are enriched in distinct EV subpopulations, with PKD-2 alone located in the cilium distal tip and EVs shed from this site. Shedding of CLHM-1 containing EVs increased in response to the presence of hermaphrodite mating partners, while release of tip-derived PKD-2 EVs decreased under these conditions, suggesting that

these subpopulations are differentially shed in response to physiological stimulus. We discovered that the heterotrimeric KLP-11-containing and homomeric OSM-3 kinesin-2 motors play distinct roles in CLHM-1 EV biogenesis, colocalization of ciliary proteins, and EV cargo enrichment. Complete elimination of all kinesin-2 motors decreased shedding of EVs containing PKD-2, but did not inhibit CLHM-1 cilia entry or inclusion in EVs, indicating that intraflagellar transport differentially impacts biogenesis of discrete EV subpopulations. This work shows that an individual cilium generates heterogeneous EVs with different signaling potentials and that spatial determinants regulate both EV cargo enrichment and biogenesis.

B136/P2531

Characterization of ciliary associated renal extracellular vesicles

A. Frei[1], **H. May-Simera**[1], A. Volz[1], J. Weinmann-Menke[1], M. Ueffing[2], K. Boldt[2], E. Albers[1]; [1]Johannes Gutenberg University, Mainz, GERMANY, [2]University of Tübingen, Tübingen, GERMANY.

Primary cilia are required for a variety of cellular processes such as signal transduction and cell communication during development and tissue homeostasis. Defects in ciliary function lead to a broad range of diseases, with renal dysfunction as a common feature representing a significant cause of morbidity and mortality in patients. Recent studies showed that primary cilia are able to transmit signals via the release of extracellular vesicles (EVs). Although the putative role of EVs in processes during organ development and homeostasis is not well know, it is emerging that EVs can influence key signalling pathways involved in kidney development and pathogenesis. Changes in EV-mediated signalling due to ciliary dysfunction could thus impact tissue homeostasis leading to disease pathogenicity such as renal cyst formation. In our study we focused on the release of small EVs from a variety of ciliated kidney cell lines to better understand ciliary EV biogenesis and bioactivity in renal tissues. We observed differences not only in the release but also in the composition of EVs depending on cell type as well as ciliation. In addition, we shed light on the origin of small EVs by inhibition of various release pathways. To further investigate EV based signalling mechanisms in renal pathogenesis associated with ciliopathies, we compared EVs from control and ciliary mutant cells derived from both mouse tissue and patient urine. Ciliary dysfunction greatly affected renal EV release and composition, which was differently influenced by modulation of release pathways. These results provide us with insights into EV-related ciliary signaling mechanisms which might underly ciliopathy disease pathogenesis.

A serotonergic axon-cilium synapse drives nuclear signaling to alter chromatin accessibility

S. SHEU[1], S. Upadhyayula[2], V. Dupuy[3], S. Pang[1], F. Deng[4], J. Wan[4], D. Walpita[1], H. Pasolli[1], J. Houser[5], S. Sanchez-Martinez[1], S. E. Brauchi[1], S. Banala[6], M. Freeman[1], C. Xu[1], T. Kirchhausen[5], H. F. Hess[1], L. Lavis[6], Y. Li[4], S. Chaumont-Dubel[3], D. E. Clapham[6]; [1]Janelia Research Campus/Howard Hughes Medical Institute, Ashburn, VA, [2]UC Berkeley, Berkeley, CA, [3]Université de Montpellier, Montpellier, FRANCE, [4]Peking University, Beijing, CHINA, [5]Boston Children's Hospital, Boston, MA, [6]Janelia Research Campus of Howard Hughes Medical Institute, Ashburn, VA.

Chemical synapses between axons and dendrites mediate neuronal intercellular communication. Here we describe a synapse between axons and primary cilia; the axo-ciliary synapse. Using enhanced focused ion beam-scanning electron microscopy on samples with optimally preserved ultrastructure, we discovered synapses between brainstem serotonergic axons and the primary cilia of hippocampal CA1

pyramidal neurons. Functionally, these cilia are enriched in a ciliary-restricted serotonin receptor, the 5-hydroxytryptamine receptor 6 (5-HTR6). Using a cilia-targeted serotonin sensor, we show that opto- and chemogenetic stimulation of serotonergic axons releases serotonin onto cilia. Ciliary 5-HTR6 stimulation activates a non-canonical $G_{\alpha q/11}$-RhoA pathway, which modulates nuclear actin and increases histone acetylation and chromatin accessibility. Ablation of this pathway reduces chromatin accessibility in CA1 pyramidal neurons. As a signaling apparatus with proximity to the nucleus, axo-ciliary synapses short circuit neurotransmission to alter the postsynaptic neuron's epigenetic state.

B138/P2533

Differentiated dynamic response in*C. elegans*chemosensory cilia

C. Bruggeman, **E. J. G. Peterman**, G. H. Haasnoot; Physics and Astronomy, Vrije Universiteit, Amsterdam, NETHERLANDS.

Cilia are membrane-enveloped organelles that protrude from the surface of most eurokaryotic cells and play crucial roles in sensing the external environment. For maintenance and function, cilia are dependent on intraflagellar transport (IFT). Here we investigate the response of the *Caenorhabditis elegans* phasmid chemosensory cilia to chemical stimuli to better understand the process of chemosensation. To do so we use a combination of microfluidics, to apply stimuli with a high degree of temporal control, and fluorescence microscopy, to visualize structure and dynamics of the cilia, as well as the neuronal response. We found that chemical stimulation resulted in unexpected changes in IFT and ciliary structure. Notably, stimulation with hyperosmotic solutions or chemical repellents resulted in different responses, not only in IFT, ciliary structure and cargo distribution, but also in neuronal activity. We found that in response to hyperosmotic stimuli, IFT components accumulate at the ciliary tip due to inhibition of retrograde transport. In response to chemical repellents, such as SDS or Cu^{2+}, the ciliary axoneme shrinks and IFT components are redistributed towards the ciliary base. In response to SDS we observe shedding of extracellular vesicles containing IFT components and transmembrane proteins. Repetitive stimulation with chemical repellents results in lower neuronal activity every subsequent exposure, pointing towards a mechanism of desensitization. This suggests that IFT plays a role in regulating the chemosensory response. Currently we are trying to unravel how IFT and neuronal activity are precisely linked on the molecular level. Taken together, our findings show that cilia are able to sense and respond to different external cues in distinct ways, highlighting the flexible nature of cilia as sensing hubs.

B139/P2534

Processing and Secretion of a Ciliary Peptidergic Signal

R. Luxmi[1], R. E. Mains[2], B. A. Eipper[3], S. M. King[1]; [1]Molecular Biology and Biophysics, UCONN Health, Farmington, CT, [2]Neuroscience, UCONN Health, Farmington, CT, [3]Molecular Biology and Biophysics, Neuroscience, UCONN Health, Farmington, CT.

Cilia are membrane bound microtubule-based sensory and secretory organelles that transmit and receive information from the extracellular environment. Cilia-derived vesicles (ectosomes), formed by outward budding of the ciliary membrane, contain bioactive proteins that mediate signals between individual cells and organisms. Ectosomal content is distinct from that of the cilium from which they derive and is regulated by both trafficking proteins through the transition zone and subsequently sorting them into nascent ectosomes. Peptidergic intercellular communication is evolutionary conserved, and

controls a broad array of physiological and behavioral responses. Many secreted peptides require C-terminal α-amidation in order to be bioactive. The *Chlamydomonas* genome encodes numerous genes with the potential properties of prepropeptides, and these cells secrete the peptide amidating enzyme and bioactive amidated products in ciliary ectosomes. An amidated synthetic peptide (GATI-*amide*) generated from a 91-kDa proGATI precursor acts as a chemotactic modulator, attracting *minus* gametes while repelling *plus* gametes. Full-length proGATI is heavily glycosylated and contains three stable folded domains interconnected by long, proline-rich linkers. Biochemical analysis revealed that proGATI is trafficked to the ciliary membrane, where *plus* gametes cleave it, producing a C-terminal glycosylated amidated product that is released in ciliary ectosomes during mating. Analysis of a potential prohormone convertase and the proGATI-derived products in cilia and ectosomes, links endoproteolytic cleavage to ectosome entry. Analysis of this pathway affords insight into the evolution of peptidergic signaling through regulated secretion, and will facilitate study of protein secretion through cilia in metazoans. To locate the cell surface receptor for GATI-*amide*, we designed a biotinylated GATI-*amide* synthetic peptide containing a benzoyl-phenylalanine residue that can be photo-activated by exposure to UV light. Preliminary studies revealed that this probe labels a ~70-kDa protein in isolated gametic cilia from *Chlamydomonas*. Formation of the biotinylated product is UV-dependent and competed out by addition of unlabeled GATI-*amide* peptide demonstrating probe specificity and indicating that a GATI-*amide* binding protein is localized to cilia.

B140/P2535

The tectonic complex forms a membrane diffusional barrier in mouse rod outer segments

H. M. Truong, K. O. Cruz-Colón, J. Y. Martínez-Márquez, J. R. Willer, A. M. Travis, J. N. Pearring; Department of Ophthalmology and Visual Sciences, University of Michigan, Ann Arbor, MI.

Primary cilia are thin, microtubule-based organelles that relay extracellular signals to the cell through ciliary membrane receptors. The distinct protein composition of the cilium is maintained by a membrane gate formed by the transition zone, located at the base of the cilium. In primary cilium, the transition zone generally retains receptors in this unique organelle; however, in the specialized light-sensing photoreceptor cilium (aka the outer segment) the transition zone acts to prevent non-resident proteins from accumulating in the outer segment compartment. The transition zone is delineated by the presence of electron-dense connections between the axoneme and ciliary membrane, called Y-links, as well as extracellular membrane densities, known as the ciliary necklace. While previous work has shown that membrane proteins utilize ciliary transport carriers to cross the transition zone, the molecular components forming the ciliary gate and its mechanisms regulating membrane protein composition remain ambiguous. The tectonic complex, Tctn1/2/3, is a component of the transition zone that has been shown to concentrate ciliary membrane proteins in primary cilia. We hypothesize that the tectonic complex helps form a diffusion barrier at the transition zone to maintain the unique membrane-associated protein composition of the photoreceptor outer segment. To study Tctn1 in rod photoreceptors, we generated a rod-specific Tctn1 knock-out mouse (*iCre;Tctn1*$^{f/f}$) and show that the entire tectonic complex - Tctn1/2/3 - is lost from the transition zone of rod outer segments. In the absence of the tectonic complex, outer segment morphology appears normal, however, membrane proteins typically excluded from the outer segment begin to accumulate within the outer segment. Mislocalization of these proteins is detrimental to rod health, resulting in photoreceptor degeneration by 6 months. Interestingly, we find that ciliary transport carriers are not affected by loss of tectonics but instead, the rate of membrane protein diffusion within the transition zone is increased. We conclude

that the tectonic complex helps form the membrane diffusional barrier at the transition zone to prevent non-resident membrane proteins from mislocalizing to the outer segment. Ultimately, these results establish how the transition zone functions as a membrane ciliary gate both within photoreceptors and primary cilia.

Mutations in the microcephaly gene,*RRP7A*, converge on defective TGFB/BMP signaling and associated trafficking events at the primary cilium

J. L. Fialová[1], J. Stensbøl[1], S. Antony[2], E. Dyke[3], L. B. Pedersen[1], N. N. Kasri[3], K. Boldt[2], L. A. Larsen[4], S. T. Christensen[1]; [1]Department of Biology, University of Copenhagen, Copenhagen, DENMARK, [2]Molecular Biology of Retinal Degenerations, Institute for Ophthalmic Research, University of Tübingen, Tübingen, GERMANY, [3]Donders Institute for Brain, Cognition and Behaviour, Radboud University Medical Centre, Nijmegen, NETHERLANDS, [4]Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, DENMARK.

Background and objective: We previously identified a homozygous missense mutation (W155C) in Ribosomal RNA (rRNA) Processing 7 Homolog A, RRP7A, segregating with primary microcephaly (MCPH; MIM #251200) in a consanguineous family with 10 affected individuals. RRP7A is highly expressed at the ventricular zone in the developing human neocortex in apical radial glial cells (aRGCs) to control rRNA processing, neurogenesis and cell cycle entry, which in part is associated with defects in the timely resorption of primary cilia [Farooq et al. (2020) Nat. Comm. 11, 5816]. Here we addressed the possible function of RRP7A at the primary cilium to regulate cellular signaling events that converge on neurogenesis and ciliary resorption to control brain development. **Methods and results:** Live imaging of RPE-1 cells stably expressing GFP-tagged RRP7A validated localization of RRP7A to the primary cilium, and immunofluorescence microscopy (IFM) showed prominent RRP7A localization to primary cilia laminating the neural rosette of cerebral organoids, marking the developmental signature of aRGCs, which expands the pool of neural progenitors and produces post-mitotic neurons during neocortex development. Proteomics of the RRP7A interactome in HEK293T and RPE-1 cells revealed novel interactors that converge on ciliary trafficking events and canonical TGFB/BMP signaling; interactions all affected by the patient mutation. IFM and western blotting analyses showed that TGFB/BMP-mediated R-SMAD signaling, which regulates aRGC self-renewal and differentiation, and which we show to induce ciliary resorption in human dermal fibroblasts and RPE-1 cells, is reduced at the primary cilium in HDFs carrying the patient mutation in RRP7A and in RPE-1 cells stably expressing the mutant version of RRP7A. In support of a ciliary link to regulation of canonical TGFB/BMP signaling during neocortex development, IFM analysis of cerebral organoids showed that R-SMAD activation at the neural rosette is confined to primary cilia of the aRGCs. In contrast, non-canonical TGFB/BMP pathways as well as PDGFRA signaling at the cilium are not perturbed in patient HDFs and RPE-1 cells expressing mutant RRP7A. These signaling phenotypes were recapitulated in RPE-1 cells subjected to siRNA-mediated depletion of RRP7A. **Conclusions:** We propose that RRP7A regulates key functions of primary cilia, including canonical TGFB/BMP signaling, to control the expansion of neural progenitors and ultimately the number of cortical neurons, providing novel insight into regulation of developmental signaling, brain development and MCPH. **Funding:** This project has received funding from the European Union's Horizon 2020 research & innovation program Marie Sklodowska-Curie Innovative Training Networks (ITN) grant No. 861329.

MRAP2: A universal adapter for ciliary GPCR localization

M. Konjikusic, J. Reiter; University of California, San Francisco, San Francisco, CA.

Growing evidence indicates that GPCRs, the largest class of receptor proteins, function differently in different subcellular locations, including the plasma membrane, endosome and Golgi. Recently, my lab and others have found that a select number of GPCRs localize to the membrane of the primary cilium. The primary cilium is a solitary, immotile, antenna-like projection that can transduce multiple types of intercellular cues. While we have a growing understanding of which GPCRs localize to cilia, how these GPCRs localized to cilia remains unknown. Recently, in collaboration with the Vaisse lab, we have shown that MC4R, integral for energy homeostasis and the single most common mutated gene in monogenic obesity, relies on a mysterious single-pass transmembrane receptor, MRAP2, for localization to the cilium. *MRAP2* has also been implicated in human obesity and female infertility. More recently, we have found that MRAP2 can traffic multiple other GPCRs to the cilium, outside of MC4R. Additionally, we report that MRAP2 expression is much wider than MC4R, implicating broader functions than that of MC4R localization in energy homeostasis. Future experiments will focus on identifying phenotypes associated with loss of *Mrap2* function in mouse other than obesity, and specifically identifying which GPCRs *Mrap2* can traffic to the cilium endogenously. We will also work to identify how exactly MRAP2 is trafficking multiple GPCRs to the cilium through structure function approaches *in vitro*.

A novel role for the conserved G protein regulator RIC-8/Synembryn in *C. elegans* neuronal cilia biology

C. Campagna, I. Nechipurenko; Worcester Polytechnic Institute, Worcester, MA

G protein coupled receptors (GPCRs) modulate key physiological processes via heterotrimeric G (αβγ) proteins. Many GPCRs and their downstream effectors localize to specialized cellular compartments called primary cilia, which mediate transduction of all major signaling pathways in mammals. Defects in cilia structure or function result in a spectrum of genetic disorders called ciliopathies that are commonly associated with neurological deficits. Likewise, genetic perturbation of select cilia-localized GPCRs and G protein alpha subunits (Gα) in experimental models modulates cilia morphology and impairs neuronal functions. What remains incomplete is our knowledge of the mechanisms by which G proteins shape cilia morphology, and the extent to which disruption of ciliary Gα signaling contributes to neurodevelopmental phenotypes.

We discovered that RIC-8, a non-canonical activator of Gα, localizes to cilia and regulates cilia membrane morphology in *C. elegans* sensory neurons – a previously unreported function for this highly conserved protein (ortholog of human *RIC8A* and *RIC8B*). RIC-8 has been demonstrated to function as a guanine-nucleotide exchange factor (GEF) to activate monomeric Gα independently of GPCRs and as a chaperone to fold nascent Gα. We show that the RIC-8 C-terminus containing GEF and chaperone activities is required for ciliogenesis and identify $G\alpha_{i/o}$ ODR-3 as a client Gα of RIC-8 in this context. Specifically, *odr-3* mutants recapitulate the *ric-8*-dependent cilia phenotypes, and RIC-8 physically associates with and regulates levels of ODR-3 in sensory neurons. We will present our ongoing efforts to molecularly define the novel *ric-8*-dependent ciliogenic pathway in the *C. elegans* model.

Condensation Defects of Pericentromeric Major Satellite DNA Underlie Subfertility in Hybrid Female Mice

W. El Yakoubi, T. Akera; Cell and Developmental Biology Center, National Heart Lung and Blood Institute, National Institutes of Health, Bethesda, MD.

One of the goal in the evolutionary biology is to understand the genetic control of hybrid sterility that lead to postzygotic reproductive isolation between closely related species. Following Haldane's rule, hybrid sterility is limited to heterogametic sex which is the male in mammals and flies. According to this law much more attention has been paid to the nature of reproductive isolation in male than in female. By using the F1 hybrid between *Mus musculus domesticus* (Hereafter *musculus*) and *Mus spretus* (hereafter *spretus*) we provide the first cell biological mechanism of female subfertility leading to reproductive isolation between these two species. It consists on defective chromosomal condensation due to less condensin II enrichment on the chromosomes in hybrid oocytes. Especially, the *musculus* centromeres, containing higher copy number of the major satellites repeats than *spretus* centromeres, are much more sensitive to low dosage of condensin II and are prone to stretching. Therefore, the stretching of the *musculus* centromeres causes lagging of only *musculus* chromosomes at anaphase of meiosis I and high rate of aneuploid eggs. Interestingly, the centromere stretching and aneuploidy rate phenotypes are both rescued by the overexpression of the condensin II specific subunit NCAPG2 which is found down regulated in the hybrid oocytes. Together, we propose that differences in both condensin II regulation and major satellite copy number between closely related species can cause reproductive isolation.

Investigating the Mechanisms Underlying Meiotic Chromosome-specific Differences

K. Billmyre[1], Z. Yu[1], E. Kesler[1], R. Hawley[1,2]; [1]Stowers Institute for Medical Research, Kansas City, MO, [2]University of Kansas Medical Center, Kansas City, KS.

Inheritance of a complete set of chromosomes is critical for fertility and production of viable offspring. However, chromosomes are vastly different in size and structure, and thus cells must be capable of accurately segregating an array of diverse chromosomes. For example, the largest human chromosome can be as much as 5 times larger than the smallest and in *Drosophila* 46 times larger. Currently, the mechanisms underlying meiotic recombination and segregation of specific chromosomes are not understood. One key component of the meiotic machinery is a large multi-protein structure called the synaptonemal complex (SC). During meiosis, the SC holds homologous chromosomes together and is necessary for proper recombination and chromosome segregation. In yeast, in-frame deletions within the transverse filament (TF) protein, a key SC component, decrease the width of the SC and cause chromosome missegregation. In *Drosophila melanogaster*, we find that small in-frame deletions in the TF protein of the SC result in fragmentation of the SC and chromosome-specific defects in meiotic recombination and pairing. To determine if the width of the SC is altered in our mutants with chromosome-specific meiotic defects, we imaged meiotic chromosome spreads with super-resolution STED microscopy. In these TF deletion mutants, the width of the SC is reduced significantly more than is predicted based on the size of the deletions. Further work is necessary to determine if changes in the

width and fragmentation of the SC play a role in the chromosome-specific recombination defects. Therefore, we are currently examining pairing, double-strand break placement, and recombination on individual chromosomes in TF deletions mutants using the Lac*O*/Lac*I* system combined with super-resolution imaging and chromosome tracing. Additionally, we are creating point mutants to identify residues within the small deletions that are responsible for SC phenotypes seen in these mutants. Our work has generated a fly model that exhibits chromosome-specific meiotic behaviors and defects, which could lead to a greater understanding of the basics of meiotic biology and human infertility.

Novel mechanism for spontaneous chromosome 12 aneuploidy in hiPSCs

M. Narozna, C. O. DuBose, J. R. Daum, G. J. Gorbsky; Cell Cycle and Cancer Biology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK.

Human induced pluripotent stem cells (hiPSCs) offer tremendous potential in replacing damaged tissues and organs. They are generated from the patient's cells and reprogrammed under the influence of pluripotency-inducing factors. After differentiation into various cell types, they may be reintroduced for therapy with limited chances of immune rejection. However, to be used for therapy cells must be propagated in culture both before and after reprogramming. Previous work has shown that hiPSCs can accumulate genetic aberrations, potentially limiting their usefulness in therapy and in research. An often detected abnormality is trisomy (gain of an additional copy of the entire chromosome) of chromosome 12. Normally, chromosome 12 trisomic cells become dominant in the culture, but how the trisomy arises and how it becomes dominant remain unknown. Although trisomic cells proliferated slightly faster than their diploid precursors, mathematical modeling showed that the difference in growth rates was insufficient to account for the rapid dominance of the trisomic cells. To understand potential mechanisms, we performed dual color fluorescent in-situ hybridization (FISH) and the whole chromosome 12 paint in hundreds of mitotic and interphase cells from various passages of hiPSCs passages, including the critical transition passages where the trisomic cells gained dominance. Surprisingly, analyses of cells from the transition passages (during which trisomy arises) in anaphase showed many cells with three signals from chromosome 12 oriented to one pole and two oriented to the other pole. We also detected single, potentially unpaired chr12 chromatids apart from aligned chromosomes in metaphase cells. Chromosome 10, mapped as a control, never showed these abnormalities. These data suggest that transition passages show a high proportion of cells entering mitosis with two normal chromosome 12's and one half chromosome 12 (single chromatid). We propose that this unusual chromosome content may come about through incorporation of a missegregating chromosome 12 in micronuclei that then fail to replicate. In support, we found by FISH that chromosome 12 was more often detected in micronuclei than would be expected by random incorporation of chromosomes. Our findings implicate a completely novel mechanism of aneuploidy that may be of profound importance for understanding genome instability in stem cell biology and that has strong implications for the use of hiPSCs in therapy and research.

Mitotic R-loops direct RBMX and Aurora B kinase to maintain centromeric cohesion

T. Stukenberg; Biochemistry and Molecular Genetics, University of Virginia, School of Medicine, Charlottesville, VA.

Recent work has shown that R-loops exist at mitotic centromeres, but the dynamics of R-loops and their functions during mitosis are not well understood. To address this, we mapped R-loops during synchronous mitotic progression. During prophase R-loops associated with transcription are reduced, while R-loops associated with repetitive sequences, particularly α-satellite regions increase. These dynamics were dependent on Aurora B kinase activity. We also found an enrichment of R-loops at CTCF/Cohesin sites in interphase cells and these are also dynamically controlled during mitosis by Aurora B. Over 80 percent of CTCF sites that also bind cohesin have R-loops and these R-loop sites are often cell type specific suggesting that R-loops control the generation of TADs during differentiation. Mitotic R-loops are required to maintain sister chromatid cohesion demonstrating a functional link between cohesin and R-loops. This requires a pathway where R-loops localize RBMX to centromeres, which in turn binds Aurora B to localize Sgo1 and maintain cohesion. We conclude that R-loops are dynamically rearranged by Aurora B during mitosis and R-loops play important roles in controlling cohesin and higher order chromatin structure throughout the cell cycle.

Oligopaint FISH reveals transcription-associated meiotic pairing initiation in Lepidopteran insects

L. F. Rosin, E. P. Lei; NIH/NIDDK, Bethesda, MD.

Precise homolog pairing is essential for accurate meiotic chromosome segregation in species from plants to humans. Failure to accurately segregate chromosomes in meiosis can lead to nondisjunction and infertility or aneuploidy in progeny. Yet, the mechanisms regulating homolog recognition and pairing are unknown. In many species, it is thought that DNA double-strand breaks (DSBs) facilitate the search for homology. However, some species including insects like fruit flies (Diptera) and moths (Lepidoptera) are able to accurately pair their homologs before DSB formation or without the need to ever form crossovers. Here, we employ the highly specific Oligopaint fluorescence *in situ* hybridization (FISH) technology to interrogate homolog recognition and the homolog pairing process in the silkworm moth *Bombyx mori* and the pantry moth *Plodia interpunctella*. Our studies demonstrate that meiotic pairing in male moths occurs asynchronously through numerous partially paired intermediate structures. Similar to findings from the holocentric nematode *C. elegans*, we find that meiotic pairing in holocentric moths is initiated at chromosome ends. However, unlike *C. elegans*, chromosome ends in moths are not necessarily gene-poor, and gene-rich chromosome ends pair earlier than gene-poor ends. Finally, our preliminary studies employing RNA FISH suggest that genes near early-pairing chromosome ends are indeed transcribed during early meiotic prophase. Together, our data support a model in which transcription, the transcription machinery, or transcripts themselves facilitate homolog recognition and meiotic pairing initiation in Lepidopteran insects. Whether or not these mechanisms are more broadly conserved remains an area for future study.

Chromosome Atlas: A trip around chromosome formation during mitosis

F. Cisneros Soberanis[1], E. Simpson[2], A. Beckett[3], N. Pucekova[1], I. Prior[3], D. Booth[2], W. Earnshaw[1]; [1]Wellcome Centre for Cell Biology, University of Edinburgh, Edinburgh, UNITED KINGDOM, [2]Biodiscovery Institute, University of Nottingham, Nottingham, UNITED KINGDOM, [3]Biomedical Electron Microscopy Facility, University of Liverpool, Liverpool, UNITED KINGDOM.

INTRODUCTION. During mitosis, cells compact their DNA to segregate it equally to their daughter cells. Chromosome compaction starts during prophase and continues along prometaphase. During metaphase, the chromosomes are compacted and localise at the metaphase plate pushed/pulled by the microtubules. In anaphase, the microtubules pull the chromosomes to the spindle poles and the chromosomes start to decompact. This work explores the changes in chromosome structure along the different stages of mitosis using volume electron microscopy and 3D reconstruction. **METHODS.** To enrich the mitotic population, we genetically modified RPE1 hTERT cell line to introduce a CDK1 mutant sensitive to an ATP analogue. We pre-synchronised them in G1 using a CDK4/6 inhibitor. Then, we released and blocked them in G2 using an ATP analogue. Finally, we washed out the ATP analogue to let them go to mitosis. We processed the cells for electron microscopy using *en block* staining and we imaged them using SBF-SEM. From the 3D reconstruction analysis, chromosomes 1-5 and 19-22 were identified by size and centromere position. We measured morphological characteristics such as volume, surface and length. Also, we evaluated the interaction with other subcellular structures. **RESULTS.** In prophase cells, the chromosomes were forming attached to the nuclear envelope, their morphology was supple and the chromosome surface was rough. After the nuclear envelope break-down, in prometaphase, the chromosomes detached from the nuclear envelope. The chromosome surface looked smoother. The chromosome lengths were variable between cells and centromeres showed a severe stretching caused by the microtubule interactions. During metaphase, the chromosomes looked stiffer. The centromere stretching decreased and the volume and length kept homogeneous between the cells. In anaphase, when the sister chromatids are separated, the chromosomes start to decompact. Some chromosomes showed an S shape caused by two kinetochores in the same chromosome. However, the segregation was correct as the microtubules were pulling in the same direction, this event hasn't been shown by light microscopy due to the limited resolution. **CONCLUSION.** We concluded that the nuclear envelope could be important for the early stages of chromosome compaction. The centromere stretching could be decreasing in subsequent mitotic stages due to the increase in chromosome stiffness. The increase in chromosome stiffness could be associated with the increase of chromosome scaffold proteins interacting with the chromatin and rearrangement in the structure.

Mechanical regulation of chromosome loss in lung cancer spheroids

A. Anlas, B. Hayes, D. E. Discher; University of Pennsylvania, Philadelphia, PA.

During cancer progression, changes in the tumor microenvironment could lead to increased physical confinement and drive chromosome segregation errors in cancer cells. While most solid tumors exhibit chromosomal instability, the mechanisms that lead to chromosome missegregation and loss are unknown. Here, we used the CRISPR/Cas9 system to engineer H23 lung adenocarcinoma cells that carry a monoallelic chromosome reporter for the constitutively active Lamin-B1 gene to track chromosome loss. H23 cells with the LaminB1-GFP reporter were cultured in 1% methylcellulose or agarose to

generate spheroids. We analyzed mitotic events, cellular contractility and chromosome loss at different regions within spheroids. Our data suggest that chromosome loss is increased in cancer cells at the physically confined core of lung cancer spheroids. Future work will determine the mechanotransduction pathways that regulate chromosome missegregation in lung adenocarcinoma spheroids growing under confinement.

The Skp1-Cullin-F-box ubiquitin ligase complex is dynamically regulated throughout mouse spermatogenesis

I. D. Wolff[1], J. Moore[2], S. Gray[2], P. E. Cohen[1]; [1]Biomedical Sciences, Cornell University, Ithaca, NY, [2]School of Life Sciences, University of Nottingham, Nottingham, UNITED KINGDOM.

Sexually reproducing animals generate gametes through the process of meiosis, a reductional cell division that yields a haploid oocyte or sperm. Meiosis I proceeds through two distinct stages: prophase I, when homologous chromosomes are physically tethered through the formation of crossovers, and M-phase, when homologs and sister chromatids are separated in the first and second meiotic divisions, respectively. To prevent errors in chromosome segregation, meiotic progression is strictly regulated to ensure that major events are completed before subsequent downstream events initiate, however, a distinct molecular cue that senses completed crossover formation then triggers cell cycle progression has not yet been found. Recently, the SCF (Skp1-Cullin-F-box) E3 ubiquitin ligase complex has been implicated in meiotic cell cycle progression: a core SCF component, SKP1, is essential for progression from prophase I to M-phase, and SCF may be regulated by the crossover protein CNTD1 to promote downstream degradation of cell cycle inhibitors. However, it remains unclear how the SCF complex is biochemically regulated throughout the meiotic program. In this work, we investigate the molecular composition of the SCF complex during spermatogenesis in mouse. We identified a testis-specific post-translational modification on SKP1 that is lost in two null mutants, *Cntd1* and *Mlh1*, both of which reduce crossover frequency to ~5-10% of wild type levels. Gravitational cell sorting of spermatocytes revealed that this modification appears during the zygotene and pachytene substages of prophase I, correlating to the period of crossover maturation. In addition, we identified a crossover independent phosphorylation event on SKP1 that is enriched in M-phase spermatocytes and may be important for SCF complex assembly, particularly the interaction between SKP1 and F-box proteins. Altogether, these data indicate that the SCF ubiquitin ligase complex is biochemically regulated within different meiotic contexts in a dynamic fashion to achieve differing signaling outcomes. Our work also implicates post-translational modifications on SCF subunits as a critical mechanism for direct molecular crosstalk between crossover formation and meiotic cell cycle progression.

Centromere Innovations within a Mouse Species

N. Pandey[1], C. Gambogi[1], J. Dawicki-McKenna[1], U. Arora[2,3], G. Logsdon[4], J. Ma[5], P. Lamelza[5], M. Lampson[5], B. Dumont[2,3], B. Black[1]; [1]Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, [2]The Jackson Laboratory, 600 Main Street, Bar Harbor, ME, [3]Tufts University, Boston, MA, [4]University of Washington School of Medicine, Seattle, WA, [5]School of Arts and Sciences, University of Pennsylvania, Philadelphia, PA

Mammalian centromeres direct faithful genetic inheritance during cell division. Despite this critical function, the highly repetitive DNA sequence at centromeres is rapidly evolving. The prevailing model for this rapid evolution invokes competition during female meiosis wherein selfish centromeres are preferentially inherited. Intraspecific and interspecific hybrid mice have recently provided molecular clues into meiotic competition (Iwata-Otsubo, *et al.*, 2017, ***Curr. Biol.***, 27:2365-73; Akera *et al*., 2019, ***Cell***, 178:1132-44), yet the strains/species investigated to date have relatively homogeneous centromeres between chromosomes. Transient evolutionary centromere intermediates are predicted yet largely unexplored. At the molecular level, the only known sequence-specific centromere DNA binding protein, CENP-B, can modulate centromere competition (Kumon, *et al*., 2021, ***Cell***, 184:4904-18) and is thus a prime candidate to be impacted by rapid centromere DNA sequence changes. Here we focus on a mouse species, *M. pahari,* which diverged from *M. musculus* ~5 M years ago. We find two different types of *pahari* centromeres: one present on most of the autosomes and largely devoid of the recognition element for CENP-B (the CENP-B box) and one found on a single autosome that has ~100-fold greater number of CENP-B boxes. Both types of centromeres have related sequence that we define as "π-sat". We report the full, contiguous (6-16 Mbp) sequences for both types of centromeres. The centromere with high levels of CENP-B has larger kinetochores, potentially strengthening microtubule attachments to the spindle. We find this is counterbalanced by relatively high levels of pericentromeric heterochromatin (i.e. H3K9me3 enrichment) and accumulation of the microtubule destabilizing kinesin, MCAK. Indeed, this balance leads to similar fidelity in mitotic chromosome segregation between *M. pahari* chromosomes despite a large divergence in molecular composition. Thus, this mouse species naturally provides an example of how highly divergent centromeres transiently co-exist prior to homogenizing during mammalian chromosome evolution.

Persistently unaligned polar chromosomes link increased microtubule stability to biased aneuploidy landscape in tumor cells

K. Vukušić, S. Kodba, P. Risteski, I. M. Tolić; Ruder Boskovic Institute, Zagreb, CROATIA.

Congression is a movement of chromosomes toward the equatorial plane of the mitotic spindle during which kinetochores acquire end-on attachments to microtubules, a key step for error-free mitosis. It was recently reported that interphase nuclear chromosome organization dictates probability of chromosome mis-segregation during mitosis by biasing mis-segregations toward chromosomes positioned at nuclear periphery and behind spindle poles in non-transformed cells with weakened mitotic checkpoint. However, the mechanisms that induce a biased aneuploidy landscape in tumor cells, in which the mitotic checkpoint is rarely defective, are unclear. Here, by establishing a database of multiple live human cell lines imaged through mitosis, we show that congression frequently failed specifically in tumor cells, resulting in chronically unaligned polar chromosomes, which were a major

contributor to strong mitotic delays. Furthermore, in a minority of tumor cells, unaligned chromosomes remained at the pole through mitosis, resulting in aneuploidy. By tracking chronically unaligned chromosomes in U-2 OS cells, we show that they originated preferentially from the nuclear periphery and were situated behind spindle poles during early mitosis, contrary to pairs that rapidly aligned, indicating that delayed passage across polar region impedes speed of chromosome congression. Furthermore, delayed alignment of chromosomes severely abolished their stability within the metaphase plate after the congression attempt, contrary to pairs that aligned rapidly during prometaphase, including the subset of peripheral polar chromosomes. Even after successful alignment, persistent laggards repeatedly followed polar chromosomes, whereas chromatin bridges were not related to this phenomenon, indicating a connection between delayed alignment and the higher incidence of merotelic attachments. Intriguingly, by combining live cell imaging with STED microscopy, we report that treatment of non-transformed cells with nanomolar doses of nocodazole increased the stability of the kinetochore microtubules and produced chronically unaligned polar chromosomes characterized by complex types of end-on attachments, thus mimicking the phenotype of tumor cells. We conclude that increased microtubule stability, a known hallmark of tumorigenesis, preferentially affects the congression of peripheral polar chromosomes, giving rise to chronically unaligned polar chromosomes that enter a vicious cycle of hampered alignment that results in strong mitotic delays and biased aneuploidy landscape in tumor cells. Therefore, both in the case of reduced and increased mitotic duration, the peripheral polar chromosomes are biased toward mis-segregation and micronuclear entrapment.

Fragmented chromosomes from micronuclei are repaired by non-homologous end joining to generate complex genome rearrangements

Q. Hu[1], J. E. Valle-Inclan[2], A. Guyer[1], E. G. Maurais[1], Y. Lin[1], I. Cortés-Ciriano[2], P. Ly[1]; [1]Department of Pathology, Harold C. Simmons Comprehensive Cancer Center, University of Texas Southwestern Medical Center, Dallas, TX, [2]European Molecular Biology Laboratory, European Bioinformatics Institute, Wellcome Genome Campus, Hinxton, UNITED KINGDOM.

Chromosome segregation errors during mitosis can generate abnormal nuclear structures called micronuclei. The accumulation of DNA double-strand breaks (DSBs) within micronuclei triggers the catastrophic shattering of the mis-segregated chromosome through a process termed chromothripsis. Error-prone DSB repair of chromosome fragments can subsequently generate a spectrum of genomic alterations, including both simple and complex rearrangements found in cancers and developmental disorders. How distinct DSB repair pathways recognize and process these lesions remain poorly understood. Here we used CRISPR/Cas9 to systematically inactivate genes spanning distinct DSB processing or repair pathways and interrogated the structural rearrangement landscape of mis-segregated chromosomes. Deletion of core non-homologous end joining (NHEJ) components - including DNA ligase 4, DNA-PKcs, and XLF, as well as the NHEJ-promoting factor 53BP1 - substantially reduced the formation of complex rearrangements, suggesting that NHEJ is essential for re-ligating fragmented chromosomes. By contrast, inactivation of alternative end-joining or recombination-based DSB repair did not alter the frequency and types of rearrangements induced by micronucleation. Whole-genome sequencing revealed that rearranged chromosomes from cells lacking NHEJ were comprised of relatively simple rearrangements without the characteristic patterns of cancer-associated chromothripsis. In the absence of NHEJ, chromosome fragments were rarely engaged by other DSB repair pathways, resulting

in the accumulation of persistent DNA damage in the nucleus. Thus, we provide evidence supporting NHEJ as the exclusive DSB repair pathway generating complex rearrangements following chromothripsis from mitotic errors.

Reorganisationof Centromere Chromatin During the G2-Mitosis Transition Requires Condensin

K. Samejima[1], C. A. Brackley[2], N. Gilbert[3], D. Marenduzzo[4], W. C. Earnshaw[1]; [1]Wellcome Centre for Cell Biology, University of Edinburgh, Edinburgh, United Kingdom, [2]School of Physics and Anatomy, University of Edinburgh, Edinburgh, United Kingdom, [3]IGMM, University of Edinburgh, Edinburgh, United Kingdom, [4]School of Phyics and Astronomy, University of Edinburgh, Edinburgh, United Kingdom

Abstract: Structural analysis of the DNA and chromatin organisation of vertebrate centromeres is complicated by the presence of complex highly-repetitive satellite DNA arrays. However, several species, including equids and chickens, have one or several chromosomes with evolutionarily new centromeres assembled on non-repetitive DNA. Chickens have such centromeres on chromosomes Z, 5 and 27. The DT40 chicken B lymphocyte cell line is a particularly favourable system in which to study the three-dimensional organisation of centromere DNA as it is female (Z/W), so has a single copy of the Z chromosome. The Z chromosome is the 5th largest (83 Mb) and is metacentric, so its centromere conformation is not influenced by telomere proximity. As an additional benefit, synchronisation of DT40 CDK1^{as} cells in late G_2 and mitosis is straightforward and reproducible.We have previously published a detailed study of mitotic entry in DT40 CDK1^{as} cells using Hi-C. Unfortunately, the usual Hi-C resolution (40-100 kb) is not sufficient to resolve structural detail within chicken core centromeres (CENP-A domain ~30 kb) and the sequence cost to obtain 1 kb resolution would be prohibitive. Therefore, we have applied Capture-C analysis to construct a high-resolution interaction map of the Z centromere in G_2 and mitosis in wild type and cells depleted of condensin and cohesin, taking advantage of our CDK1as/AID tagged cell lines. Our Capture analysis of WT cells indicated that core centromere chromatin exhibits strong inter core interactions during G_2. In contrast, a striking bi-partite organisation appears in mitosis. Furthermore, our analysis demonstrated that condensin is essential for the structural transition of centromeric chromatin from G_2 to mitosis.

Actin limits egg aneuploidies associated with female reproductive ageing

S. Dunkley[1], B. Mogessie[2]; [1]School of Biochemistry, University of Bristol, Bristol, UNITED KINGDOM, [2]Department of Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT.

Ageing is accompanied by aneuploidy in mammalian eggs, which underlies common pregnancy failures in reproductively older females. This is consistent with gradual, ageing-related depletion of centromeric cohesion proteins leading to premature separation of sister chromatids. However, such progressive cohesion loss does not satisfactorily explain the sharp rise in egg aneuploidy near the end of female reproductive life. Here we show that F-actin helps to keep most sister chromatids together after centromeric cohesion has deteriorated in ageing mammalian eggs. By combining targeted protein degradation with advanced microscopy of chromosomal dynamics in eggs of young and aged females, we demonstrate that actin mitigates premature sister chromatid separation (PSSC) arising from centromeric cohesion loss by limiting microtubule-dependent chromatid disengagement. We propose that impairment of this function underlies ageing-related exponential rise in egg aneuploidy.

Defining CLS-2 and SPD-1 Function in Central Spindle Assembly during *C. elegans* Sperm Meiosis

S. Gomez, 1st, M. M. Garcia, C. Huynh, B. R. Lobos, D. Chu; Cellular and Molecular Biology, San Francisco State University, San Francisco, CA.

Male infertility is a serious concern for many Americans. To elucidate how infertility arises, researchers are using the Caenorhabditis elegans nematode to study chromosome segregation. In C. elegans, different forms of cell division use different mechanisms to ensure proper chromosome segregation. In the case of mitosis and oocyte meiosis, a central spindle structure composed of microtubules assembles in the midzone between segregating chromosomes. The central spindle produces pushing and pulling forces in both to coordinate chromosome segregation. In the case of C. elegans sperm meiosis, few microtubules are present in the midzone except those tied to the lagging unpaired X chromosome, a unique feature of male sperm meiosis. The central spindle structure is initiated by the kinetochore protein, CLS-2, at the midzone region of the segregating chromosomes. CLS-2 then recruits SPD-1, a microtubule bundler protein, to elongate the spindle. It is unknown whether the presence of the lagging unpaired X chromosome implies that there is a distinctive mechanism of chromosome segregation in sperm meiosis. We hypothesize that CLS-2 and SPD-1 do not play a significant role in central spindle assembly in sperm meiosis. Instead, sperm meiosis relies on the pulling forces of the kinetochore-connected microtubules rather than the push/pull forces generated by the central spindle. We will deplete CLS-2 and SPD-1 in young adult C. elegans males using the novel auxin-inducible degradation system and apply immunostaining techniques to observe our proteins of interest. Our preliminary data shows that CLS-2 and SPD-1 fail to localize to the midzone during sperm meiosis except to the lagging unpaired X chromosome. In males depleted of CLS-2 and SPD-1, any influence of a present central spindle will be removed. By removing the push/pull influence of the central spindle and using confocal live-imaging to observe the resulting phenotype, we expect to see DNA segregate at a similar rate to wild-type which will confirm that sperm meiosis does not rely on a central spindle to coordinate chromosome segregation. Understanding SPD-1 and CLS-2 function can elucidate the molecular mechanisms required for forming healthy sperm.

From Surfactant to glue: how Ki-67 regulates chromosome surface properties

A. Hernandez-Armendariz[1,2], S. Cuylen-Haering[1]; [1]EMBL, Heidelberg, Germany, [2]Heidelberg University, Heidelberg, Germany

Compartmentalization into functional units is a key principle of cellular life. In addition to membrane-bound organelles, eukaryotic cells utilize membrane-less biomolecular condensates to locally concentrate proteins and nucleic acids. While we are beginning to understand how membrane-less condensates assemble and disassemble, we know very little about the biological processes that take place at the surface of such condensates.

The surface of the largest membrane-less cellular assembly, the mitotic chromosome, is covered by the intrinsically disordered protein Ki-67. Our previous studies have revealed that Ki-67 has dual functionality. In early mitosis, Ki-67 functions as a surfactant to prevent chromosomes from collapsing into a single chromatin mass, whereas it actively promotes chromosome clustering during exit from mitosis. How Ki-67 switches between these two opposing processes - chromosome dispersal and

chromosome clustering - has remained unknown.
Here, we demonstrate that Ki-67's biophysical properties radically change during anaphase onset, when all chromosomes merge into a single cluster. Ki-67's amphiphilic character is lost as its molecular brush structure collapses and the soluble pool of the protein forms condensates. Our study uncovers a cell-cycle-regulated mechanism that controls individualization and coalescence of chromosomes during mitosis.

Naturally occurring variants in human chromosome segregation genes reveal novel Chromosomal Instability aiding Variant (CIVa) in kinetochore-microtubule bridges

A. Islam, C. Manjarrez, X. Song, T. Gore, **V. Draviam**; Queen Mary University of London, London, United Kingdom

Chromosomal Instability (CIN) is a hallmark of several developmental abnormalities, intellectual disabilities and aggressive cancers. Yet, in a vast majority of CIN syndromes, the underlying molecular drivers remain unknown. To address this knowledge gap, we are collating a comprehensive map of Chromosomal Instability aiding Variants (CIVa) taking advantage of human genome sequencing efforts. We first assessed the prevalence of Loss-of-Function (LoF) variants in 135 chromosome segregation genes from over 150,000 humans across multiple ethnicities [https://draviam-lab.github.io/CIVa/]. The assessment of CIVa predictions revealed a surprisingly high incidence of heterozygous and homozygous LoF variants in three chromosome-microtubule attachment bridging proteins: Ndc80, Astrin and SKA3. Next, we systematically probed the impact of CIVas using a quantitative framework, including single-cell microscopy and population-level isoform expression studies. Analysing subcellular dynamics following controlled protein variant expression revealed the naturally occurring Astrin p.Q1012* as a harmful variant. The Astrin p.Q1012* variant fails to localise normally at kinetochores; induces chromosome misalignment; prolongs the process of cell division, and promotes chromosome missegregation and DNA damage. Other frameshift variants observed in Ndc80, Astrin and SKA3 genes are likely to generate shorter isoforms which do not compromise chromosome segregation in monoallelic forms. Thus, we present a scalable quantitative framework to stratify CIVa predictions - an essential step towards precision healthcare for CIN syndromes.

Chromosome Atlas: A trip around chromosome formation during mitosis

F. Cisneros Soberanis[1], E. Simpson[2], A. Beckett[3], N. Pucekova[1], I. Prior[3], D. Booth[2], W. Earnshaw[1]; [1]Wellcome Centre for Cell Biology, University of Edinburgh, Edinburgh, UNITED KINGDOM, [2]Biodiscovery Institute, University of Nottingham, Nottingham, UNITED KINGDOM, [3]Biomedical Electron Microscopy Facility, University of Liverpool, Liverpool, UNITED KINGDOM.

INTRODUCTION. During mitosis, cells compact their DNA to segregate it equally to their daughter cells. Chromosome compaction starts during prophase and continues along prometaphase. During metaphase, the chromosomes are compacted and localise at the metaphase plate pushed/pulled by the microtubules. In anaphase, the microtubules pull the chromosomes to the spindle poles and the chromosomes start to decompact. This work explores the changes in chromosome structure along the different stages of mitosis using volume electron microscopy and 3D reconstruction. **METHODS.** To enrich the mitotic population, we genetically modified RPE1 hTERT cell line to introduce a CDK1 mutant

sensitive to an ATP analogue. We pre-synchronised them in G1 using a CDK4/6 inhibitor. Then, we released and blocked them in G2 using an ATP analogue. Finally, we washed out the ATP analogue to let them go to mitosis. We processed the cells for electron microscopy using *en block* staining and we imaged them using SBF-SEM. From the 3D reconstruction analysis, chromosomes 1-5 and 19-22 were identified by size and centromere position. We measured morphological characteristics such as volume, surface and length. Also, we evaluated the interaction with other subcellular structures. **RESULTS.** In prophase cells, the chromosomes were forming attached to the nuclear envelope, their morphology was supple and the chromosome surface was rough. After the nuclear envelope break-down, in prometaphase, the chromosomes detached from the nuclear envelope. The chromosome surface looked smoother. The chromosome lengths were variable between cells and centromeres showed a severe stretching caused by the microtubule interactions. During metaphase, the chromosomes looked stiffer. The centromere stretching decreased and the volume and length kept homogeneous between the cells. In anaphase, when the sister chromatids are separated, the chromosomes start to decompact. Some chromosomes showed an S shape caused by two kinetochores in the same chromosome. However, the segregation was correct as the microtubules were pulling in the same direction, this event hasn't been shown by light microscopy due to the limited resolution. **CONCLUSION.** We concluded that the nuclear envelope could be important for the early stages of chromosome compaction. The centromere stretching could be decreasing in subsequent mitotic stages due to the increase in chromosome stiffness. The increase in chromosome stiffness could be associated with the increase of chromosome scaffold proteins interacting with the chromatin and rearrangement in the structure.

Argonautes from the AGO family are key players in sex chromosome inactivation during spermatogenesis

M. Carro; Cornell University - Ithaca, NY, Ithaca, NY

Production of healthy sperm requires highly regulated gene expression for each stage of spermatogenesis. Argonaute proteins are RNA binding proteins that associate with small non-coding RNAs (smRNAs) and coordinate downstream post-transcriptional gene-silencing events in the cytoplasm. The four members of the AGO clade of Argonaute proteins are expressed in the germline during spermatogenesis. Previous work from our lab supports for a role of Argonautes in Meiotic Silencing of Unpaired Chromatin (MSUC) and Meiotic Sex Chromosome Inactivation (MSCI). AGO3 and 4 localize in the nuclei of pachytene spermatocytes, at sites of asynapsis and in the transcriptionally silenced XY subdomain named the sex body. Loss of *Ago4* results in aberrant sex body morphology and upregulation of Ago3, suggesting that these proteins might have overlapping functions. Triple Ago314 knockout and heterozygous males have a subtle fertility phenotype with decreased testis size, reduced sperm counts, and increased germ cell apoptosis. Study of prophase I progression revealed that knockout spermatocytes show mislocalization of sex body markers, including γH2AX and TOPBP1. To investigate how the lack of AGOs could alter gene regulation during spermatogenesis, we performed RNA seq and smRNA seq in spermatocytes from different genotypes. Loss of AGO3,1 and 4 causes differential expression of Prophase I associated genes and upregulation of sex-linked genes, along with ingression of RNA pol II to the sex body, supporting a role of AGOs in MSCI. SmRNA seq revealed differential expression of micro RNAs from a cluster located in the Fragile X region that could act as candidate AGO binding partners. In addition, we performed a co-immunoprecipitation of AGO3, followed by Mass spectrometry and smRNA seq. Interestingly, we found several proteins involved in chromatin

remodeling as potential interactors, suggesting that AGO3 function resides at the nuclear level, and thus may involve transcriptional control rather than the more traditional role of Argonautes in post-transcriptional mechanisms in the cytoplasm.

B163/P2557

Identification of molecular targets of PICH remodeling activity for faithful chromosome segregation

B. Lama; University of Kansas, Lawrence, KS

Mitosis is a complex process with many regulatory mechanisms involved for faithful chromosome segregation. Different proteins and protein modifications help ensure correct mitosis, one such important protein modification is SUMOylation, a post-translational modification. Loss of mitotic SUMOylation shows aberrant chromosome structure, chromosome separation defects, and delayed mitosis in the eukaryotic cell. Either inhibiting SUMOylation or stabilizing SUMOylation showed a comparable defect in chromosome segregation, hence this transient /dynamism of SUMOylation of mitotic proteins is critical for faithful chromosome segregation. Polo-like kinase 1 interacting checkpoint helicase (PICH) is a DNA translocase belonging to an SNF2 nucleosome remodeling family protein that does not have robust histone remodeling activity. Loss of PICH function increase chromosome segregation defects thus its remodeling activity is required for preventing genome instability. We identified PICH has a SUMO-interacting motif (SIM), which is required for preventing chromosome bridge formation. The conditional PICH depletion and replacement to mutant showed that PICH's translocase activity and SIM are required for preventing chromosome bridge formation and for controlling the abundance/localization of chromosomal SUMOylated proteins. These observations provide the hypothesis that PICH is the remodeling factor of mitotic chromosomal SUMOylated proteins that are required for faithful chromosome segregation. Here, we aim to identify the chromosomal target protein of PICH's remodeling function, which could be SUMOylated or non-SUMOylated. Using the His6-tag on endogenous SUMO-2 protein in different PICH-replaced cell lines, we isolated chromosomal SUMOylated proteins under loss of PICH function. Identification of purified protein using label-free quantitative mass spectrometry revealed several candidate proteins specifically increased in loss of PICH function. These are the potential SUMOylated target of PICH remodeling activity. Conditional PICH-depletion using the AID system results in mis regulation of chromosomal structural protein and defects in progression in mitosis, and identified proteins are known to involve in these phenotypes. With these observations, we propose potential molecular targets and functions of PICH's remodeling activity in mitosis for faithful chromosome segregation.

B164/P2558

The Chromosomal Passenger Complex Stabilizes the Inner Kinetochore in Mitosis

M. Bonner, **J. Haase**, A. E. Kelly; NIH/National Cancer Institute, Bethesda, MD

The kinetochore is assembled at centromeres on specialized nucleosomes that contain the histone H3 variant, CENP-A. The inner kinetochore, made up of sub-complexes referred to as the constitutive centromere-associated network (CCAN), directly links the centromeric chromatin to the microtubule-binding proteins at the outer kinetochore, which in higher eukaryotes are assembled upon entry into mitosis. Recent cell biological and structural work has demonstrated that the CCAN undergoes a reorganization upon entry into mitosis, but the mechanistic underpinnings of this process are not completely understood. We have previously shown that the chromosomal passenger complex (CPC) is

required to maintain proper CCAN levels at centromeres in mitosis, independently of its kinase subunit Aurora B, and that this process is required to detect errors in kinetochore-microtubule attachment. However, it remains unclear how the CPC regulates CCAN levels at centromeres. Here, using Xenopus egg extracts, we found that CCAN proteins such as CENP-C and the CENP-N/L complex display dynamic exchange at centromeres during interphase but rapidly become immobilized upon entry into mitosis. Strikingly, CPC depletion or mutations that affect its interactions with chromatin result in persistent CCAN turnover throughout mitosis, which leads to a substantial decrease in CCAN concentration at centromeres. Inhibition of the phosphatase PP1, but not of PP2A, rescues the effects of CPC depletion on CCAN stability, implicating another kinase in this process. These results suggest that the CPC promotes the stabilization of the CCAN at centromeres in early prophase to promote the proper attachment of microtubules to kinetochores.

A quantitative survey of current and prospective measures of chromosomal instability in model systems identifies strengths and weaknesses

A. Lynch, S. Bradford, R. Lera, A. Zhou, B. Weaver[,1], M. Burkard[,1]; University of Wisconsin - Madison, Madison, WI

Chromosomal instability (CIN) is the persistent reshuffling of cancer karyotypes via chromosome mis-segregation over time. In cancer, CIN can exist at different levels, and these levels determine whether it restrains or promotes tumor progression. Quantitative measures of CIN may predict metastases and response to the chemotherapeutic paclitaxel. Despite the potential clinical significance mis-segregation rates remain challenging to assess in human cancer despite an array of proposed measurement methods. To evaluate measures of CIN, we compared quantitative methods with defined CIN models. We implemented multiple inducible cell culture models of CIN by distinct mechanisms and comprehensively applied multiple CIN measures including fixed and timelapse fluorescence microscopy, chromosome spreads, 6-centromere FISH, bulk transcriptomics, and single cell DNA sequencing (scDNAseq). To induce multipolar spindles and polar chromosomes, we overexpressed PLK4-WT or sequentially inhibited CENP-E and MPS1 respectively in MCF10A-PLK4-WT-tetOn cells. To induce bridging chromosomes, we expressed a dominant negative TRF2 mutant in CAL51-TRF2-DN-tetOn cells. While fixed and timelapse imaging correlated well in most cases ($R = 0.76$; $p < 0.001$), fixed imaging underestimated the presence of mis-segregated polar chromosomes in anaphase. Of the commonly used cytogenetics methods we tested, chromosome spreads and 6-centromere FISH correlated well ($R = 0.77$; $p < 0.01$) and exhibited baseline non-modality rates of ~50% and ~5% respectively. Yet neither method was sensitive to structural CIN or mis-segregation of only a few chromosomes. We used scDNAseq to measure CIN and propose a measure of CIN, Mis-segregations per Diploid Division (MDD), which accounts for differences in proliferation rates and ploidy levels between tumors and correlates very well with imaging methods ($R > 0.75$; $p < 0.05$). Accordingly, we propose CIN in tumors be measured using MDD as a primary metric. This analysis of scDNAseq data also validated an increase in CIN caused by HSET inhibition in the setting of widespread multipolar spindle formation (PLK4 overexpression), as reported by previous imaging studies. Importantly, we found no increase in CIN70/HET70 scores in any of our inducible models, indicating these widely cited transcriptional CIN measures are not indicative of ongoing CIN. This systematic analysis of common CIN measures' respective sensitivity will guide the measure of CIN in the clinical setting and highlights the primacy of single-cell methods.

A non-centromeric locus experiences biased segregation during female meiosis in mice

F. Clark, T. Akera; NHLBI, NIH, Bethesda, MD

Proper chromosome segregation is a key component of meiosis. Multiple cellular mechanisms exist to ensure the equal and random segregation of homologous chromosomes, producing complete haploid genomes and genetic diversity among gametes. However, some genetic elements exhibit selfish mechanisms, altering chromosome segregation for their own benefit, often at the cost of organismal fitness and fertility. Mouse chromosome 2 harbors such a genetic element, a repeat with a 127 kb monomer, called R2d2. Known to experience strong transmission ratio distortion (TRD) in heterozygous females, R2d2 is thought to preferentially segregate to the egg in female meiosis. This TRD is also correlated with decreased fertility. We found that in heterozygous mice, the chromosome with the R2d2 repeat lags during anaphase of meiosis. In female meiosis, cytokinesis is asymmetric, incorporating most of the cytoplasm into the egg. Therefore, this lagging behavior could allow R2d2 to avoid segregation to the polar body by remaining near the spindle midzone long enough to be incorporated into the egg. The question remains, what mechanism regulates this chromosome-specific lagging behavior. To better examine this, cytogenetic studies of mouse oocytes provide a tractable tool to test the hypothesis that R2d2 alters its own segregation by acting as a neo-centromere. Surprisingly, a FISH-based technology, OligoPaint, revealed no co-localization between R2d2 and canonical centromere proteins, implying that R2d2 may have evolved another way of facilitating chromosome-spindle interactions to bias segregation.

Defining the Independence and Localization ofMaintenance Genome Stability Protein 1

B. R. Jordan, **J. S. Glavy**; University of Texas At Tyler Fisch College of Pharmacy, Tyler, TX

Genome Stability is fundamental for the preservation and proper transmission of genetic material through generations. Maintenance of Genome Stability Protein 1 (MGSP1) is a promising modulator for safeguarding DNA. MGSP1 promotes replication fork maintenance and antiviral signaling. Our investigations establish MGSP1 to be independent of its previous classification as a progeria-associated protein and more in line with its yeast Maintenance of Genome Stability (MGS). Key to MGSP1's function is its localization in the nucleus, specifically at nuclear pore complexes (NPCs). In our study, we map its nuclear localization signal (NLS) domain that directs the protein nuclear positioning except during stages of mitosis. While MGSP1 connection to p53 and ataxia-telangiectasia mutated (ATM) pathway is known, we further show that MGSP1 maintains associates with these proteins in aneuploidy tripolar mitotic cells. Its cellular location and intersecting partners may play an important role in tempering DNA stresses to preserve cell division.

Spindle Assembly 2

B169/P2562

Mechanics of the anaphase spindle

P. Real Calderon[1], J. Lemière[1], R. Daga[2], F. Chang[1]; [1]University of California, San Francisco, San Francisco, CA, [2]CABD, Seville, SPAIN.

In the fission yeast *Schizosaccharomyces pombe*, the mitotic spindle can be regarded as a simple bundle of overlapping microtubules that elongates during anaphase to push the nuclei and chromosomes apart. We have discovered conditions under which the majority of cells fail during anaphase. In these cells, the spindle continues to elongate but the poles cannot move past a certain point, so that the spindle gradually adopts a bent shape rather than its normal straight shape. Ultimately, these spindles fail abruptly, by either breaking near the spindle mid-zone or near the spindle pole body. We hypothesize that these spindles exert pushing forces to elongate and bend their microtubules into this shape. Using simple beam theory, preliminary estimates suggest that the spindle exerts 100's picoNewton forces to bend itself, and that similar forces are needed to break the spindle. The cross-linker protein Ase1 (PRC1 orthologue) contributes to spindle stability, while kinesin motor like proteins (Cut7, Pkl1, Klp9) are individually dispensable for formation of the bent spindles. We are currently analyzing spindle curvature to discern the effects of Ase1 and the spindle midzone region on the rigidity of the spindle. Initial results show that the bent spindles preferentially break at the edge of the Ase1/MT overlap, identifying this as a fragile site. Our studies develop a tractable system to probe the mechanics and robustness of a simple spindle.

B170/P2563

Self organization of the metaphase human mitotic spindle

W. Conway, 2022, G. Fabig, R. Kiewsiz, T. Mueller-Reichert, D. J. Needleman; Harvard University, Cambridge, MA.

During eukaryotic cell division, the mitotic spindle is responsible for segregating chromosomes to the newly formed daughter cells. The spindle is a bipolar, self-assembled structure primarily composed of microtubules, molecular motors, and other microtubule associated proteins. The manner by which the spindle's constituents give rise to its structure and behaviors remains poorly understood. We employed a combination of serial section electron tomography, live cell polarized light microscopy, and biophysical modeling to develop an active liquid crystal theory that describes how forces shape metaphase human mitotic spindles. In the spindle interior, we found that local interactions between neighboring microtubules align the microtubules along well-defined trajectories of growth and motion. By examining how the aspect ratio of the spindle boundary scales with spindle volume, we found that the ellipsoid spindle boundary is the result of a balance of surface tension, due to microtubule crosslinking, and extensile active stress, from molecular motor activity. Taken together, this provides a framework for understanding the self-organization of human mitotic spindles, and the contributions of different molecular constituents and different classes of microtubules. We are in the process of extending this work to understand the monopolar spindles that result when the molecular motor, kinesn-5, is inhibited.

B171/P2564

Protein Regulator of Cytokinesis 1 assists Kinesin-12 in a Kinesin-5 independent pathway of mitotic spindle assembly

B. M. Salazar[1,2,3], R. Ohi[2]; [1]Doctoral Program in Cancer Biology, University of Michigan, Ann Arbor, MI, [2]Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, [3]Rogel Cancer Center, University of Michigan, Ann Arbor, MI.

The mitotic spindle is a bipolar microtubule-based machine that segregates chromosomes during cell division. Mistakes in spindle assembly result in cell death and/or the generation of aneuploid daughter cells. Spindle bipolarity stems from the activity of Eg5, a tetrameric motor that slides anti-parallel microtubules apart. Inhibition of Eg5 leads to mitotic arrest and apoptosis, making Eg5 a promising target for anti-mitotic cancer therapies. However, cells can develop resistance to Eg5 inhibitors (Kinesin-5 inhibitors (K5Is)) by deploying an alternate Kinesin-12 motor, Kif15, to drive spindle assembly. Like Eg5, Kif15 slides anti-parallel microtubules apart, suggesting that Kif15 uses this mechanism to promote spindle assembly. We model K5I resistance by selecting for cells that grow in the presence of K5Is, referred to as kinesin-5 inhibitor resistant cells (KIRCs). Interestingly, we observe that Kif15 becomes enriched at the spindle equator in KIRCs, a site expected to be enriched in anti-parallel microtubule overlaps. We hypothesized that this zone of anti-parallel microtubule overlaps is expanded in KIRCs, providing an optimal architecture for Kif15 to work as a spindle assembly motor. We further speculated that this KIRC-specific microtubule architecture may be facilitated by specific protein factors and to investigate this possibility, we focused on Protein Regulator of Cytokinesis 1 (PRC1), a microtubule-associated protein well known to bundle anti-parallel microtubules. PRC1 is best known for its cytokinetic functions, but growing evidence indicates that PRC1 is important during pre-anaphase mitosis. Here we show that KIRCs require PRC1 for spindle assembly, as 1) depletion of PRC1 by RNAi reduces the efficiency of spindle assembly in KIRCs, and 2) overexpression of PRC1 greatly improves spindle assembly in KIRCs. These results suggest a model in which PRC1-mediated bundling of spindle microtubules creates a more favorable architectural environment for Kif15-driven mitotic spindle assembly in the context of Eg5 inhibition.

B172/P2565

Investigating centriole-based assembly of spindle microtubules in the absence of pericentriolar material matrix in human cells

J. Xu[1], F. Metinger[1,2,3,4], A. Desai[1,2,3], K. Oegema[1,2,3]; [1]Department of Cell and Developmental Biology, School of Biological Sciences, University of California, San Diego, La Jolla, CA, [2]Department of Cellular and Molecular Medicine, University of California, San Diego, La Jolla, CA, [3]Ludwig Institute for Cancer Research, La Jolla, CA, [4]Cell proliferation and gene editing unit, Okinawa Institute of Science and Technology, Onna, JAPAN.

Centrioles are small cylindrical structures composed of a nine-fold symmetric array of stabilized microtubules. Centrioles recruit a much larger pericentriolar material (PCM) matrix assembled from the coiled-coil protein CDK5RAP2 to form centrosomes. During mitosis, the main function of centrosomes is to catalyze the assembly of microtubules for spindle formation. It was long assumed that microtubule generation was performed by the PCM matrix. In particular, the main component of the PCM matrix CDK5RAP2 contains docking sites (CM1 motifs) that recruit microtubule-nucleating γ-tubulin complexes. In recent work, we have shown that in addition to the PCM matrix, there is a second pathway anchored

to centrioles that is sufficient to generate microtubules for spindle assembly. Spindles can form using the PCM matrix-based pathway when centrioles are removed and using the centriole-anchored pathway when the PCM matrix is removed. However, spindle assembly fails when both centrioles and the PCM matrix are removed (Watanabe, Meitinger et al. J Cell Biol., 219(12):e202006010, 2020). Although potent for the generation of spindle microtubules, the centriole-based pathway remains poorly understood. To dissect this pathway, we are investigating foci comprised of centriole-proximal components that form when the centrosomal ubiquitin ligase TRIM37 is deleted and centrioles are removed by chemical inhibition. These foci lack PCM matrix, but function as robust MTOCs that accelerate spindle assembly in the absence of centrosomes; notably, while these foci contain centriole-proximal components such as PLK4 and SAS-6 and have been shown to require PLK4 for their assembly, they do not contain the PCM matrix component CDK5RAP2 (Meitinger et al., Nature 585(7825):440-446, 2020). We are thus using these foci to understand microtubule generation by centriole-proximal components. Specifically, we are performing systematic inducible gene deletions under conditions where these foci form (TRIM37Δ RPE1 cells treated with the PLK4 inhibitor centrinone). This effort should help elucidate the centriole-based pathway that supports spindle formation when the PCM matrix is absent and yield a deeper understanding of the microtubule generation pathways that contribute to spindle assembly in human cells.

B173/P2566

Pushing the envelope: force balance in fission yeast closed mitosis

M. A. Begley[1], P. Zareiesfandabadi[2], A. Sharma[1], M. B. Rapp[1], M. W. Elting[1,3]; [1]Department of Physics, North Carolina State University, Raleigh, NC, [2]Department of Biology, Duke University, Durham, NC, [3]Quantitative and Computational Developmental Biology Cluster, North Carolina State University, Raleigh, NC.

In the fission yeast *S. pombe*, the mitotic spindle consists of a single bundle of parallel and antiparallel microtubules, crosslinked by motors and non-motor MAPs, that segregates chromosomes inside a closed nuclear envelope. Forces provided by both motors and microtubule dynamics work to elongate the spindle and segregate the cell's chromosomes during mitosis. Meanwhile, the nucleus morphs from a spheroid, through a peanut-shaped intermediate, and finally into a barbell shape before separating into two daughter nuclei. While it is assumed that spindle elongation drives nuclear shape changes, the mechanics underlying these transitions are very poorly understood. To examine the mechanics underlying closed cell division, we molecularly and mechanically perturb mitotic *S. pombe* cells. We sever specific mitotic structures, including the spindle and the nuclear envelope, by laser ablation, and we quantify the subsequent response to these acute perturbations using live cell confocal microscopy. We observe that motor-based force on the spindle that is recruited in response to laser ablation is able to dynamically re-shape the nuclear envelope. It has previously been shown that increasing envelope tension can cause the spindle to bow or curve, and we find that relieving envelope tension by laser ablation allows the spindle to straighten. The dynamics of this process report on the material properties of the spindle, nuclear envelope, and the nucleoplasm. We also perturb the long term mechanics of the spindle (by genetic deletion of crosslinkers and motors) and of the nuclear envelope (by altering membrane synthesis), and combine these changes with laser ablation. Finally, we perform a similar set of experiments in *S. japonicus*, the phylogenetic cousin of *S. pombe*, which goes through semi-open mitosis, in which nuclear envelope closure is not required. We find differences in spindle mechanics

between the two species, suggesting possible feedback between spindle and nuclear envelope structure and mechanics.

B174/P2567

RNA Localization to the Mitotic Spindle

C. Remsburg, K. Konrad, J. Song; University of Delaware, Newark, DE.

Mitosis is a fundamental and highly regulated process that acts to faithfully segregate chromosomes into two identical daughter cells. The timing of mitosis is essential, as prolonged mitosis can result in a myriad of disorders, including chromosome nondisjunction. Transcript localization of genes involved in mitosis at the mitotic spindle may be one way to ensure that mitosis occurs in a timely manner. We identified the transcripts of several genes involved in mitosis, including *AuroraB*, *Polo kinase*, and *Cyclin B* to be localized at the mitotic midzone in dividing cells of sea urchin and mammalian cell lines. Using the sea urchin as a model, we found that disruption of actin dynamics with cytochalasin D does not affect the localization, but disruption of microtubule polymerization with colchicine results in lack of localization of these RNA transcripts. These data suggest that localization of these transcripts is microtubule-dependent. Treating embryos with kinesore, which prevents kinesin-1 from binding to its cargo, results in a more diffused localization of these RNA transcripts. Additionally, treating embryos with ciliobrevin D, a dynein inhibitor, results in a change in localization of these RNA transcripts. These preliminary results indicate that kinesin-1 and dynein are likely motors responsible for localization of the RNA. We also identified that the cytoplasmic polyadenylation element (CPE) within the 3'UTR of *Aurora B*, a recognition sequence for the CPEB protein, is essential for localization of the transcript to the mitotic spindle. Blocking this sequence results in arrested development during early cleavage stages, indicating that transcript localization is important for early development. Understanding how RNA localization occurs to the mitotic spindle is critical for the fundamental understanding of cell division, as this has consequences in causing birth defects and predisposition to cancer.

B175/P2568

Evolutionary and functional divergence in the uncoupled microtubule networks of Naegleria

A. S. Kennard[1], K. B. Velle[1], C. Ballatore[2], L. K. Fritz-Laylin[1]; [1]University of Massachusetts, Amherst, Amherst, MA, [2]University of California San Diego, La Jolla, CA

The mitotic spindle is an essential component of cell division machinery throughout eukarya, but the organization and dynamics of this microtubule-based structure vary significantly across species. We aim to understand the organization and function of the mitotic spindle in the unicellular eukaryote *Naegleria gruberi*, which last shared an ancestor with animals and fungi over a billion years ago. *Naegleria* grows and divides as an amoeba, but under stress can rapidly differentiate into a transient flagellate state. Intriguingly, unlike nearly all eukaryotes studied to date, interphase *Naegleria* amoebae lack any microtubules whatsoever; instead, *Naegleria* transcribes and translates complete microtubule cytoskeletons de novo for mitosis and flagellar differentiation. Using RNA-Seq of cells undergoing synchronized cell division or flagellar differentiation, we find that the microtubule-associated genes upregulated during each of these processes are largely distinct. This genetic uncoupling of mitotic and flagellar gene repertoires in *Naegleria* provides a unique opportunity to study how tubulins and microtubule associated proteins diverge when constrained by only one of these two ubiquitous functional requirements. In line with this, we have shown that the *Naegleria* tubulins expressed during

mitosis are significantly divergent relative to model tubulins as well as *Naegleria* flagellar tubulins, with variation at key residues that suggest distinct microtubule properties. We are currently extending this investigation to *Naegleria*'s 42 kinesins. Consistent with the extreme divergence of *Naegleria* tubulins relative to model tubulins, we find that many conventional microtubule inhibiting drugs do not affect *Naegleria* growth, implying that these inhibitors may not bind to the divergent mitotic tubulins. We have identified microtubule stabilizing agents called phenylpyrimidines that block *Naegleria* cell division, arrest the spindle in metaphase, and lead to the formation of multipolar spindles, suggesting microtubule dynamics contribute to in maintenance of *Naegleria* spindle bipolarity. The conserved and divergent properties of *Naegleria* spindles make *Naegleria* a unique system for uncovering core principles underlying spindle assembly and function in diverse evolutionary contexts.

A mechanical signal regulates Dynein loading on the nuclear envelope

V. Nunes[1], D. Castro[1], M. Dantas[1], M. Piel[2], P. Aguiar[1], H. Maiato[1], J. Ferreira[1]; [1]i3S - UP, Porto, PORTUGAL, [2]Institut Curie, Paris, FRANCE.

Increasing evidence shows that the nucleus is an active player during mitotic entry. Accordingly, chromosomes and other nucleus-associated components, which directly contribute to mitotic spindle assembly, also regulate nuclear mechanics. Importantly, in preparation for mitosis, cells undergo an extensive cytoplasmic and nuclear reorganization. These nuclear modifications are expected to elicit changes in the mechanical properties of the nucleus.
To address how these changes directly impact early spindle assembly, we followed mitotic entry in cells with compromised nuclear organization and structure, measured nuclear envelope (NE) fluctuations and extracted high-resolution quantitative data for both centrosome and nucleus-related metrics.
Our results allow us to propose a model where mitotic chromosome condensation increases intranuclear stiffness. This increased stiffness is transmitted by telomeres to SUN proteins at NE. In turn, this SUN protein-mediated strain on the nucleus is transmitted to the Bicaudal D2 (BicD2) and NudE/NudEL pathways, triggering Dynein loading to the NE. This recruitment of Dynein then ensures centrosome-NE tethering and correct centrosome positioning on the shortest nuclear axis, upon nuclear envelope permeabilization (NEP).
We propose that a mechanical signal triggered by mitotic chromosome condensation during the transition from G2 to mitosis ensures efficient spindle assembly and helps coordinate cytoplasmic and nuclear events.

B177/P2570

Over-accumulation of the ER blocks recruitment of centrosomal proteins resulting in mitotic failure

K. R. Rollins, J. T. Blankenship; Biological Sciences, UNIVERSITY OF DENVER, DEPARTMENT OF BIOLOGICAL SCIENCES, Denver, CO.

The Endoplasmic Reticulum makes contacts with organelles through the cell and has recently been shown to participate in processes beyond its canonical roles of calcium storage and protein synthesis. The ER also undergoes a remarkable transition in morphology during cleavage divisions in the syncytial *Drosophila* embryo, but whether this change in ER appearance modulates mitotic events is less clear. Mitotic divisions require massive remodeling of various membranous organelles such as the nuclear envelope and plasma membrane. Here, we examine the behaviors of the ER and its impact on

centrosomal and spindle function during the rapid cleavage divisions of the syncytial embryo. We see that the ER retracts and clusters around the spindle poles where it appears to form a coated structure around the spindle. As a means of perturbing this structure, we disrupted Rab1 function in the early embryo and observed an enhanced buildup of ER at the spindle poles. Interestingly, this led to large-scale defects in the division cycles. Mitotic spindle assembly is disrupted and displays a "mini-spindle" phenotype. These mini-spindles appear to be due to defects in centrosomal-based recruitment of microtubule nucleation factors. Our results suggest that the overaccumulation of ER can suppress the association of Centrosomin and Spd2 to the spindle piles leading to reduced γ-tubulin function. Finally, we show that the division failures and ER spindle-pole accumulation in *Rab1* knockdown embryos can be rescued with a Dynein inhibitor, demonstrating that Dynein motor activity is essential for the spindle association of the ER during mitosis. These results suggest that ER levels must be carefully tuned during mitotic processes to ensure proper assembly of the division machinery.

B178/P2571

miR-31 regulates actin dynamics to impact cell division during early development

M. Testa; University of Delaware, Newark, DE.

miR-31 is a highly conserved microRNA that has been shown to be important in various cancers, bone homeostasis, myogenesis, auto-immunity, lymphatic development, and embryonic development. Using the purple sea urchin as a model, we identified miR-31 and some of its targets to localize at the midzone of the mitotic spindle and perinuclearly in divided blastomeres. We also observed that miR-31 inhibitor-injected embryos display longer astral microtubules and increased interpolar and kinetochore microtubules, as well as increased filamentous actin compared to the control. These results lead to our hypothesis that miR-31 may regulate mitosis. We identified *Rab35*, *Fascin*, and *Gelsolin* to be directly regulated by miR-31. Rab35 is a member of the Rab family of small GTPases that plays essential roles in vesicular trafficking between the plasma membrane and endosomes as well as actin remodeling in eukaryotic cells. Rab35 localizes Fascin to the leading edge of the cell membrane, where Fascin bundles actin. Fascin has also been shown to regulate actin filaments for spindle migration and polar body extrusion in mice. Gelsolin is an actin-binding protein that is a key regulator of actin filament severance. Prior studies have shown that actin regulation is integral to mitosis and proper mitotic spindle assembly/disassembly. Since early cleavage stage embryonic development must be rapid, and strictly controlled to ensure the faithful segregation of chromosomes, miR-31 may regulate actin dynamics to mediate mitosis. Removal of miR-31's suppression of *Fascin* and *Rab35* lead to embryonic delay and arrest, phenocopying miR-31 inhibitor injected embryos. Identifying how miRNAs mediate spindle formation and mitosis is critical to the understanding of early embryonic development, and the predispositions to various diseases such as cancer.

Monopolar spindles in RPE-1 cells are still bipolar, follow an intrinsic nematic order and exhibit a domain wall

G. Fabig[1], W. Conway[2,1], G. Ha[2], M. Basaran[2], R. Kiewisz[3], D. J. Needleman[2], T. Müller-Reichert[1]; [1]Medizinische Fakultät "Carl Gustav Carus", TU Dresden, Dresden, GERMANY, [2]Harvard University, Cambridge, MA, [3]Simons Machine Learning Center, New York Structural Biology Center, New York, NY.

The bipolar metaphase spindle is crucial in mitosis to reliably segregate chromosomes without errors to the newly forming daughter cells. An active liquid crystal theory, where microtubules locally align relative to one another, can quantitatively describe the steady state morphology of bipolar spindles, as well as the density and orientation fluctuations around the steady state. In this theory, microtubules grow along trajectories defined by the orientation field of the spindle, meaning that newly polymerizing microtubules grow along the trajectories of existing microtubules in the spindle. In prior work, we demonstrated that both kinetochore and non-kinetochore microtubules in mitotic human metaphase spindles are strongly aligned along the same orientation field. The trajectories defined by this field connect the kinetochores to the spindle poles. Here, we investigate this theory by perturbing the geometry of the spindle using a small molecule inhibitor of the plus-end directed motor kinesin-5, Monastrol (at a concentration of 200 µM). Upon treatment, the bipolar metaphase spindle changes to a monopolar spindle, with the condensed chromosomes surrounding the two centrosomes. Interestingly, the two centrosomes do not merge in the center of the monopole but instead stay at a defined steady-state distance and rotate around each other as observed by light microscopy. We used serial-section electron tomography after high-pressure freezing to reconstruct the trajectories of microtubules in these monopolar spindles and found that the two centrosomes in the center of the monopolar spindle are still arranged in a bipolar fashion with the two centrosomes organizing microtubules into a bipolar “mini spindle”. This “mini spindle” is surrounded by microtubules pointing radially outwards in an aster geometry. Kinetochore microtubules grow from chromosomes at the outer edge of the spindle towards the spindle center along the aster trajectories. The majority of the kinetochore microtubules stop at the boundary between the aster and the “mini spindle” domain wall and do not make direct contact with the centrosomes. Only kinetochore microtubules growing in the orientation of the pole-to-pole axis of this “mini- spindle” can make reliable contact to the centrosomes. This observation confirmed our previous finding that existing microtubules are crucial to guide kinetochore microtubules towards the centrosome and a disturbance of the nematic order will prevent them from growing further.

B180/P2573

NuMA can provide mechanical robustness to mitotic spindle poles independent of dynein

N. H. Cho[1,1], S. Dumont[1,1,2]; [1]University of California, San Francisco, San Francisco, CA, [2]Chan Zuckerberg Biohub, San Francisco, CA

Every cell division, the mitotic spindle builds itself to segregate chromosomes equally into two daughter cells. Together, both motor and non-motor proteins organize microtubules to give rise to spindle structure and function. One essential non-motor protein is NuMA, which recruits the motor dynein to microtubule minus-end cargos to assemble spindle poles and binds microtubules and oligomerizes independent of dynein *in vitro*. While it’s clear that spindles without NuMA or dynein have severely compromised function and mechanics, whether and how NuMA contributes to spindle mechanics independent of dynein is not known. To address this question, we generated NuMA mutants we

hypothesize cannot bind dynein based on sequence analysis. We show that overexpression of these mutants does not enrich dynein at spindle poles, unlike full-length NuMA overexpression. Further, these mutants are not sufficient to rescue spindle structure in NuMA-KO human RPE1 cells, consistent with them not recruiting dynein. However, we demonstrate that overexpressing these NuMA mutants is sufficient to mechanically reinforce spindles, preventing pole fracture under PDMS-based cell confinement while poles of control RPE1 spindles fracture. Thus, NuMA can reinforce the spindle independent of its motor partner dynein. We propose that NuMA not only recruits dynein to the spindle, but crosslinks spindle microtubules independent of dynein to increase spindle mechanical robustness. NuMA may as such play a unique physical role in the spindle, both targeting the motor dynein and crosslinking its microtubule cargos.

B181/P2574

Biophysical modeling of spindle dynamics inCaenorhabditis elegansembryos

Y. N. Young[1], R. Farhadifar[2], M. J. Shelley[3]; [1]NEW JERSEY Institute of Technology, Newark, NJ, [2]Flatironinstitute, New York, NY, [3]New York University/Flatironinstitute, New York, NY

In eukaryotic cells, the mitotic spindle forms during cell division and ultimately separates the chromosomes into the daughter cells. The position and orientation of the division plane, which is of fundamental importance for proper growth and development, are regulated by the spindle's position and orientation. Despite extensive knowledge about the molecular basis of spindle positioning and dynamics, the underlying force mechanisms remain elusive. Here, we developed a coarse-grained model of the spindle, which accounts for the dynamics of microtubules nucleating from centrosomes and their interactions with motor proteins localized on the cell cortex. We show that pulling forces from these motor proteins are enough to explain spindle positioning and elongation dynamics. Beyond a certain number of motors, the model exhibits an oscillatory behavior for the spindle, where the spindle axis rotates periodically. Our model quantitatively explains observed spindle dynamics in C. elegans embryos, such as elongation, asymmetric positioning, and oscillation. It also quantitatively predicts the scaling of these traits with cell size.

B182/P2575

Mechanism of spindle length control by the Tpxl-1AurA complex in the *C. elegans* embryo

J. L. Meaders, K. Oegema, A. Desai; University of California, San Diego, La Jolla, CA

A major regulator of spindle assembly is the conserved Aurora A Kinase (AurA) and its activator Tpx2. Tpx2-AurA is proposed to form an activity gradient that radiates out from the poles along spindle microtubules. Disrupting this gradient in the *C. elegans* embryo by depleting the Tpx2 ortholog TPXL-1 or preventing its interaction with AurA leads to abrupt spindle shortening immediately after nuclear envelope breakdown; the resulting spindles are extremely short and exhibit chromosome segregation defects. Importantly, spindle shortening is prevented by depletion of the conserved Ndc80 complex, the core kinetochore microtubule binding module, or by mutations that disrupt its ability to interact with microtubules. By contrast, loss of kinetochore dynein, removal of the Ska complex, or depletion of kinetochore-localized microtubule dynamics regulators did not suppress spindle shortening. These results suggest that the TPXL-1-AurA activity gradient serves as a molecular ruler that controls spindle length by determining whether end-on kinetochore-attached microtubules are in a polymerizing or depolymerizing state. How the TPXL-1-AurA activity gradient forms and regulates kinetochore-

microtubule attachments are open questions. Here, we tackle these questions using transgene-based replacements in the *C. elegans* embryo. Surprisingly, we find that disrupting the TPXL-1-AurA gradient by perturbing the TPXL-1-microtubule interaction does not result in the severe spindle shortening observed following TPXL-1 depletion. Unexpectedly, loss of the putative microtubule-interaction region led to a notable increase in the localization of TPXL-1-AurA to chromosomes. We hypothesize that this gain in chromosome localization may place TPXL-1-AurA in the vicinity of target substrates where it might cause kinetochores to assume a state conducive to polymerization of attached microtubules. We are currently testing this idea by identifying the region in TPXL-1 responsible for its chromosomal localization. In terms of targets of TPXL-1-AurA at the kinetochore, we are currently assessing whether TPXL-1-AurA could act directly on the Ndc80 complex. Overall, this effort is beginning to uncover the molecular mechanisms by which conserved Tpx2-AurA complexes control spindle assembly by regulating kinetochore-microtubule attachment dynamics.

B183/P2576

CAPS is required for chromosome attachment to the mitotic spindle

S. Spencer, B. Setu, S. Heiland, Q. Nie, P. Wombacher; Saint Louis University, Saint Louis, MO

In a screen for transcriptional targets of Epidermal Growth Factor Receptor signaling in Drosophila, our lab identified *CG10126*, a small calcium-binding protein orthologous to the human protein Calcyphosine. We find that both CG10126 and Calcyphosine show calcium-dependent binding to tubulin, and both are localized to kinetochore microtubules during mitosis. Knockdown of either gene (in *Drosophila* or human cells, respectively) produces defects in mitosis, most notably chromosomes that fail to congress during metaphase and the formation of multipolar spindles. In vitro assays suggest that CAPS cross-links and stabilizes microtubules to promote k-fiber formation. Further, coprecipitation assays suggest that CG10126 and CAPS associate with other proteins important for microtubule bundling. Our data suggests that CG10126 and CAPS play important and conserved roles in k-fiber formation and attachment of spindle microtubules to chromosomes during mitosis.

B184/P2577

Multiple Chromosome-Based Motors Regulate Spindle Length in *C. elegans* Oocytes

H. Horton, S. Wignall; Northwestern University, Evanston, IL

Female reproductive cells (oocytes) of most species form microtubule-based spindles that lack centrosomes, but the mechanisms by which these spindles assemble and mediate chromosome segregation are still poorly understood. Interestingly, *C. elegans* oocytes undergo chromosome congression and segregation independently of microtubule-kinetochore attachments; rather, microtubule bundles associate laterally with chromosomes to form “channels” that the chromosomes move through. Additionally, a ring-shaped protein complex made up of over fifteen known components forms around the center of each chromosome and is essential for spindle assembly as well as chromosome congression and segregation. How the ring complex (RC) interacts with the spindle in order to facilitate these microtubule-dependent functions is poorly understood.We previously found that KLP-19, a RC component and plus-end directed kinesin, is necessary for chromosome congression to the metaphase plate. Recent work using auxin-mediated depletion of KLP-19 indicates an additional role in spindle organization; specifically, we find that metaphase spindles become significantly longer when KLP-19 is depleted. Because other kinesin-4 family members have been proposed to pause microtubule

polymerization, we hypothesized that KLP-19 was performing a similar function on the meiotic spindle in order to regulate spindle length. To test this hypothesis, we generated an ATPase-defective KLP-19 mutant that binds to, but does not walk on, microtubules in order to generate an “over-paused” state. In this mutant, KLP-19 localizes broadly across the spindle microtubules and spindles are significantly shorter, indicating a role for KLP-19 in maintaining spindle length, possibly through microtubule pausing.Another kinesin, KLP-7, is a well-characterized microtubule depolymerase and RC protein that prevents spindle over-elongation; current investigation aims to identify the relationship between the spindle-length mediating functions of KLP-7 and KLP-19. Furthermore, we observe that depletion of KLP-7 on metaphase spindles results in the establishment of end-on kinetochore attachments. Altogether, we find that the RC components KLP-19 and KLP-7 each make unique mechanistic contributions to microtubule regulation at the chromosome, thus clarifying the function of this important protein complex in spindle architecture.

B185/P2578

Microtubule pivoting ensures passage of polar chromosomes across the centrosome required for timely alignment

V. Štimac, I. Koprivec, I. Tolić; Rudjer Boskovic Institute, Zagreb, Croatia

To ensure faithful mitosis, chromosomes located at different nuclear positions during nuclear envelope breakdown (NEB) need to properly congress to the metaphase plate. The most unfavorably positioned chromosomes are polar chromosomes, which are located behind the spindle pole at NEB and make up around 7 out 46 chromosomes in human cells. These chromosomes first need to approach the spindle pole and at a later point slide towards the metaphase plate in a motor-dependent manner. However, the mechanism of their passage across the polar region and its importance for faithful mitosis remain unknown. Here we show, by using live-cell confocal microscopy with high spatial and temporal resolution, that polar chromosomes are the last to reach the metaphase plate. They also stall behind the pole, indicating that the centrosome creates a physical barrier for their movement. To test this hypothesis, we removed one centrosome using centrinone, which indeed resolved the observed delay, suggesting the existence of an additional and distinct mechanism of congression in a polar region. We reveal that this mechanism is based on pivoting of chromosome-attached astral microtubules around the spindle pole, by imaging the microtubule plus end marker EB3. The angle that the kinetochores of these chromosomes form with the spindle axis changed during the period of rapid spindle elongation, indicating a role of centrosome separation in this process. By using different kinesin-5 (Eg5) inhibitors to stop or reverse spindle elongation, we confirmed that pivoting occurs due to a hydrodynamic drag force created by centrosome movement. Superresolution STED microscopy of astral microtubules and Mad2, a marker of unstable attachments, revealed that polar chromosomes are mostly laterally attached to one astral microtubule that emanates from the pole behind which they are situated, with other more complex attachments observed less frequently. Finally, we show that polar chromosomes cause aneuploidy in 62% of cases when the spindle checkpoint is weakened, highlighting their importance in faithful chromosome segregation. Altogether, we propose a model in which pivoting of microtubules around the spindle pole, driven by spindle elongation, promotes the movement of polar chromosomes towards the spindle body and consequently their proper congression to the spindle equator.

Centromeres

B186/P2579

Centromeric Chromatin Persists with No New Assembly in Oocytes over the Fertile Lifespan of Mice

A. Das[1], K. G. Boese[2], K. Tachibana[3], B. E. Black[4], M. A. Lampson[2]; [1]Biochemistry and Biophysics, Biology, University of Pennsylvania, Philadelphia, PA, [2]Biology, University of Pennsylvania, Philadelphia, PA, [3]Biochemistry, Max Planck Institute of Biochemistry, Munich, GERMANY, [4]Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA.

Centromeres direct genetic inheritance but are not themselves genetically encoded. Instead, centromeres are defined epigenetically by the presence of a histone H3 variant, CENP-A. New assembly of centromere chromatin is inhibited by cyclin dependent kinases and therefore restricted to G1 phase of the cell cycle. In somatic cells in culture, G1 assembly is sufficient to replenish centromere chromatin after dilution by partitioning between sister centromeres in S phase. Mammalian oocytes arrest in prophase I for months in mice or decades in humans without an opportunity for new assembly by the conventional G1 pathway. Two models have been proposed for maintaining centromere identity through this long arrest: (1) stability of CENP-A nucleosomes assembled before the arrest or (2) a specialized prophase assembly pathway that continually replenishes centromere chromatin during the arrest. To distinguish between these models, we inhibited assembly by conditional knockout of *Mis18a*, an essential assembly factor, early in prophase I. To confirm that genetic deletion of *Mis18a* fully removes the protein, we assessed the ability of zygotes from *Mis18a* knockout mothers compared to wild type mothers, to assemble tagged CENP-A at the first mitotic division where conventional CENP-A assembly would occur using maternal protein. We find that unlike wild type embryos, all *Mis18a* maternal knockout embryos fail to assemble CENP-A, indicating a complete absence of the protein. We find no effect of *Mis18a* deletion on either CENP-A chromatin levels in the oocyte or the ability of the oocyte to be fertilized by WT sperm, even after 6-8 months of aging. Thus, we conclude that centromere chromatin is maintained throughout the oocyte prophase arrest without new assembly consistent with the first model. This is in stark contrast to the other prominent H3 variant, H3.3, that requires continual replenishment. Our findings show that CENP-A nucleosomes assembled before meiosis are sufficient to support essential chromosome segregation functions in meiosis and centromere inheritance through the female germline.

B187/P2580

Modulating CENP-A Nucleosome Mobility Dictates Centromere Chromatin Accessibility

D. P. Melters[1], K. C. Neuman[2], T. Rakshit[3], Y. Dalal[1]; [1]National Cancer Institute, Bethesda, MD, [2]National Heart Lung and Blood Institute, Bethesda, MD, [3]Shiv Nadar University, Dadri, INDIA.

Histone variants fine-tune transcription, replication, DNA damage repair, and faithful chromosome segregation. Mechanical stress can induce transcription within seconds, yet whether and how nucleosome variants encode unique mechanical properties to their cognate chromatin structures remain elusive. One of the most divergent histone variants is the H3 variant CENP-A, which is functionally essential for faithful chromosome segregation and primarily localized to the centromere. Although CENP-A nucleosomes are buried in pericentric heterochromatin, centromeric chromatin remains transcriptionally active. This suggests that centromeric chromatin is readily accessible to the transcriptional machinery even when bound to kinetochore proteins. This puzzling dichotomy can be

explained either by intrinsic mechanical properties or by epigenetic alterations drive by chromatin effectors. We therefore first set out to determine the elasticity properties of CENP-A nucleosomes unbound or bound to inner kinetochore protein CENP-C. We found that CENP-A nucleosomes are twice as elastic compared to H3 nucleosomes. Upon binding of CENP-C, CENP-A nucleosomes rigidified three-fold. To understand how changing the mechanical properties of CENP-A nucleosomes impact chromatin dynamics, we used high-speed atomic force microscopy. With high-speed AFM, we can quantitatively track individual nucleosomes in the context of chromatin, similar to live cell imaging. A quantitative analysis of CENP-A chromatin showed that CENP-A nucleosomes are very mobile, with a diffusion coefficient consistent with numbers previously reported for H3 nucleosomes. Interestingly, CENP-C strongly restricted the diffusion coefficient of CENP-A nucleosomes, thus limiting nucleosome mobility. This observation correlated with clustering of CENP-A chromatin in vitro and in vivo. Furthermore, upon overexpressing CENP-C in vivo, we observed a loss of centromeric RNA polymerase 2 and centromeric transcription, as well as an almost 3-fold reduction in new CENP-A loading. Altogether, these data suggest a model in which the inner kinetochore proteins are critically involved in modulating material properties of CENP-A nucleosomes, which in turn fine-tunes chromatin accessibility and thus centromeric transcription required for new CENP-A loading. This model predicts that in cycling cells two populations of CENP-A exist: one population that binds the kinetochore and one population that creates an intrinsically open chromatin state permissive of transcription.

B188/P2581

Pairing of non-exchange centromeres in meiotic prophase promotes their subsequent segregation at anaphase I

B. Rapacz, J. Evatt, A. Sadli, D. Dawson; Department of Cell Cycle and Cancer Biology, Oklahoma Medical Research Foundation, Oklahoma City, OK.

The homologous partners enter meiosis as separate chromosomes, but during meiotic prophase, the partners usually become connected by crossovers. These crossovers tether the partners together, which allows them, as a unit, to bi-orient on the meiotic spindle and segregate correctly in anaphase I. Nonetheless, in multiple organisms, when a single chromosome pair fails to experience a crossover (called non-exchange pair) the pair still segregates properly. This demonstrates that there are mechanisms, beyond crossing-over, that help homologous partners bi-orient on the spindle in meiosis. This study was undertaken to investigate one possible mechanism, the centromeric chromatin tether. Our previous work demonstrated that in budding yeast, the centromeres of non-exchange partners are paired in meiotic prophase. Here we show that this pairing is necessary to allow them to segregate from each other at anaphase I. Using live cell imaging experiments, we are exploring how meiotic prophase pairing promotes bi-orientation on the metaphase spindle. Our data suggest the model that in prophase the chromatin of the paired centromeres becomes tethered providing an inter-centromere bridge that allows cells to use a tension-sensing mechanism to bi-orient the partner centromeres. We hypothesize that cohesins link together chromatin loops from the paired centromeres in prophase. Our ongoing studies are testing this model.

B189/P2582

Evolutionary innovation in the CENP-T histone fold domain regulates centromere binding and kinetochore size

D. Dudka[1], K. Boese[1], A. L. Nguyen[2], B. Akins[1], B. E. Black[3,4,5], I. M. Cheeseman[2,6], M. A. Lampson[1,5]; [1]Department of Biology, School of Arts and Sciences, University of Pennsylvania, Phildalephia, PA, [2]Whitehead Institute for Biomedical Research, Cambridge, MA, [3]Department of Biochemistry and Biophysics, Perelman School of Medicine, University of Pennsylvania, Phildalephia, PA, [4]Epigenetics Institute, University of Pennsylvania, Philadelphia, PA, [5]Penn Center for Genome Integrity, University of Pennsylvania, Philadelphia, PA, [6]Department of Biology, Massachusetts Institute of Technology, Cambridge, MA.

Centromeres direct chromosome segregation by building kinetochores to mediate attachments to spindle microtubules. Evolutionary theory suggests that centromere proteins innovate to reduce fitness costs associated with selfish centromere DNA sequences, which bias their segregation to the egg in female meiosis. There is experimental evidence for selfish centromeres, and molecular evolution analyses have identified recurrent amino acid changes in centromere proteins, but the functional impacts of these changes remain untested. Here, we show that the histone fold domain (HFD) of a key centromere scaffold protein, CENP-T, has evolved to reduce its binding to mouse centromeres. Reversing innovation by swapping a divergent HFD into mouse CENP-T increases recruitment to mouse centromeres in both mitosis and meiosis, dependent on rapidly evolving residues, and increases kinetochore size. A divergent CENP-T HFD also promotes localization to pericentromeres, suggesting innovation to restrict kinetochore assembly to specific centromere regions. We propose that microtubule attachment errors associated with larger kinetochores are a fitness cost of selfish centromeres, favoring innovation to limit kinetochore formation.

B190/P2583

FREEDA: a fully automated molecular evolution pipeline maps positive selection across rodent kinetochores and reveals functional divergence in CENP-O

D. Dudka[1], B. Akins[1], M. A. Lampson[1,2]; [1]Department of Biology, School of Arts and Sciences, University of Pennsylvania, Philadelphia, PA, [2]Penn Center for Genome Integrity, University of Pennsylvania, Philadelphia, PA.

Cell biology research typically focuses on functions of conserved protein domains. However, rapid protein divergence by positive selection often leads to crucial innovations whose detection requires specialized expertise in molecular evolution and computational biology. Here, we present a stand-alone, automated pipeline, FREEDA (Finder of Rapidly Evolving Exons in De novo Assemblies), for detecting positive selection in candidate proteins in frequently used vertebrate cell biology models: human, mouse and chicken. FREEDA takes advantage of the ever-growing number of non-annotated genome assemblies and streamlines the widely used molecular evolution and genomic tools, while providing a simple graphical user interface tailored for cell biologists without expertise in computational biology and molecular evolution. FREEDA displays regions under positive selection within the amino acid sequence and within 3D structural models predicted by AlphaFold. We provide a comprehensive map of positive selection across the rodent kinetochore including nearly 100 proteins. We further show that a key centromeric complex, CENP-OPQUR, evolves under positive selection across three different taxa: primates, rodents and birds, suggesting recurrent functional innovation. Leveraging natural variation, we

show that divergence of the CENP-O C-terminus regulates centromere binding. Overall, we demonstrate how molecular evolution analyses can reveal regulation of protein function, and we provide an accessible computational tool to guide cell biology research.

B191/P2584

A tale of two CENP-C's: Bridging the long prophase pause to support oocyte ploidy

J. Fellmeth[1], H. Sturm[2], J. K. Jang[3], N. Changela[3], K. S. McKim[3]; [1]Biology, Millersville University, Millersville, PA, [2]Rutgers University, Piscataway, NJ, [3]Biology, Rutgers University, Piscataway, NJ.

The centromere is an epigenetic mark that acts as a loading site for the kinetochore during meiosis and mitosis. This mark is characterized by an H3 variant known as CENP-A (CID in *Drosophila*) which replaces canonical H3 at the centromeres during G1 with the help of CENP-C and CAL1 (HJURP in mammals). Failure to re-establish a proper centromere after division, or failure to recruit an effective kinetochore during M-phase both can result in aneuploidy via chromosome segregation defects which is a hallmark of many cancers, infertility, and developmental disorders. CENP-C is a critical component of establishing both the centromere and kinetochore. During mitosis, these functions occur in quick succession. However, during female meiosis, these two functions are separated by a long prophase pause. This prophase pause is implicated in the increase in the occurrence of aneuploidies in women over the age of 34. Because CENP-C is one of the few components that links the centromere and kinetochore through the prophase pause, we have chosen to investigate this role using mutants and RNAi knockdown of CENP-C.
CENP-C that is incorporated into cells prior to onset of meiosis is involved in centromere establishment and CID recruitment, this population is also critical for establishing homolog synapsis via centromere pairing, establishment of SC and cohesins, and preventing centromeric crossovers. This population of CENP-C is stable and remains at the centromeres until diluted via chromosome division. We have identified another population of CENP-C that is dynamic during meiotic prophase and acts to recruit kinetochore proteins and promote chromosome segregation prior to metaphase I. This study shows that CENP-C function in meiosis provides kinetochore support and centromere support as it does in mitosis, but that these two functions are not linked. We propose that the dynamic nature of CENP-C during the long prophase pause is necessary to prevent errors in chromosome segregation

B192/P2585

HistoneH3/H4 chaperones prevent the mislocalization of CENP-A for chromosomal stability

R. Shrestha[1], V. Balachandran[1], A. Rossi[1], H. Kim[2], P. Vadlamani[3], C. Hammond[4], L. Ozbun[1], S. Lin[5], K. Cheng[5], R. Chari[6], G. Pegoraro[1], A. Groth[7], D. Foltz[3], M. Basrai[1]; [1]National Cancer Institute, NIH, Bethesda, MD, [2]Genetics Branch, NCI, NIH, Bethesda, MD, [3]Northwestern University, Chicago, IL, [4]Novo Nordisk Center for Protein Research, University of Copenhagen, Copenhegan, Denmark, [5]National Center for Advancing Translational Sciences, NIH, Bethesda, MD, [6]Genome Modification Core (GMC), Frederick National Lab for Cancer Research, NCI, Frederick, MD, [7]Novo Nordisk Center for Protein Research (CPR), University of Copenhagen, Copenhegan, Denmark

Unequal distribution of chromosomes into two daughter cells and/or structural rearrangements of the genome causes chromosomal instability (CIN) and aneuploidy that are observed in many cancers. One of the key determinants that prevents CIN is the structural integrity of centromeric chromatin that ensures faithful chromosome segregation. Restricting the localization of the evolutionarily conserved

centromeric histone H3 variant CENP-A to the centromeres is essential for chromosomal stability. Overexpression and mislocalization of CENP-A has been reported in many cancers and correlated with poor prognosis. Using cell biology assays and miFISH, we have previously shown that the mislocalization of overexpressed CENP-A to non- centromeric regions contributes to aneuploidy, CIN and karyotypic heterogeneity in cell lines and xenograft tissues. Therefore, it is important to define mechanisms that prevent mislocalization of CENP-A. Here we used an image based high-throughput genome-wide siRNA screen to identify gene depletions that increase nuclear CENP-A in HeLa cells. Amongst the top hits were components of NuA4 complex (EP400 and TRRAP), histone chaperones (CHAF1B, CHAF1A, and HIRA) and a member of the DnaJ family of heat shock proteins (DNAJC9). We focused on defining the roles of CHAF1B in preventing mislocalization of CENP-A. Our results showed an enrichment in protein levels of CENP-A, mislocalization of CENP-A and CIN phenotypes in CHAF1B depleted cells. Previous studies have shown that depletion of H3.3 chaperone DAXX suppresses mislocalization of overexpressed CENP-A. We observed increased expression of DAXX, but not other histone chaperones upon CHAF1B depletion. Consistent with these results, depletion of DAXX suppressed the mislocalization of CENP-A and CIN phenotypes in CHAF1B depleted cells. Based on our results, we propose that increased levels of DAXX promiscuously chaperone overexpressed CENP-A to non- centromeric regions, and this contributes to CIN upon CHAF1B depletion. In summary, we have identified factors that prevent CENP-A mislocalization and defined a role of CHAF1B in restricting the localization of CENP-A to centromeric chromatin to prevent CIN. These studies will advance our understanding for the causes and consequences of CIN in CENP-A overexpressing cancers.

EWSR1 (Ewing Sarcoma Breakpoint Region 1) Maintains Centromere Identity

K. Kitagawa, R. Kitagawa, A. Becker, P. Houghton; Greehey Childrens Cancer Research Institute, UT Health San Antonio, San Antonio, TX.

The centromere is essential for ensuring high-fidelity transmission of chromosomes. CENP-A, the centromeric histone H3 variant, is thought to be the epigenetic mark of centromere identity. CENP-A deposition and maintenance at the centromere is crucial for proper centromere function and inheritance. Despite its importance, the precise mechanism of maintenance of CENP-A, i.e., the maintenance of centromere position, remains obscure. Here, we report a novel mechanism to maintain centromere identity. We found that CENP-A interacts with EWSR1 (Ewing Sarcoma Breakpoint Region 1) and EWSR1-FLI1 (the oncogenic fusion protein in Ewing sarcoma). EWSR1 is required for maintaining CENP-A at the centromere in interphase cells. EWSR1 and EWSR1-FLI1 bind to CENP-A through the SYGQ2 region within the prion-like domain, which is important for phase separation. EWSR1 binds to R-loops through its RNA-recognition motif (RRM) *in vitro*. Both domain/motif are required for maintaining CENP-A at the centromere. Therefore, we conclude that EWSR1 guards CENP-A in centromeric chromatins by binding to centromeric RNA. The fusion protein CENP-A-RRM localized at the centromere in EWSR1-depleted cells, supporting our conclusion.

B194/P2587

Constitutive methylation of budding yeast CENP-A contributes to chromosomal instability

P. K. Mishra[1], N. Ali[2], W. Au[1], L. Boeckmann[1], Y. Takahashi[1], P. Castineira[1], K. Bloom[3], P. Thorpe[2], M. Basrai[1]; [1]NCI, NIH, Bethesda, MD, [2]Queen Mary University, London, UNITED KINGDOM, [3]UNC, Chapel Hill, NC.

The centromere (CEN) is essential for high fidelity chromosome segregation as CEN dysfunction leads to chromosomal instability (CIN) and aneuploidy, the hallmark of cancer cells. CEN identity is specified epigenetically by specialized nucleosomes containing the evolutionarily conserved CEN-histone H3 variant (Cse4 in budding yeast, CENP-A in humans), which is essential for faithful chromosome segregation. However, the epigenetic mechanisms that regulate CENP-A function have not been clearly defined. We have recently identified post-translational modifications (PTMs) of budding yeast CENP-A such as phosphorylation, acetylation and methylation. In this study, we report that cell cycle dependent methylation of Cse4 regulates kinetochore structure-function and high fidelity chromosome segregation. We show that methylation of Cse4 is regulated by the cell cycle with the highest enrichment of methylated Cse4 observed in the G2/M but not in G1 cells. In agreement with these results, ChIP experiments uncovered high levels of methylated Cse4 at the CEN chromatin in the G2/M cells. A methyl-mimic cse4 mutant (cse4-R37F) shows reduced levels of CEN-associated kinetochore proteins, defects in structural integrity of the CEN chromatin, synthetic lethality with kinetochore mutants, and CIN phenotype suggesting that constitutive methylation of Cse4 is detrimental to faithful chromosome segregation. Our ongoing studies are focused on the identification and characterization of enzymes that contribute to methylation of Cse4. In summary, our results from budding yeast provide new insights into molecular mechanisms by which constitutive methylation of Cse4 contributes to CEN dysfunction and CIN.

B195/P2588

Probing centromere strength in the genesis of age-related oocyte aneuploidy

T. Lemonnier[1], M. Dumont[2], S. Redemann[3], D. Fachinetti[2], B. Mogessie[1]; [1]Yale University, New Haven, CT, [2]Institut Curie, Paris, France, [3]University of Virginia, Charlotteville, VA

Chromosome segregation errors are surprisingly common in mammalian oocyte meiosis. This generally results in egg aneuploidy, which is a leading cause of miscarriages, infertility and genetic disorders. Moreover, the incidence of egg aneuploidy increases dramatically with advancing maternal age. It has long been known that meiosis violates Mendel's law of random segregation as some chromosomes are more likely to be retained in the egg, and thus to be passed on to the progeny. Recent studies have shown that centromere strength (centromeric protein content) and spindle asymmetries in intrinsic spindle properties underpin this phenomenon of biased meiotic segregation. We are interested in understanding whether such bias also underlies egg aneuploidy, wherein some chromosomes are more predisposed to mis-segregation. We are therefore investigating existence of chromosome-specific aneuploidies and the molecular basis for biased chromosome mis-segregation in mammalian oocytes. By coupling techniques to specifically identify each chromosome with centromere protein content measurements and single cell sequencing, we seek to examine chromosome-specific segregation errors that contribute to high incidence of egg aneuploidy at advanced reproductive ages. Our preliminary data indicate that abundance of the centromeric protein CENP-A varies between chromosomes as well as between reproductively young and older female mice. Furthermore, targeted degradation of CENP-A in

oocytes of reproductively young animals induces chromosomal alignment defects. Our analyses of centromeric-DNA sequences such as minor satellites also revealed inter-chromosomal differences in young and aged mice. These initial data indicate existence of centromere strength discrepancies between oocyte chromosomes that could lead to chromosome-specific segregation errors in reproductively older females.

Cancer Therapy: Targeting Kinases 2

B197/P2589

ROR1 is negatively regulating CREB3L1 through activation of DNMT3A, in Triple-Negative breast cancer.

V. L. Reed, B. Peethambaran; Saint Joesph's University, Philadelphia, PA.

Triple Negative breast cancer (TNBC) is the most aggressive form of breast cancer. This disease lacks any cell-surface receptors used for therapeutic targets, such as estrogen, progesterone, or Human epidermal growth factor receptor 2 (HER2). Patients with TNBC have very limited therapeutic options besides chemotherapy, which often causes them undesirable side effects and creates a resistance to treatment. TNBC tumors are highly heterogeneous and contain many different types of CSCs, leading to increased epithelial to mesenchymal transition (EMT). Thus, CSCs are partially blamed for the high instance of chemotherapy resistance in TNBC patients. ROR1, a receptor tyrosine kinase, is thought to be associated with CSCs and to activate oncogenic pathways, such as PI3K/AKT. This gene is specifically expressed only during early fetal development and in cancerous tissues. TNBC patients that have high expression of ROR1 are found to have increased disease state and poor prognosis, compared to those with low ROR1 expression. Therefore, this protein is of high research interest to be investigated as a potential therapeutic target for TNBC. CREB3L1, a transcription factor that works as a tumor suppressor and is found to be associated with poor prognosis in TNBC patients, when expressed at low levels. This current study works to develop a novel molecular mechanism that explains how ROR1 is negatively regulating CREB3L1 in TNBC. We hypothesize that ROR1 is activating DNA methyltransferases, specifically DNMT3A, which epigenetically modifies CREB3L1 to reduce its expression in TNBC. Knocking down ROR1 shows that the protein level of CREB3L1 increases, while the protein level of DNMT3a decreases. This work will provide further understanding of the oncolytic properties associated with ROR1 in TNBC, helping to potentially form a basis for cell-targeted based therapies for TNBC patients.

B198/P2590

Novel ROR1 inhibitor CPD86 suppresses cell survival and migration in triple-negative breast cancer.

T. Ta, 1[1], S. R. R. Gupta[2], V. Reed[1], C. Scanlon[1], N. Fultang[1], B. Peethambaran[1]; [1]Biological Sciences, Saint Joseph's University, Philadelphia, PA, [2]Department of Zoology, University of Delhi, New Delhi, INDIA.

Breast cancer is the second most common cancer in women in the United States, with approximately 15-20% of new cases characterized as triple-negative breast cancer (TNBC), the most aggressive subtype. It is histologically characterized by the absence of hormone receptors that are typically targeted by hormone therapies such as Tamoxifen or Docetaxel, leading to difficulty in treatment. The standard of care for TNBC consists of traditional chemotherapy and radiation which are often highly toxic to both TNBC cells and normal cells. Therefore, it is critical to identify novel anti-cancer compounds that specifically target TNBC with minimal damage to normal tissues. It has been reported that receptor

orphan tyrosine kinase-like receptor 1 (ROR1) is an oncofetal protein overexpressed specifically in several human malignancies such as breast, lung, pancreatic and prostate cancers, but not in adult normal tissues. Blockade of ROR1 signaling has been shown to inhibit proliferation and induce apoptosis of cancer cells. Through *in silico* molecular docking, we characterized a novel compound that interacts strongly and inhibits ROR1 (hereafter referred to as **CPD86**). Our study aims to investigate the anti-TNBC effect of this compound both *in vitro* and *in vivo*. Preliminary evidence shows that **CPD86** suppresses cell migration and induces cell apoptosis at a half-maximal inhibitory concentration of approximately 2 μM toward MDA-MB-231 cells (TNBC cells with high ROR1 expression). We hypothesize that treatment with **CPD86** will increase apoptosis and decrease cell proliferation, migration, and invasion in TNBC cells, but not in MCF-10A cells (normal breast epithelial cells with no ROR1 expression). We will also test the efficacy of **CPD86** in inhibiting tumor growth in a cell-derived xenograft mice model of TNBC. ROR1 inhibitors could be of potential therapeutic approach for TNBC and the data would serve as proof-of-concept justification for their evaluation in other ROR1-upregulated cancers.

B199/P2591

Scamp3 Regulates EGFR and Modulates AKT and ERK Signaling Pathways

A. Acevedo-Díaz[1], B. Morales-Cabán[2], **I. J. Suarez-Arroyo**[2]; [1]Biology, University of Puerto Rico, Bayamon, PUERTO RICO, [2]Biochemistry, Universidad Central del Caribe-School of Medicine, Bayamon, PUERTO RICO.

Triple Negative Breast Cancer (TNBC) treatment development remains challenging due to disease heterogeneity and the absence of specific molecular targets. The secretory carrier membrane protein 3 (SCAMP3) is overexpressed and associated with poor prognosis in a variety of cancers and is identified as a regulator of epidermal growth factor receptor (EGFR). Accordingly, we aimed to investigate the association of SCAMP3 with the EGFR signaling pathway in TNBC. We hypothesize that SCAMP3 regulates EGFR degradation and induces EGFR signaling to promote TNBC. To assess how EGFR signaling is affected, we used our SUM-149 WT and SCAMP3 knockout models (SC3KO). Immunoblots showed that SCAMP3 knockout in SUM-149 abolished ERK1/2. Later, we inhibited EGFR activation with the tyrosine kinase inhibitor (TKI) erlotinib. EGFR inhibition reduced ERK phosphorylation in SCAMP3-expressing cells but was not affected in depleted cells. However, ERK phosphorylation increased compared to SCAMP3-depleted cells treated with vehicle. Interestingly, the treatment decreased AKT phosphorylation in the absence of SCAMP3. Furthermore, inhibition of EGFR did not affect STAT3. This result may suggest that SCAMP3 is involved in regulating the EGFR, AKT, and ERK pathways. Therefore, we sought to investigate the molecular mechanism behind the regulation of EGFR by SCAMP3. We examined the impact of SCAMP3 silencing on receptor degradation after EGF stimulation in a time-course experiment. Upon stimulation, the percentage of EGFR retained in the cell decreased in SCAMP3 knockout cells as early as 30 min showing an acceleration in the degradation kinetics of EGFR. In summary, depletion of SCAMP3 decreases ERK phosphorylation independently of its interaction with EGFR. Concurrently, the reduction of AKT phosphorylation depends on the downregulation of both. Furthermore, the absence of SCAMP3 accelerates the degradation of EGFR. We conclude that SCAMP3 contributes to cancer development through the regulation of multiple pathways and has the potential to be a target for breast cancer therapy.

B200/P2592

Silencing SCAMP3 Sensitizes TNBC Cells to EGFR Inhibitor

A. C. Acevedo-Diaz[1], **V. M. Hernandez-Cosme**[2], I. J. Suarez-Arroyo[2]; [1]Biochemistry, Universidad Central del Caribe, Bayamon, PUERTO RICO, [2]Biochemistry, Universidad Central De Caribe, Bayamon, PUERTO RICO.

Triple negative breast cancer (TNBC) is one of the most lethal subtype of breast cancer and patients with metastatic TNBC have a 5-year survival rate of 11%. These cancer cells are characterized by being negative for estrogen and progesterone receptors, and human epidermal growth factor receptor 2 (HER2). Nonetheless, there is a gap in knowledge regarding therapeutic agents that may work against TNBC. We have previously reported that secretory carrier-associated membrane protein 3 (SCAMP3) is highly expressed in TNBC cells and in breast cancer tissues. Preliminary studies showed that SCAMP3 is associated with epidermal growth factor receptor (EGFR) endocytosis. EGFR acts as a mechanism of transport of cancer-associated signaling proteins, like signal transducer and activator of transcription 3 (STAT3). EGFR and STAT3 have been associated with TNBC poor prognosis, metastasis, stem cell maintenance, and drug resistance. Our preliminary studies focus on identifying the effects of silencing SCAMP3 in association with the inhibition of EGFR or STAT3 using erlotinib and C188-9 inhibitors, respectively. To this end, we knocked out SCAMP3 in SUM-149 TN (inflammatory breast cancer (IBC) cells) and MBA-MB-468 (TN-non-IBC cells) using CRISPR-CAS9. MBA-MB-468 WT and SC3KO cells were treated with erlotinib or C188-9 with 1μM - 10μM for 72h. SUM-149 WT and SC3KO cells were treated with C188-9 for 72h. Then, cells were fixed with methanol and stained with propidium iodide, and fluorescent intensity was measured utilizing a spectrophotometer to assess cell viability after treatment. We found that MBA-MB-468 WT cells treated with C188-9 were sensitive (IC50 = 8.338 μM) to the treatment. While MBA-MB-468 SC3KO cells were resistant (IC50 = 13.62 μM) to C188-9. On the other hand, we confirmed, as stated in the literature, that MBA-MB-468 WT cells are resistant (IC50 = 10.14 μM) to erlotinib. Interestingly, SC3KO cells were sensitive (IC50 = 5.689 μM) to treatment. Furthermore, we found that SUM 149 WT and SC3KO cells were sensitive (WT: IC50 = 3.474 μM; SC3KO: IC50 = 3.477 μM) to C188-9. Altogether, our results suggest that knockout of SCAMP3 sensitizes cells to EGFR inhibitor and plays a key role in the cytotoxicity effect of STAT3 inhibitor. Interestingly, knockout of SCAMP3 in IBC cells had no effect on the toxicity associated with erlotinib in these cells. These findings could point out that targeting SCAMP3 is a promising treatment for those TNBC patients with resistance to EGFR inhibitors.

B201/P2593

Scamp3 knockout sensitizes triple negative breast cancer cells to erk inhibitory treatments

B. M. Morales-Cabán, I. Suarez-Arroyo; Biochemistry, University of Central Del Caribe, Bayamon, PUERTO RICO.

Triple-negative breast cancer (TNBC) is the most aggressive and deadly type of breast cancer and its lethality is due to the absence of estrogen and progesterone receptors and HER2). The absence of targeted therapies creates the need to identify molecular targets with the potential to serve as effective therapeutic agents. Increased expression of the secretory carrier membrane protein 3 (SCAMP3) was identified in breast cancer cells and tissues and it has been associated with the growth, progression, and survival of TNBC cells. Increased activation of the extracellular signal-regulated kinase (ERK) signaling pathway is closely related to tumor formation, progression, and metastasis in TNBC. We found that in

the absence of SCAMP3,ERK is inhibited and TNBC cells proliferation is reduced. Thus, we aim to elucidate the role of SCAMP3 in the regulation of ERK in TNBC development. To investigate how SCAMP3/ERK contributes to the TNBC cellular response, we knockout the expression of SCAMP3 (SC3-KO) in TNBC SUM-149 using the CRISPR/Cas9 technique and overexpressed (SC3-OE) SCAMP3 in non-tumorigenic epithelial cells MCF-10A. The cells were treated with MK-8353, an ERK inhibitor, at different concentrations (62nM - 64uM) to assess cell viability at 24, 48, and 72 hours. Our results show that SUM-149 SC3-KO were still sensitive to MK-8353 at 72h in comparison with WT. However, we observed the effect of treatment is time dependent in these cells (24h: WT: IC50=1.7µM, SC3-KO: 2.1µM; 48h: WT: IC50=1.3µM, SC3-KO: 1.5µM; 72h: WT: IC50=0.22µM, SC3-KO: 0.74 µM). On the other hand, MCF-10A SC3-OE showed a resistance to ERK inhibitor at early times (24h: control: IC50=11µM, SC3-OE=21µM; 48hcontrol: 0.170µM, SC3-OE=1.6µM) when compared to control cells. Interestingly, SC3-OE showed an increase cytotoxic effect at 72h control IC50=120nM, SC3-OE=600nM). To compare our results observed in TNBC cells, we used the HER2+ cell line, SUM-190 and its isogenic model of SCAMP3 knockout treated with MK-8353. Interestingly, we found similar results to SC3-OE cells 24h: WT: IC50=11.4µM, SC3-KO=27.9µM; 48h: WT: IC50=1µM, SC3-KO=2.8µM; 72h: WT: IC50=0.50 µM, SC3-KO=0.40 µM). Altogether, our results demonstrate that overexpression of SCAMP3 is associated with ERK inhibitor resistance as early times of exposure. Furthermore, is required longer exposure time to inhibitor to increase cytotoxic effects in HER2+ silenced cells in comparison to TNBC. Taken together, our study suggests that SCAMP3 plays a crucial role in the effectivity of ERK treatment

B202/P2594

Diminazene aceturate exhibits anti-tumor activities in human cervical carcinoma via inhibition of c-MYN oncogenic signaling

R. Gharbaran[1], L. Somenarain[1], S. Redenti[2]; [1]Biological Sciences, Bronx Community College/The City University of New York, Bronx, NY, [2]Biological Sciences, Lehman College/City University of New York, Bronx, NY.

The pro-protein convertase furin gain spotlight in the current COVID-19 pandemic. Recent structure-based analysis showed that diminazene (DIZE), an anti-parasitic drug, is a competitive inhibitor to furin. Here, we investigated anti-tumor activities of DIZE-induced inhibition of furin in human cervical carcinoma. Kaplan-Meier analyses on expression data retrieved from Human Genome Atlas showed that overexpression of furin mRNA expression is associated with shortened survival ($p<0.001$). Immunofluorescence studies confirmed the expression of furin in Hela cells, a well-studied cellular model of human cervical carcinoma. Water-soluble tetrazolium 1 (WST-1) cell proliferation assay showed DIZE caused dose-dependent decrease in growth of Hela cells after treatment for 48 h. The observe response was associated with transcriptional downregulation of cell proliferation markers Ki67 and PCNA. Acridine orange-ethidium bromide (AO-EtBr) dead-live assay revealed significant cell death associate DIZE. Staining with a caspase3/7-specific dye showed caspase activation and immunofluorescence showed increased caspase 3 activity in DIZE-treated cells. In addition, DIZE-treated cells showed transcriptional downregulation of furin and the oncogene c-MYC. These results suggest that DIZE maybe consider a candidate molecule for human cervical carcinoma therapeutics. However, further research is needed to evaluate its anti-tumor mechanisms.

B203/P2595

Phosphomevalonate kinase as novel target of radiosensitizer in lung cancer cells

S. Park, M. Kwon, S.-Y. Jeong; Asan Medical Center, Seoul, Korea, Republic of

Radiotherapy (RT) plays a crucial role in the local treatment of lung cancers. However, although RT locally targets and controls malignant lesions, due to RT-resistance, RT is still not an effective treatment for lung cancer. In this study, we identified the phosphomevalonate kinase (PMVK) as a novel radiosensitizing target and explored the underlying mechanism for the first time. Cell viability and survival fraction after RT were significantly decreased by PMVK knockdown in lung cancer cell lines. PMVK knockdown cells showed increased apoptosis, DNA damage and G2/M phase arrest after RT. DNA damage increased by siRNA PMVK plus RT was induce by inhibiting the DNA HR repair pathway via siRNA PMVK-induced RPA1 downregulation. Moreover, a stable shRNA PMVK mouse xenograft models verified *in vivo* radiosensitizing effects. Furthermore, PMVK expression was increased in lung cancer tissues and significantly correlated with patient survival and recurrence. Collectively, our results demonstrate that knockdown of PMVK enhances radiosensitivity in lung cancer through DNA damage repair pathway, suggesting that knockdown of PMVK may offer an effective therapeutic strategy to improve therapeutic efficacy of RT.

B204/P2596

Image-based phenotypic profiling of a chemogenomic screening library identifies novel druggable targets in the EGFR-pathway

K. Tanabe; Tokyo Women's Medical University, Tokyo, Japan

The gene encoding epidermal growth factor receptor (EGFR) is a major driver gene in cancer. Many drugs targeting EGFR-associated molecules have been developed, yet many have failed in clinical trials due to a lack of efficacy and/or unexpected side effects. In this study, I used image-based phenotypic profiling to screen a pharmacologically active compound library with the aim of identifying new druggable targets in the EGFR pathway. As anticipated, the phenotypic screen identified compounds that produce phenotypes resulting from targeting a known specific molecule or pathway. The assay also showed that compounds with diverse known mechanisms of action produced similar, EGFR-related cellular phenotypes. Biochemical assays revealed that those compounds share a previously unappreciated common target/pathway, showing that the image-based assay can identify new target molecules that are independent of the compound’s known target.

Cancer Therapy: Metabolism

Hormetic effect of an Ethanolic Graviola Leaf Extract on HGF-1 cells viability.

C. Cassé; University of Puerto Rico, Mayagüez,PR, PR.

Plant-extracted compounds have been used for centuries in traditional pharmacopeia. Some of them have proven to be excellent drug alternatives for cancer treatment as they target metabolic pathways that are key to cancer cells such as apoptosis, energy-producing catabolic pathways, and the response to oxidative stress. Since some anticancer drugs have been shown to produce dose-dependent biologically opposite effects, it is crucial to determine the range of doses for which the compounds have maximum

therapeutical benefits. Annona muricata or Graviola is a tropical tree that is common in the Puerto Rican landscape. Although a plethora of studies conducted *in vitro* and *in vivo* studies have indeed reported that extracts prepared from the Graviola root, fruit, bark, and leaves possess antiproliferative activities in a large variety of cancer cells, the efficiency of Graviola extracts to curb the progression of head and neck cancers has been overlooked. Furthermore, the bioactivity of Graviola extracts on sane/non-cancerous cells has largely been ignored. The present work reports the *in vitro* antiproliferative/anticancer behavior of an ethanolic Graviola leaf extract on squamous cell carcinoma cell lines 9 and 25 vs. a sane/non-cancerous human gingival fibroblast cell line -1. Our results show that the Graviola extract induces cell death in the squamous cell carcinoma cell lines at all concentrations tested and a dose-dependent biphasic concentration-dependent/hormetic effect on the fibroblastic cells. This suggests that, at low doses, the phytochemicals present in the prepared Graviola extract could offer potential therapeutic avenues for curbing the progression of head and neck cancers.

B206/P2598

Versatile Metabolic Activities of Lupane-, Oleanane-, and Ursane- type Pentacyclic Triterpenes in Lung Cancer Cells

G. Torres[1], S. Estrada[2], D. Pérez[3], Y. Delgado[1]; [1]Biochemistry & Pharmacology Department, San Juan Bautista School of Medicine, Caguas, PR, [2]Biology Department, University of Puerto Rico-Cayey, Cayey, PR, [3]Neuroscience Department, Universidad Central del Caribe, Bayamón, PR.

In recent times, a great interest has been motivated on plant derived compounds known as phytochemicals. The pentacyclic oleanane-, ursane-, and lupane-type triterpenes are phytochemicals that exert significant activities against diseases like cancer. Lung cancer is the leading cause of cancer-related death worldwide. Although chemotherapy (eg. cisplatin) is the treatment of choice for lung cancer, its effectiveness is hampered by the dose-limiting toxic effects and chemoresistance. Herein, we investigated the metabolic activities of several pentacyclic triterpenes: oleanolic acid, ursolic acid, asiatic acid, betulinic acid, betulin, and lupeol on non-small cell lung carcinoma A549 cells. From our studies, we confirmed that all these triterpenes showed cytotoxic activities in the μM range after 24h of incubation. Then, we performed metabolic activity assays as DNA damage, cell cycle arrest, reactive oxygen species (ROS) production, caspase-3 activation, and induction of EGFR, MAPK, and Ki67 using flow cytometry. All the pentacyclic triterpenes showed to activate caspase-3 and ROS production. In addition, these triterpenes induced cell cycle arrest in S-phase and DNA double-strand breaks by activation of the histone H2A.X. Furthermore, the signaling of MAPK, EGFR, and Ki67 were activated in cells treated with the triterpenes confirming the cell cycle arrest and DNA damage. In summary, our results could change the way first- and second-line anticancer therapies are implemented and selected giving an important adjuvant role to these phytonutrients. These results demonstrate the important adjuvant role of these triterpenes and the great potential in the treatment of lung cancer.

B207/P2599

The metabolic activity of Deferasirox in combination with Doxorubicin chemotherapy against lung carcinoma

S. Estrada-Mojica[1], G. Torres[2], D. Pérez3[3], Y. Delgado[2]; [1]Biology Department, University of Puerto Rico-Cayey, Cayey, PR, [2]Biochemistry & Pharmacology Department, San Juan Bautista School of Medicine, Caguas, PR, [3]Neuroscience Department, Universidad Central del Caribe, Bayamón, PR.

In cancer cells, iron metabolism is commonly altered because of an increased dependence on iron compared with normal cells. Accumulating evidence suggests that iron overload is associated with lung cancer (LC). Doxorubicin (Doxo) is a naturally occurring anthracycline chemotherapy commonly used in LC. However, Doxo is not very effective in non-small cell lung carcinoma (NSCLC) type that represents approximately 85% of LC. Due to this, there is a need to develop alternatives to increase the efficacy of Doxo in NSCLC. Herein, we studied Deferasirox (Def), an FDA-approved iron chelator as a strategy for iron deprivation in combination with Doxo in NSCLC. Viability assay results showed that Def has synergistic cytotoxic effects in combination with low μM concentrations of Doxo after 24 h of incubation in A549 NSCLC cells. The metabolic activity of Doxo in combination with Def seems to involve downregulation of the PI3K, EGFR and MAPK. In addition, the combination of Doxo with Def induced cell cycle arrest in S-phase and DNA double-strand breaks. Iron deprivation induced by Def or other iron chelators in combination with chemotherapeutic drugs could thus help to improve the effectiveness of cancer therapy in NSCLC.

B208/P2600

Iron metabolism regulated via DMT1-dependent early endosome-mitochondria interactions is associated with metastatic capacity of invasive breast cancer cells

J. Barra, I. Crosbourne, J. M. Lamar, M. Barroso; Albany Medical College, Albany, NY

Iron translocation into mitochondria can be facilitated by transient and direct interactions between early endosome (EE) and mitochondria. We show that Divalent Metal Transporter 1 (DMT1) mediates mitochondrial iron translocation via EE-mitochondria interactions in invasive MDA-MB-231 breast cancer cells. DMT1 also regulates EE speed, labile iron pool (LIP) and mitophagy levels. Moreover, DMT1 silencing impaired both mitochondrial metabolism and invasion in MDA-MB-231. Re-expression of DMT1 in MDA-MB-231 DMT1-KO cells rescues all these phenotypes. Importantly in invasive breast carcinoma patient's tumor samples, DMT1 is upregulated and associated with lower overall free survival. Our results show that DMT1 bridges EE and mitochondria to support higher mitochondrial iron translocation and lower LIP levels, necessary for sustaining mitochondrial bioenergetics and invasive cancer cell migration. To explore DMT1's role in cancer related processes, we used both 3D multicellular spheroids and *in vivo* metastasis experiments. We found that DMT1 ablation disrupts the normal shape/morphology of MDA-MB-231 spheroids. Immunofluorescence showed a significant difference in EE-mitochondria association between periphery and center of spheroids upon DMT1 silencing. Surprisingly, DMT1 silencing does not affect the number of lung metastases but significantly increases their size. To characterize the role of DMT1 in metastatic growth, we are evaluating EE-mitochondria interactions in WT vs DMT1 KO metastatic tissue sections. Interestingly in metastatic cancer cell lines derived from MDA-MB-231, with tropism for brain (BrM2) and lung (LM2) tissues, DMT1 and transferrin receptor (TfR) decreases compared to parental cells. We observed that EE-mitochondria association is lower in BrM2 cells compared to its parental counterpart. Finally, spheroid morphology among the two

metastatic cell lines compared with the parental cells were drastically different, presenting some of them more cells at the periphery e.g., in BrM2, indicating a more invasive phenotype. YAP/TAZ are master regulators of metastatic growth. Silencing of YAP but not TAZ, positively regulates the levels of DMT1, ferroportin and ferritin. However, TfR was not affected by YAP/TAZ silencing. We hypothesize that the presence of DMT1 is critical for the invasive phenotype, but once metastatic cells reach their niche, DMT1 may need to be downregulated for efficient metastatic growth. The characterization of iron metabolism regulatory mechanisms and its difference between parental and metastatic cells using 3D cell culture and *in vivo* experiments, should provide important insights into both metastatic cellular mechanisms and new possibilities for therapies against metastatic growth.

Modulating Arginine Metabolism in Breast Tumor Microenvironment via Sepiapterin - A Novel Immunotherapeutic Strategy for Breast Cancer

V. R. Fernando, V. Sharma, X. Zheng, S. Furuta; University of Toledo, Toledo, OH.

The immunosuppressive nature of the breast tumor microenvironment (TME) often renders immunotherapy moderately responsive. Current approaches employing cytokines to induce immunostimulation in breast TME fail to move towards clinical trials due to their systemic toxicity. Hence there is a critical need for a safe strategy that can improve the immunogenicity of breast TME. We aimed to address this by targeting the arginine metabolism to induce an immunogenic shift in breast TME. Tumor cells and tumor-associated macrophages (TAMs) utilize arginine metabolism to influence the immunosuppressive milieu by producing polyamines that promote tumor progression over nitric oxide (NO) that exert anti-tumor activities. Such differential arginine utilization is due to the reduced biosynthesis of tetrahydrobiopterin (BH4), the essential cofactor of NO synthase (NOS), in malignant tumors and immunosuppressive M2-TAMs. Our objective was to redirect the arginine metabolism in breast TME towards NO production to induce a strong immunostimulatory shift by supplementing sepiapterin, the endogenous precursor of BH4. Using *in vitro*, *ex vivo* and *in vivo* models of breast TME, we studied the effect of sepiapterin treatment on both tumor cells and M2-TAMs. Employing a combination of ELISA, flow cytometry and imaging techniques, we evaluated sepiapterin-induced changes in arginine metabolism, immune responses and tumor growth. Our *in vitro* and *ex vivo* results show that sepiapterin treatment significantly reduced polyamine levels while increasing NO levels in both tumor cells and M2-TAMs. The treatment also led to the reprogramming of M2-TAMs to immunostimulatory M1-TAMs. Furthermore, sepiapterin-treated *ex vivo* and *in vivo* tumors showed a significant reduction in tumor epithelia and tumor size. Interestingly the expression of immune checkpoint ligand, PD-L1 was abrogated in sepiapterin-treated tumors via inactivation of STAT3. In conclusion, our findings provide the first evidence that sepiapterin supplementation can be employed as a safe and potent immunotherapeutic strategy for breast cancer.

The anti-tumorigenic mechanisms of 4R cembranoid in non-small cell lung carcinoma

J. G. Cirino, I. Suarez, A. Acevedo, N. Sabeva, Y. Ferrer; Universidad Central Del Caribe, Bayamon, Puerto Rico

Eighty-four percent of lung cancers are classified as non-small cell lung carcinomas (NSCLC), with an average 5-year survival rate of 26% due to less sensitivity to traditional treatments such as radiation and

chemotherapy. Chemotherapies such as cisplatin and carboplatin are platinum-based and cause adverse effects on non-cancerous healthy cells. Therefore, the need for non-toxic treatments is crucial for a better prognosis in patients. In our search for these anticancer agents, our group tested and demonstrated that (1*S*,2*E*,4R,6*R*,-7*E*,11*E*)-2,7,11- cembratriene-4,6-diol (4R), a cembranoid extracted from *Nicotiana tabacum*, is non-toxic and has anti-proliferative and anti-tumorigenic activity in NSCLC. 4R has been shown to negatively modulate the alpha 7 nicotinic acetylcholine receptor (α7nAChR), which induces signaling that promotes cellular proliferation and survival. Our studies aim to elucidate the specific mechanism of 4R's anti-tumorigenic effect in NSCLC. Based on our data, we hypothesize that 4R, as a negative modulator of nicotinic signaling, will help inhibit molecular cascades involved in survival and proliferation while also inducing apoptosis. To do this, we first detected the levels of the α7nAChR in NSCLC cell lines compared to primary normal lung cells (MRC5) by Western blot (WB). Results showed significant overexpression of the α7nAChR in A549 and Lewis Lung Carcinoma (LLC) lung cancer cell lines when compared to MRC5 ($P<0.0001$). We then evaluated the α7nAChR negative modulator LYNX-1, in LLC cells. Results demonstrated that when treated with 4R, LYNX-1 expression significantly increases compared to its vehicle (*$p<0.0383$). We also studied Akt expression and activation, a key protein kinase for cell survival downstream of α7nAChR, by WB in LLC. Results demonstrated that 4R-treated cells significantly decreased phospho-S473 and total Akt (**$p<0.0078$ and **$p<0.0061$, respectively). Furthermore, we studied the pro-apoptotic protein BAD and observed a significant decrease in phosphor-S112 when treated with 4R (*$p<0.0453$). In summary, our results suggest that in NSCLC, 4R negatively regulates α7nAChR signaling by upregulation of LYNX-1. This modulation decreases the activation of pro-survival pathways and promotes the activation of pro-apoptotic proteins such as BAD. Thus, we propose that 4R could potentially serve as a novel, non-toxic alternative or adjuvant treatment against NSCLC.

Targeting of 7- or 24-dehydrocholesterol reductase decreased cancer progression in head and neck cancer.

B.-S. Lee, J. Padilla, K. D. Brock, S. Choi, J. Lee[,1]; The George Washington University, Washington, DC

The elevated expression of cholesterol metabolism has been associated with many cancer including head and neck squamous cell carcinoma (HNSCC). However, the molecular mechanisms between cholesterol biosynthesis and head and neck cancer have not yet been studied. In this study, we identified upregulation of dehydrocholesterol reductase such as DHCR7 or DHCR24 in HNSCC compared with adjacent normal tissues from the same patients using RNA sequencing data. We observed protein expression level of DHCR7 or DHCR24 in head and neck cancer cell lines through Western blotting. We also checked high expression of DHCR7 or DHCR24 in HNSCC tissues from patients using immunohistochemistry. Yet, when DHCR7 or DHCR24 was knocked down using siRNA, the viability of HNSCC cells was decreased in MTT assays. In parallel, we adapted small inhibitory drugs; AY9944 for DHCR7 inhibition and Triparanol or SH-42 for DHCR24 inhibition. Treatment of AY9944, Triparanol, or SH-42 also resulted in decreased viability of HNSCC cells. Moreover, when we used a cholesterol blocker, MCD, the cell viability was decreased, whereas the cells overcame cell death by adding the combination of cholesterol and LDL. Taken together, we concluded that head and neck cancer requires DHCR7 and DHCR24 activity involved in cholesterol metabolism for cancer growth. Our data suggest that targeting DHCR7 or DHCR24 using AY9944, Triparanol or SH-42 is one of the potential strategies that will definitely help with cancer treatment for head and neck cancer.

B212/P2604

Viperin-Induced Metabolic Reprogramming and Cancer Progression

J. J. Kim, K. M. Choi, J. H. Yoo, K. S. Kim, Y. Gu, J. Y. Seo; Yonsei University College of Medicine, Seoul, Korea, Republic of

Viperin is a multifunctional interferon (IFN)-inducible protein that possesses antiviral properties, mediates signaling pathways, and regulates cellular metabolism. Recent studies have shown that viperin increases lipogenesis and glycolysis *via* inhibition of fatty acid β-oxidation in mitochondria, suggesting that its function can be exploited to drive metabolic alteration of cancer cells. Here, we show that viperin plays a critical role in cancer metabolism. Analyses of human tissue microarray and data from the cancer genome atlas reveal that viperin is inversely correlated with the survival rate of cancer patients. We screened viperin expression in various cancer cell lines and generated viperin knockdown or stably expressing cell lines. Using these cell lines, we demonstrated that viperin promotes glycolysis and lipogenesis in cancer cells, resulting in enhancement of cancer progression. Additionally, viperin expression is upregulated by the deficiency of fatty acids and oxygen and by the production of IFNs *via* the PI3K/AKT/mTOR/HIF-1αand JAK/STAT pathways, respectively. Therefore, these results indicate that viperin drives metabolic reprogramming and cancer progression, suggesting that this protein might be a potential target in the development of anticancer therapeutics.

Extracellular Matrix and the Cytoskeleton in Cancer

Depletion of Rnd3 in lung cancer decreases both invasion and migration in a ROCK1 independent manner

N. Garcia Garcia[1], D. Richey[1], C. Ashby[2], **K. R. Ryan**[1]; [1]Biochemistry and Molecular Biology, University of Arkansas Medical Sci, Little Rock, AR, [2]Biomedical Informatics, University of Arkansas Medical Sci, Little Rock, AR.

Background:Lung cancer is one of the most common cancer types, with a 5-year relative survival rate of ~21%. Most lung cancers metastasize resulting poor prognosis. Expression levels of Rnd3 have been linked to several cancers and Rnd3 is involved in the regulation of several cellular processes which are commonly dysregulated in cancer. Objective:Investigate the effect low Rnd3 expression has on lung adenocarcinoma patient survival and utilize a proteomic approach to study the effect of Rnd3 knockdown in the lung adenocarcinoma cell line, A549 cells. Methods:Analyze TCGA survival data of lung adenocarcinoma patients to generate Kaplan-Meier survival plots for patients expressing low Rnd3 compared to high Rnd3 expression. Perform tandem mass tag mass spectrometry on Rnd3 knockdown (low) compared to control Rnd3 expressing (high) A549 cells to generate global protein profiles. Use Ingenuity Pathway Analysis (IPA) to identify pathways and processes altered in the low Rnd3 expressing cells compared to control cells. Validate the predicted findings *in vitro* using transient Rnd3 knockdowns and identify signal pathways involved in the regulation of these processes using inhibitors and double knockdowns. Results:Our analysis of TCGA survival data of lung adenocarcinoma patients shows that patients expressing low levels of Rnd3 expression have significantly higher survival probability rates compared to patients expressing high levels of Rnd3. We utilized proteomics to generate global protein expression profiles of Rnd3 expressing (high) and Rnd3 knockdown (low) A549 cells, to gain insight into

how low Rnd3 expression maybe beneficial to patient survival. Then used IPA which predicted low Rnd3 expression decreases cell migration and invasion, two hallmarks of metastasis. We validated these predictions *in vitro* by knocking down Rnd3 expression in A549 cells, which significantly decreased both cell migration and invasion compared to control A549 cells. We also showed that Rnd3 regulation of both cell migration and invasion was independent of ROCK1 signaling, a known regulator of Rnd3, indicating a novel pathway. Summary:Our data has substantiated the role of Rnd3's involvement in lung cancer cell migration and invasion and identified a new pathway involved in Rnd3 regulation, which may lead to identifying key regulators and new therapeutic targets of lung cancer metastasis.

B214/P2606

Ezrin Asserts its Roles on Osteosarcoma Metastasis Through Interacting with RNAs

E. Deniz[1], T. Shaw[1], P. Tiwari[1], L. Penalva[2], J. Toretsky[1], A. Uren[1]; [1]Lombardi Comprehensive Cancer Center, Georgetown University Medical Center, Washington, DC, [2]UT Health San Antonio, Children's Cancer Research Institute, San Antonio, TX.

Osteosarcoma (OS) is the most frequent primary bone cancer of children and adolescents. Most patients exhibit microscopic pulmonary metastases during initial diagnosis. In cases of clinical metastases, prognosis is worse. Therefore, besides treating primary tumor, patients need interventions to cease metastasis. Ezrin is a cytoskeletal linker that bridges F-actin to membrane. It is essential in maintaining fundamental cellular processes including shape, polarity, adhesion and motility of cells. Its levels correlate with OS grades and homing of metastatic OS in lung depends on ezrin as shown by xenograph and allograph models.

We identified a compound, NSC305787, that directly binds to and interferes with the functions of ezrin. We investigated the underlying molecular mechanisms by multiple genome wide approaches. Principal component (PC) analysis on the transcriptomic patterns in ezrin high (K7M2) and low (K12) cells in response to NSC305787 treatment clearly segregated the two different cells by PC1 depending on their ezrin levels and only K7M2 cells by PC2 depending on the compound treatment, showing a striking selective effect of NSC305787 on ezrin. Proteomic analysis listed differential abundancy of proteins in response to ezrin levels and upon NSC305787 treatment. Work with surface plasmon resonance proved that ezrin has a tendency to directly bind to RNA, specifically towards RNAs containing G-quadruplexes. Hence, we immunoprecipitated ezrin from cells and identified co-precipitated RNAs. Integrated analysis of such data pointed out ezrin-bound RNAs, whose levels as RNA or as protein product changed in response to the inhibition of ezrin with NSC305787. The list includes genes previously associated with migration and cytoskeleton properties. Additionally, ezrin high cells resisted mechanically stressed growth conditions and proliferated at comparable rates with or without attachment to solid surface, whereas, ezrin low cells were dependent on solid attachment for proliferation. Lastly, we created ezrin null cells to study its molecular functions in detail.

In conclusion, we hypothesize that ezrin has diverse functions including binding to RNA in addition to its canonical roles on maintaining cytoskeleton. Precise definitions of molecular mechanisms of metastasis will led us develop better intervention modalities to cease metastasis in osteosarcoma.

B215/P2607

SNED1: A novel regulator of ECM organization

D. Pally, M. Davis, F. Lee, A. Naba; University of Illinois At Chicago, Chicago, IL.

The extracellular matrix (ECM) is a complex meshwork of proteins that plays critical roles in health and disease. In the context of cancer, the ECM acts either as a barrier or as a permissive microenvironmental cue to the growth and dissemination of cancer cells. Using a proteomic approach to profile the ECM composition of tumor microenvironment, my mentor, Dr. Naba, identified a novel ECM protein, SNED1 and established, for the first time, its role as breast cancer metastasis promoter. Histological characterization of *SNED1* knockdown tumors revealed the presence of a thick ECM layer surrounding the tumors and were less invasive. This suggests that SNED1 may regulate breast cancer metastasis by contributing to remodeling the tumor ECM and making the tumor microenvironment conducive for cancer cell invasion. Cell-derived matrices (CDMs) are an excellent model to study ECM organization since it recapitulates many biochemical and biophysical properties of *in vivo* ECMs. To test the role of SNED1 on ECM architecture, we have generated *Sned1*^{KO} mouse embryonic fibroblasts (MEFs) that can be engineered to re-express SNED1 and obtain CDMs. We observed that lack of SNED1 in CDMs resulted in poorly aligned ECM as quantified by fibronectin and collagen I fiber orientation, while overexpression of *SNED1* resulted in aligned fibronectin and collagen I fibers. We further observed that SNED1 co-localizes with fibronectin and collagen I fibers suggesting that SNED1 might mediate ECM organization by interacting with these two abundant structural ECM proteins. Further investigations to understand SNED1-collagen I interactions revealed that SNED1 does not affect collagen I fibril formation kinetics but it decreased collagen I fiber density as observed using confocal reflectance microscopy. Taken together, our results suggest that SNED1 plays an active role in shaping ECM architecture by interacting with other ECM proteins. Future work will focus on identifying the mechanisms by which SNED1-dependent ECM remodeling may affect cancer cell invasion, a key event during cancer metastasis.

B216/P2608

Cells in hybrid Epithelial-to-Mesenchymal Transition state can induce invasivity of surrounding epithelial cells

J. Geay[1,2], S. Seetharaman[3], L. Blanchoin[4,1], M. Théry[1,2,5]; [1]CytoMorpho Lab, CEA/CNRS/Unité de Thérapie Cellulaire, Hôpital Saint Louis, Paris, FRANCE, [2]Institut Pierre Gilles de Gennes, Paris, FRANCE, [3]James Frank Institute, Department of Physics, University of Chicago, Chicago, IL, [4]CytoMorpho Lab, Interdisciplinary Research Institute of Grenoble, CEA/CNRS/Université Grenoble Alpes, Grenoble, FRANCE, [5]CytoMorpho Lab, Laboratoire de Physiologie Cellulaire et Végétale, Interdisciplinary Research Institute of Grenoble, CEA/CNRS/Université Grenoble Alpes,, Grenoble, FRANCE.

The epithelial-to-mesenchymal transition (EMT) is an extensively studied phenomenon in the context of cancer and metastasis. Over the last few years, the existence of a hybrid intermediate state of EMT has been described, where cells keep some epithelial markers, but also gain some mesenchymal markers. This particular state has been suggested to promote invasiveness, tumor progression and metastasis. A recent study showed that the loss of FAT1, which is a highly mutated protocadherin in cancers, led to a hybrid state of EMT, and induced invasion and metastasis. However, the mechanisms of this hybrid state induction remain elusive. In skin squamous carcinoma cells, using a combination of cell biology and biophysical approaches, we show that the knockout of FAT1 displays reversed cell polarity, a main characteristic of an EMT induction. Moreover, the loss of FAT1 leads to drastic remodelling of the

actomyosin network and a reduction in traction forces. Surprisingly, we found that FAT1 KO did not display remarkable migration properties, but instead increases the invasion capacities of adjacent wild type cells. In addition, WT cells exposed to conditioned medium of FAT1 KO culture exhibit a less contractile phenotype, similar to that of KO cells and increased invasive capacities in 3D migration assay . Thus, we propose a mechanism by which FAT1 mutated cells in tumors, through their hybrid state of EMT, impart invasive properties to non-mutated cells, and thereby promote extensive metastasis.

B217/P2609

Invadopodia formation is spatially and functionally coupled to the nuclear envelope by septin 9

J. Okletey[1], T. Jones[1], C. Montagna[2], E. Spiliotis[1]; [1]Biology, Drexel University, Philadelphia, PA, [2]Radiation Oncology, Rutgers University, New Brunswick, NJ.

Metastatic cancer cells invade through the extracellular matrix (ECM) of tissues by forming invadopodia, actin-rich protrusions which secrete matrix metalloproteinases (MMPs). Invadopodia formation is stimulated by growth factors (e.g., epidermal growth factor; EGF) and requires membrane recruitment of the scaffold protein TKS5, cortactin and other actin regulators. Invadopodia formation takes place preferentially at plasma membrane regions around the nucleus, and previous work has indicated that invadopodia physically interact with the nuclear envelope. It is poorly understood, however, how invadopodia formation is spatially controlled. Here, we show that invadopodia formation requires septin 9 (SEPT9), a member of the septin family of GTPases that is overexpressed in breast cancer, and enhances cancer migration and invasion. In the highly invasive breast cancer MDA-MB-231 cells, SEPT9 isoform 1 (SEPT9_i1) localizes to domains of the nuclear rim and along the ventral surface of the nuclear envelope. SEPT9_i1 is also enriched at base and along invadopodia, which form in 2D gelatin degradation and 3D chemoinvasion assays. Depletion of SEPT9_i1 alters the morphology of nuclei, which become ruffled and indented. This phenotype is accompanied with a significant reduction in the number and length of invadopodia, and a loss in the spatial bias in the localization of invadopodia around the nucleus at steady state and upon stimulation with EGF. We show that depletion of SEPT9_i1, but not SEPT9_i2, results in dramatic reduction of TKS5, cortactin and pTyr421-cortactin clusters at the ventral cell membrane and impairs the degradative and invasive abilities of MDA-MB-231 cells in gelatin degradation and transwell chemoinvasion assays. In SEPT9-depleted cells, TKS5 and Cortactin are diffusely mislocalized about the nuclear envelope and/or abnormally localize to perinuclear aggregates, with MT1-MMP (MMP-14) shifting from perinuclear-cytoplasm to peripheral edges - suggesting enrichment in peripheral focal adhesion sites. Taken together, these data suggest that the machinery of invadopodia formation is coupled to the nuclear envelope by a septin-mediated mechanism that spatially biases ECM degradation to the perinuclear over peripheral regions of the cell membrane, which enables the cancer cells to thread the nucleus through the ECM during metastasis.

B218/P2610

Modulation of ASAP1 in FN-RMS cells accelerates tumor progression and metastasis as revealed by intravital microscopy

S. M. Hammoudeh, Y. Ng, M. P. Yadav, H. Yoon, M. E. Yohe, R. Weigert, P. A. Randazzo; National Cancer Institute, NIH, Bethesda, MD.

ASAP1 is a multidomain ADP-ribosylation factor (Arf) GTPase-activating protein (GAP) involved in the regulation of the actin cytoskeleton, focal adhesions dynamics and receptor tyrosine kinases trafficking.

ASAP1 expression levels correlate with progression of solid tumors (e.g. breast, colorectal, pancreatic, ovarian, gastric, and prostate cancer). The first evidence for a role of ASAP1 in cancer progression was the discovery that the amplification of ASAP1 gene on chromosome 8 correlates with poor prognosis in uveal melanoma. A similar amplification of chromosome 8 has been reported in ~72% of fusion negative rhabdomyosarcoma (FN-RMS) tumors, suggesting a potential role for ASAP1 signaling in the progression of FN-RMS. To determine the function of ASAP1 in tumor growth, invasion and metastasis, we used a tongue orthotopic xenograft of FN-RMS which recapitulates physiologically relevant tumor progression and metastasis to lymph nodes and lungs, two of the common metastatic sites in patients. Using intravital microscopy, we observed that injected ASAP1-expressing control FN-RMS cells fused into myofibril-like structures, exhibited dynamic branching, and invaded the local tongue muscle. On the other hand, ASAP1-depleted FN-RMS cells initially exhibited an accelerated growth of the primary tumor and a reduction in the intercellular fusion as compared to the control group. Notably, at later stages, ASAP1 depletion led to a decrease in the size of the primary tumors but increased the rate and growth of early metastases within the tongue and in locoregional lymph nodes resulting in a shorter survival of the mice in comparison to those with ASAP1-expressing FN-RMS tumors. While further investigation is required into the cellular and molecular mechanisms, these results suggest a role for ASAP1 in controlling cell behaviors that determine whether cells survive at the primary site with local invasion or intravasate and metastasize.

B219/P2611

Novel γ-Ionizing radiation-induced RIP1-IL1 β axis promotes migration and invasion of non-small cell lung cancer cells

A. Kang, J. Kwon, **J. Park**; KIRAMS, SEOUL, KOREA, REPUBLIC OF.

We demonstrated the involvement of a novel intracellular signaling mechanism in γ-ionizing radiation (IR)-induced migration/invasion of non small cell lung cancer (NSCLC) cells. Initially, we detected IR enhanced expressions of receptor-interacting protein (RIP) 1 in A549, one of NSCLC cell lines. Next, we found intracellular signaling of RIP1-including mechanism could induce epithelial-mesenchymal transition (EMT). IR-induced RIP1 promote invasion/migration of NSCLC cells by enhancing of the expression/activity of matrix metalloproteases (MMP-2 and MMP-9) and vimentin. We also found RIP1 is located downstream of EGFR and sequentially induces Src-STAT3-EMT signaling to promote invasion/migration. Blockage of RIP1 kinase activity and expression using specific pharmaceutical inhibitor and RIP1 siRNA suppressed the levels and activities of MMP-2, MMP-9, and vimentin followed by decrease of invasion/migration. Next, we found IR-induced RIP1 also induced IL-1β expression associated with stimulation of the transcriptional factor NF-κB. IR could trigger NF-κB activation, and inhibition of NF-κB suppressed IR-induced RIP1 expression and invasion/migration as well as EMT. Additionally, treatments of siRNA and specific pharmaceutical inhibitors of RIP1 and NF-κB suppressed protein expression and secreted concentration of IL-1β in condition of IR treatment. Treatment of IL-1Ra, an antagonist protein of IL-1β, suppressed IR-induced epithelial-mesenchymal transition (EMT) followed by increase of invasion/migration *in vitro*. We also demonstrated IR could induce IL-1β expression *in vivo* and, additionally, IL-1 Receptor (R) I/II, receptors of IL-1β , *in vitro/in vivo*. Taken together, we suggest novel IR-induced cell migration/invasion machinery that IR- EGFR/ RIP1-Src/STAT3-EMT and IR-NF-κB - RIP1 - IL-1β - IL-1RI/II - EMT pathways.

B220/P2612

Adhesion Strength of Disseminating Cells Predicts Severity of Metastatic Disease

K. G. Birmingham[1], B. Yeoman[1], M. Kane[1], P. Beri[1], J. Tuler[1], I. L. Williams[2], A. Kumar[1], S. Klein[1], P. Katira[1], **A. J. Engler**[1]; [1]University of California, San Diego, La Jolla, CA, [2]Rice University, Houston, TX

Despite better outcomes with early-stage detection, local invasion significantly reduces patient survival rates for many carcinomas. Heterogeneity within and between tumors has precluded identification of predictive biological markers, but adhesion strength has emerged as a potential biophysical marker. Here we demonstrate that cells disseminating from mammary tumors are weakly adherent, and when presorted by adhesion, primary tumors created from strongly adherent cells exhibit fewer lung metastases than weakly adherent cells or unsorted populations. Migratory ontologies from tumors correlate with freshly sorted cells, suggesting that cell intrinsic differences are maintained *in vivo*. We further demonstrate that admixed cancer lines can be separated by label-free adhesive signatures using a next-generation flow chamber. When applied to metastatic tumors, the device retrospectively predicted metastatic disease from stromal samples with 100% specificity, 85% sensitivity, and AUC of 0.94. Data from this device suggest that label-free adhesive signatures may effectively predict clinical outcomes in patients.

B221/P2613

Loss-of-function of AWP1 Induces the Epithelial-mesenchymal Transition of Prostate Cancer Cells

Y. Hwang, M. Lee, E. Kim, J. Kim, D. Yoon, H. Min, Y. Sung, E. Chang; University of Ulsan College Med, Seoul, KOREA, REPUBLIC OF.

Loss-of-function of AWP1 Induces the Epithelial-mesenchymal Transition of Prostate Cancer Cells

Yumi Hwang[1,2], Myungjin Lee[1,2], Eun-Young Kim[1,2], Ji-Eun Kim[1,2], Dohee Yoon[1,2], Hyo-Jin Min[1,2], Yoolim Sung[1,2], Eun-Ju Chang[1,2,3]*

[1]Department of Biomedical Sciences, AMIST, Asan Medical Center, University of Ulsan College of Medicine, 88 Olympic-ro 43-gil, Songpa-gu, Seoul 05505, Korea.[2]Stem cell Immunomodulation Research Center, AMISST University of Ulsan College of Medicine, Asan Medical Center, 88 Olympic-ro 43-gil, Songpa-gu, Seoul 0550, Korea.[3]Department of Biochemistry and Molecular Biology, AMIST, Asan Medical Center, University of Ulsan College of Medicine, 88 Olympic-ro 43-gil, Songpa-gu, Seoul 05505, Korea.

EMT (Epithelial-Mesenchymal transition) has an essential role in tumor progression and metastatic dissemination. We here showed that zinc-finger protein AWP1 (zinc finger AN1 type 6, ZFAND6) regulates EMT in prostate cancer. The depletion of AWP1 using siRNA increased the proliferation of DU-145 cells and augmented migration ability as observed by wound healing assay. In addition, the mRNA expression of EMT markers were upregulated in DU-145 with AWP1 depletion. Especially, the protein level of α-SMA was increased in AWP1-depleted DU-145 cells. Moreover, knockdown of AWP1 in DU-145 showed increased tumor growth compared to control in subcutaneously xenografted *in vivo* model. Our results suggest that the loss-of-function of AWP1 induces EMT, contributing to prostate cancer progression.

B222/P2614

A Novel Relationship Between Small G Protein ARF1 and Arf GTPase-activating Protein ASAP1

A. Kim[1], K. E. Hebron[1,2,2], O. L. Perkins[2,2,3], X. Jian[2], S. A. Girald-Berlingeri[2,4], P. A. Randazzo[2], M. E. Yohe[1], M. E. Yohe[1,2,2]; [1]National Cancer Institute, NIH, Frederick, MD, [2]National Cancer Institute, NIH, Bethesda, MD, [3]Vanderbilt University, Nashville, TN, [4]Inova Fairfax Hospital, Falls Church, VA

Rhabdomyosarcoma (RMS) is the most common pediatric soft tissue sarcoma. The overall survival rate for patients with advanced RMS has been less than 20% for the last 30 years. Investigating novel treatment strategies for RMS is necessary to improve prognosis. PAX/FOXO1 Fusion Negative RMS (FN-RMS) is commonly associated with alterations in the RAS/RAF/MEK/ERK pathway and arises due to a disruption of differentiation in skeletal muscle precursor cells. Trametinib, a MEK inhibitor, has been shown to induce myogenic differentiation in FN-RMS cell lines. However, it is imperative to note that trametinib monotherapy is not durable. Therefore, exploring additional viable targets for combination therapy is necessary. ASAP1, an Arf GTPase-activating protein (GAP), is a candidate due to its decisive role in osteogenic and adipogenic differentiation. Additionally, ASAP1 has been shown to be overexpressed in several cancers. Furthermore, we see an overexpression of ASAP1 in FN-RMS and lower survival rates for patients with ASAP1 overexpressed FN-RMS. We believe that ASAP1 plays a role in the differentiation of FN-RMS. Upon knockdown (KD) of ASAP1, trametinib-induced differentiation was reduced. Additionally, upon KD of ARF1, we see a block in trametinib-induced differentiation. Due to these conflicting observations, we hypothesize that there may be a novel relationship between ARF1 and ASAP1. To investigate this relationship, we exogenously rescued ARF1 (WT) and ARF1[I46D] mutant, a mutation that renders ARF1 insensitive to ASAP1's GAP activity, following KD of endogenous ARF1. Overall, we see that trametinib-induced differentiation was rescued in expression of either exogenous WT or ARF1[I46D]. This supports the observation that ASAP1 may be an effector of ARF1 in addition to being an ARF-GAP. To further examine ASAP1 and ARF1's interaction, we investigated trametinib-induced differentiation upon KD of known effectors of ARF1 (GGA1, GGA2, and GGA3). We observed that, upon KD of established ARF1 effectors, there was also a decrease in trametinib-induced differentiation, suggesting that multiple ARF1 effectors impact differentiation. In conclusion, in addition to being an ARF-GAP, ASAP1 may also function as an ARF1 effector that regulates differentiation of FN-RMS. Future work will consist of investigating the downstream signaling effects of this novel ASAP1 and ARF1 interaction in FN-RMS.

Regulation of the Cytoskeleton in Breast Cancer

B223/P2615

Tight junction proteins restrict cancer cell metastasis

J. West, K. Cho, I. Roberts, A. Ewald; Johns Hopkins University, Baltimore, MD.

Breast cancer is a leading cause of cancer deaths among women. Even though metastasis drives most breast cancer deaths, our understanding of this process remains limited. Metastasis starts with invasion and needs to overcome the constraints of several types of adhesive junctions. We focus on the role of the tight junction because decreased expression of tight junction proteins is a defining feature of the highly aggressive 'Claudin-low' subtype of breast cancer. In normal epithelial cells, the tight junction mediates intercellular adhesion,barrier function, and partitioning the plasma membrane into apical and basal domains. Wehypothesized that tight junctions suppress aggressive cell behaviors, and that their

loss could induce metastasis. Using genetically engineered mouse models (GEMMs) of breast cancer, we have observed a spontaneous decrease in mRNA expression of multiple TJ components during tumor growth in vitro and in vivo. Localization of tight junction proteins is also disrupted in cells found within hyperplastic lesions. Using 3D organotypic culture assays we demonstrated that knockdown oftight junction proteins generally results inincreased growth and invasion of mammary organoids. Specifically, we have observed 2-fold increases in organoid size and average organoid growth rate after depleting the tight junction proteins, ZO1, ZO2, or Cldn7. Furthermore, in vivoknockdown of Cldn7 in orthotopic breast cancer metastasis models caused increased cellular heterogeneity in the primary tumor and increased metastatic burden in distant organs. Taken together, our results support a model in which downregulation of tight junction proteins accelerates tumor progression and increases metastatic efficiency. Our data are consistent with the observation that breast tumors with a Claudin-low phenotype are more aggressive, independent of hormone receptor status.

B224/P2616

Collagen density primes the mammary tumor microenvironment for early dissemination by promoting macrophage infiltration and an EMT-associated transcriptional program in tumor cells.

E. J. Hoffmann[1], A. R. Nobre[2], A. E. Williams[3], L. M. Arendt[3], J. A. Aguirre-Ghiso[4], S. M. Ponik[1];
[1]Department of Cell & Regenerative Biology, University of Wisconsin-Madison, Madison, WI, [2]Human Oncology and Pathogenesis Program, Memorial Sloan Kettering Cancer Center, New York, NY, [3]Department of Comparative Biosciences, University of Wisconsin-Madison, Madison, WI, [4]Department of Cell Biology, Cancer Dormancy and Tumor Microenvironment Institute, Albert Einstein College of Medicine, New York, NY.

High mammographic density due to increased collagen I deposition has long been recognized as a risk factor for breast cancer progression in women, however the biology underlying this risk factor remain largely unknown. The goal of this study is to identify the exact mechanisms by which collagen I affects breast cancer progression. In advanced tumors, stiff, aligned collagen fibers are known to promote epithelial to mesenchymal transition (EMT), invasion of cancer cells, and increase metastatic burden. Importantly, we observe key differences between normal and collagen-dense mammary glands before a tumor is present that may predispose the microenvironment to early tumor cell dissemination. One such factor is the expression of ZFP281, a transcription factor associated with stem cell primed pluripotency and recently identified as a regulator of early dissemination and dormancy in disseminated breast cancer cells. Using the MMTV-PyMT mammary carcinoma model crossed with a mutant collagen I gene, which prevents collagen proteolysis to mimic mammographic density, we identified an increase in periductal/intraepithelial macrophages and expression of the transcription factor ZFP281 in normal epithelial cells, similar to that reported for early MMTV-HER2 lesions in a WT collagen I gene background. However, this increase in $ZFP281^{+}$ cells is lost by the time a primary lesion progresses to an overt tumor. Using a 3D collagen gel cell culture model to investigate the effects of collagen I on ZFP281, we observed that increasing collagen density alone is sufficient to decrease protein levels of ZFP281 in late stage breast cancer cells, but not in normal epithelial cells. This affect appears to be primarily mediated by the increased stiffness of the matrix. This potential mechanical regulation of ZFP281 expression by collagen I, paired with the timing of fiber accumulation and reorganization, may be an important microenvironmental cue that determines the switch from early dissemination to high proliferation at the primary tumor, a common hallmark of collagen-dense mammary tumors

Investigating the Role of Compressive Stress in Cellular Unjamming

G. Cai[1], A. Nguyen[2], Y. Bashirzadeh[1], S. Lin[1], D. Bi[2], A. Liu[1]; [1]University of Michigan, Ann Arbor, MI, [2]Northeastern University, Boston, MA.

Cellular unjamming is the collective fluidization of cell motion and has been linked to many biological processes, including development, wound repair and tumor growth. In tumor growth, the uncontrolled proliferation of cancer cells in a confined space generates mechanical compressive stress. However, because multiple cellular and molecular mechanisms may be operating simultaneously, the role of compressive stress in unjamming transitions during cancer progression remains unclear. Here we investigate which mechanism dominates in a mechanically stressed monolayer. We find that long-term mechanical compression triggers cell arrest in benign epithelial cells and enhances cancer cell migration in transitions correlated with cell shape, leading us to examine the contributions of cell-cell adhesion and substrate traction to unjamming transitions. We show that cadherin-mediated cell-cell adhesion regulates differential cellular responses to compressive stress and is an important driver of unjamming. Importantly, compressive stress does not induce epithelial—mesenchymal transition in unjammed cells. Traction force microscopy reveals the attenuation of traction stresses in compressed cells within the bulk monolayer during wound healing and on microcontact printed cell islands, regardless of cell type and motility. Interestingly, as traction within the bulk monolayer diminishes with compressive pressure, traction at the leading edge of cancer cell sheets is sustained. Seeking a theoretical explanation for the observed differential cellular responses to mechanical compression, we use the self-propelled Voronoi model to map the observed cell's condition to a phase diagram with two model parameters: cell motility and target cell shape index. Using a jammed—unjammed boundary and comparing experimentally measured cell shapes and traction forces with our simulation model reveal two distinct transition paths under mechanical compression. Together, increased intercellular adhesion and attenuated traction forces within the bulk cell sheet under compression drive fluidization of the cell layer and may impact collective cell motion in tumor development and breast cancer progression.

Profilin-1/CCL2 is a novel signaling axis of tumor cell-directed migration of immune cells

I. Eder, V. Yu, M. Joy, P. Lucas, P. Roy; University of Pittsburgh, Pittsburgh, PA.

Profilin-1 (Pfn1) is an actin-binding protein that is downregulated in human breast cancer (BC). Pfn1 has been previously demonstrated to have tumor-intrinsic roles as a suppressor of tumorigenicity and dissemination in BC; however, whether Pfn1 has extrinsic immunological effects on the tumor microenvironment (TME) is unknown. We sought to investigate the effect of Pfn1 expression on the immune composition of the TME and the chemotaxis of immune cells. We performed multiplexed quantitative immunohistochemistry on a tissue microarray of clinical BC samples which revealed a significant positive correlation between tumor cell-specific Pfn1 expression and the percent of CD8+ T cells in the TME, more prominently in triple-negative breast cancer (TNBC) samples. Bioinformatics analyses of the METABRIC transcriptome dataset confirmed Pfn1 expression to be positively correlated with the CD8+ T cell fraction, in addition to, the pro-inflammatory IFN-gamma gene signature and the M1 to M2 macrophage ratio in TNBC. Co-culture studies demonstrated that elevating Pfn1 expression in TNBC cells enhances chemotactic migration of monocytes in a paracrine fashion, as well as, augments chemotactic migration of T-cells in a monocyte-dependent manner. To investigate the underlying

mechanism, we performed luminex analyses of the conditioned media of TNBC cells, and identified CCL2, a major chemoattractant of monocytes, to be dramatically upregulated and downregulated upon overexpression and knockdown of Pfn1, respectively. These data were further supported by real-time quantitative PCR-based confirmation of Pfn1-dependent changes in CCL2 transcription in TNBC cells as well as a significant positive association between Pfn1 and CCL2 mRNA expression in the clinical specimens of TNBC. Silencing CCL2 expression in TNBC cells abolished Pfn1-dependent changes in the chemotactic migration of monocytes, suggesting that CCL2 is a key mediator of Pfn1-stimulated migration of monocytes. Collectively, these findings provide the first evidence for extrinsic immunological effects of Pfn1 in BC. Since tumor infiltration of CD8+ T cells is associated with improved prognosis in BC and is a key determinant of immunotherapy success in TNBC, our work lays the conceptual foundation for future studies to explore whether Pfn1 modulation could be a novel strategy to enhance immunotherapy efficacy in BC.

Hypusine Signaling Cooperates with SLC3A2 and Fibronectin to Support Cancer Cell Proliferation

C. Geller[1], J. Maddela[1], R. Tuplano[1], R. Güth[1], J. Cantor[2], **J. Kelber**[1]; [1]California State Univ-Northridge, Northridge, CA, [2]BD Biosciences, San Diego, CA.

Elevated fibronectin expression within the microenvironment of breast cancer correlates with poor outcomes. In this regard, we reported that the DHPS-/DOHH-dependent hypusination pathway, which activates eukaryotic initiation factor 5A 1/2 (eIF5A1/2), is necessary for PEAK1 pseudokinase translation and fibronectin/TGFβ-mediated breast cancer metastasis. Using a panel of eIF5A1/2-/PEAK1-related genes together with markers of intratumoral heterogeneity, we established a bioinformatics pipeline that led us to identify solute carrier 3A2 (SLC3A2 or CD98hc) as an indicator of poor prognosis in breast cancer patients. Inhibition of SLC3A2 or DHPS decreased tumor spheroid growth. Interestingly, spiking fibronectin into culture media partially rescued spheroid growth - an effect that was abrogated by dual DHPS/SLC3A2 inhibition. Additionally, dual DHPS/SLC3A2 inhibition in cancer cells plated onto fibronectin significantly reduced the percentage of cells in S phase. Intracellular trafficking of eIF5A1/2 between the nucleus and cytoplasm has been reported to mediate its mRNA transport and protein translation functions. In this regard, we further discovered that fibronectin induced a DHPS-/SLC3A2-dependent increase in cytoplasmic eIF5A1/2 levels. Finally, we profiled breast cancer cells using a panel of functional state markers at single-cell resolution and discovered that extracellular fibronectin decreased $GRP78^{hi}$ breast cancer cells. Notably, the remaining $GRP78^{hi}$ breast cancer cells are highly proliferative and can be eliminated by dual DHPS/SLC3A2 inhibition. Taken together, these data provide a mechanistic basis for a new treatment strategy that may improve outcomes in patients harboring solid tumors rich in fibronectin and with a high proliferative index.

B228/P2620

Scaffold Protein RACK1 Inhibitor Compounds Prevent the Focal Adhesion Kinase Mediated Breast Cancer Cell Migration and Invasion Potential

H. Ullah[1], N. Ahsan[2], S. Dakshanamurthy[3]; [1]Howard University, Washington, DC, [2]The University of Oklahoma, Norman, OK, [3]Georgetown University, Washington, DC

Scaffold protein RACK1 mediates cancer cell migration mostly through regulation of focal adhesion (FA) assembly by promoting a focal adhesion kinase (FAK) activation downstream of the integrin clustering

and adhesion at the extracellular matrix (ECM). Here we demonstrated the efficacy of our recently developed RACK1 Y246 phosphorylation inhibitor compounds (SD29 and SD29-14) to inhibit the migration and invasion of MCF7 and MDA-MB-231 breast cancer cell lines. Using multiple assays, our results confirmed that inhibitor compounds effectively prevent the filopodia/lamellipodia development and inhibits the migration of breast cancer cells. A mechanistic model of the inhibitor compounds has been developed. Migration and invasion capabilities of the cancer cells define the metastasis of cancer. Thus, our results suggest a potential therapeutic mechanism of the inhibitors to prevent metastasis in diverse cancers.

B229/P2621

Triple negative breast cancer metastasis involves complex EMT dynamics and requires vimentin

E. M. Grasset, M. Dunworth, G. Sharma, M. Loth, J. Tandurella, A. Cimino-Mathews, M. Gentz, S. Bracht, M. Haynes, E. J. Fertig, A. J. Ewald; Johns Hopkins Medicine, Baltimore, MD

Triple negative breast cancer (TNBC) is an aggressive subtype, associated with early metastatic recurrence and worse patient outcomes. TNBC patient tumors express molecular markers of the epithelial to mesenchymal transition (EMT) but its role during spontaneous TNBC metastasis *in vivo* remains incompletely understood. In this study, we demonstrate that spontaneous TNBC tumors from a genetically engineered mouse model (GEMM), multiple patient-derived xenografts (PDXs), and archival patient samples exhibit large populations of hybrid E/M cells *in vivo* that lead invasion *ex vivo*. We found that the mesenchymal marker vimentin promotes invasion and represses metastatic outgrowth. We next tested the requirement for five EMT transcription factors and observed distinct patterns of utilization during invasion and colony formation. These differences suggest a sequential activation of multiple EMT molecular programs during the metastatic cascade. Consistent with this model, our longitudinal single-cell RNA analysis detected 3 different EMT-related molecular patterns. We observed cancer cells progressing from epithelial to hybrid E/M and strongly mesenchymal patterns during invasion and from epithelial to a hybrid E/M pattern during colony formation. We next investigated the relative epithelial vs. mesenchymal state of cancer cells in both GEMM and patient metastases. In both contexts, we observed heterogeneity between and within metastases in the same individual. Strikingly, we observed a complex spectrum of epithelial, hybrid E/M, and mesenchymal cell states within metastases, suggesting there are multiple successful molecular strategies for distant organ colonization. Taken together, our results demonstrate an important and complex role for EMT programs during TNBC metastasis.

B230/P2622

Hypoxic Gradients Direct the Spatial Organization of Epithelial-to-Mesenchymal Transition in an *in vitro* Breast Cancer Tumor Microenvironment

S. Anmalsetty[1], S. J. Flaherty[1], A. J. Walke[2], D. A. Scheiblin[2], L. Ridnour[3], D. A. Wink[3], S. J. Lockett[2], W. F. Heinz[2]; [1]Optical Microscopy and Analysis Laboratory, Office of Science and Technology Resources, CCR, National Cancer Institute, National Institutes of Health, Frederick, MD, [2]Optical Microscopy and Analysis Laboratory, Cancer Research Technology Program, Frederick National Laboratory for Cancer Research, Frederick, MD, [3]Laboratory of Cancer Immunometabolism, CCR, National Cancer Institute, National Institutes of Health, Frederick, MD

Poor prognosis in ER- breast cancer is strongly predicted by high expression of cyclooxygenase-2 (COX2) and inducible nitric oxide synthase (NOS2). These proinflammatory proteins, alongside a hypoxic tumor microenvironment, promote cancer cell migration, metastasis, invasion, and survival. The objective of the study was to understand the spatial relationships of epithelial (E), mesenchymal (M), and hybrid (E/M) cells in relation to hypoxia, COX2, and NOS2. We hypothesize that E/M phenotypes - defined by E-cadherin (ECAD) and vimentin (VIM) positive cells - (1) organize along cell-generated hypoxic gradients and (2) are correlated with expression of COX2 and NOS2. Restricted exchange environment chambers (REECs) mimic the cell-generated gradients of oxygen (O_2) concentration and nutrients of solid tumors in 2D live cell culture and facilitate high resolution fluorescence microscopy. 4T1 cells, a murine model of human triple-negative breast cancer, were cultured in REECs for up to 168 hours. During this time, cells migrated toward the opening in the chamber supplying O_2 and nutrients to the cells and formed a disk centered on the O_2 source. The O_2 concentration decreases radially from the normoxic disk center to the hypoxic disk edge. Over a few days of cell growth in the REECs, the proportion of VIM+ cells increased steadily, with a maximum in normoxic regions like its distribution in 4T1 mouse tumors. In hypoxic regions, discrete VIM+ clusters emerged in a spoke-like pattern aligned along the cell-generated hypoxic gradient. ECAD had similar expression dynamics to VIM. E/M cells, which are associated with high metastatic potential, increased in all regions over time. COX2 and NOS2 expression also increased significantly in response to hypoxic gradients, with COX2 being present in the normoxic region and NOS2 forming a stable ring-like pattern in the hypoxic region and centered on the O_2 source. At early time points of growth, the majority of COX2+ cells were VIM-, but after 48 hours became VIM+. Inhibition of NOS2 or COX2 decreases the number of VIM+ clusters relative to untreated samples, but the number of cells per cluster increases. This supports the hypothesis that COX2 and NOS2 are associated with the organization of E/M phenotypes in a hypoxic gradient. These results provide insight into the mechanisms of COX2 and NOS2 on tumor metastasis and further support their potential as therapeutic targets. Supported in part by NCI contract: 75N91019D00024.

Stromal PI3Kbeta regulates breast tumor cell invasion

R. Graff, C. Jakubik, A. J. Haimowitz, S. Sidoli, M. J. Gamble, A. R. Bresnick, **J. M. Backer**; Albert Einstein College of Medicine, Bronx, NY

The ability of breast cancer cells to metastasize depends on cell autonomous signaling within the tumor cells, as well as paracrine and juxtracrine interactions with stromal cells in the tumor microenvironment. We have previously shown that activation of the Class IA phosphoinositide 3- kinase PI3Kbeta in tumor cells is required for matrix degradation, invasion, and experimental metastasis. We now show the PI3Kbeta signaling is also critical for the pro-metastatic properties of two distinct stromal cell types: macrophages and platelets. We have developed a knock-in mouse expressing a mutant PI3Kbeta ($PI3Kbeta^{KKKDD}$) that has basal activity but is defective for activation. Bone marrow-derived macrophages (BMMs) from $PI3Kbeta^{KKKDD}$ mice have cell autonomous defects in invasive capacity, as they are defective for podosome-mediated matrix degradation and transendothelial migration. Importantly, they also show a reduced capacity to stimulate the invasive behavior of tumor cells. Whereas wild type BMMs stimulate matrix degradation and transendothelial migration by MDA-MB-231 breast cancer cells, these responses are significantly reduced during co-culture with $PI3Kbeta^{KKKDD}$ BMMs. RNAseq data from tumor cell-BMM co-cultures show that over 100 genes are differentially upregulated in wild type versus $PI3Kbeta^{KKKDD}$ BMMs; these include numerous chemokines and pro-metastatic factors. In parallel, we

have studied the stimulation of tumor cell invasion by interactions with platelets. Co-culture of wild type platelets with MCF-10A breast epithelial cells for 40h induced a mesenchymal morphology, up-regulated N-cadherin expression (consistent with EMT), and stimulated Matrigel invasion by 15-fold. In contrast, MCF-10A invasion was stimulated by only 8.7-fold after co-culture with PI3Kbeta^{KKKDD} platelets. PI3Kbeta^{KKKDD} platelets were defective for activation in response to ADP/collagen and showed a 2-fold decrease in binding to tumor cells in a FACS-based assay. Given that depleted thrombin-stimulated platelet membranes are capable of stimulating tumor cell invasion, we are analyzing changes in the expression of cell surface receptors and adhesion molecules in PI3Kbeta^{KKKDD} platelets. Taken together, our data suggest that PI3Kbeta plays important roles in tumor metastasis in at least 3 cell types - tumor cells, macrophages and platelets - and suggest that PI3Kbeta-selective inhibitors could be clinically useful in the treatment or prevention of metastasis.

B232/P2624

Metformin's effects on pro-metastatic gene expression in triple-negative breast cancer cells

M. Anaafi, D. Alton, B. C. Trask; Weber State University, Ogden, UT.

In recent years, metformin's use as an anti-cancer agent has been a topic of intense investigation. The anti-hyperglycemic drug has been shown to directly induce apoptosis of breast cancer cells, decrease their production of some pro-angiogenic factors, and reduce their ability to produce lung metastases in immunodeficient mice (Orecchioni, *et al.*, 2015). Although these results suggest that metformin might provide some clinical benefit, recent human studies in which breast cancer patients were treated with the drug suggest that disease-free survival is not improved (Goodwin, *et al.*, 2022). To explore why this might be the case, we investigated the effect of metformin treatment on the expression of several pro-metastatic genes, including monocyte-recruiting C-C chemokines and matrix-degrading metalloproteinases, in MDA-MB-436 triple-negative breast cancer cells using RT-qPCR. Our results support that, despite a reported mTOR-mediated decrease in global protein synthesis (Dowling, *et al.*, 2007), metformin treatment does not significantly decrease expression of several pro-metastatic genes. The ability of triple-negative breast cancer cells to produce pro-metastatic proteins even in the presence of metformin may explain the absence of an observable clinical benefit in metformin-treated breast cancer patients.

Bioprospecting native*Ganoderma*spp. extracts with selective anti-triple-negative breast cancer potential.

G. M. Silverio[1], L. Arroyo-Cruz[1], S. Sagardia-Gonzalez[2], K. Miller[2], F. Rivas[3], T. Ling[3], M. Martinez-Montemayor[1]; [1]University of Central Del Caribe, Bayamon, Puerto Rico, [2]Huerto Rico, Carolina, Puerto Rico, [3]Louisiana State University, Baton Rouge, LA

Bioprospecting native *Ganoderma* spp. extracts with selective anti-triple-negative breast cancer potential.Silverio-Alvarado G.M.[1], Arroyo-Cruz L.V.[1], Sagardía-González S.[2], Miller K.[2], Ling T.[3], Rivas F.[3], Martínez-Montemayor M. M.[11]Department of Biochemistry and Cancer Research Unit, Universidad Central del Caribe-School of Medicine, P.O. Box 60327 Bayamón, PR 00960-6032; [2]Huerto Rico, Carolina, P.R., [3]Louisiana State University, Baton Rouge, LA; **Background**: Triple-negative breast cancer (TNBC) accounts for about 10-15% of all breast cancers and tends to be more common in younger women, who are Hispanics or African Americans. TNBC is characterized by the lack of hormone (ER & PR) and the

epidermal growth factor receptor 2 (HER2). Thus, currently there are no approved targeted therapies for TNBC, and typically these women are treated with a combination of non-targeted chemotherapy, radiation, and surgery. Therefore, the development of novel therapeutic strategies is necessary to combat TNBC. *Ganoderma* is a basidiomycete white rot fungus that has been used for medicinal purposes for centuries. Much is known about *Ganoderma lucidum* and its properties against cancer, but other *Ganoderma* species, including neotropical ones, are being studied in depth for this purpose. The objective of this study is to identify the effects of native *Ganoderma*species found in Puerto Rico, and test their efficacy. Native fractions extracted from *Ganoderma multiplicatum* (GMu; F1, F2, F3, F4, F6, F7) were tested against TNBC (SUM149) and non-cancerous (MCF10A) cell lines.**Methods**: Cell viability assays were performed using 48-well plates. Cells were treated with increasing concentrations of different fractions ranging from 0 to 75 µM for 72h. After treatment, cell viability was determined by fluorescence detection (GloMax, Promega).**Results**: Our results indicate that SUM149 cancer cells have a significantly reduced viability in fractions F1-F4, F6, and F7. A greater significant inhibitory concentration was detected for F7 (IC_{50} = 3.9 µM), F1 (IC_{50} = 8.4 µM), and F2 (IC_{50} = 11.3 µM). These fractions were effective at lower concentrations compared to the other tested fractions. On the other hand, the MCF10A non-cancerous cell line results indicated that fractions for F2-F4 and F6, we could not calculate an inhibiting concentration. These were calculated only F1 and F7 showed an IC_{50} of 497.9 µM and 1,116 µM, respectively. **Conclusions**: We conclude that fractions F1, F2 and F7 can be evaluated in more depth as fractions that might contain selective anti-TNBC bioactive compounds with great therapeutic potential.

B234/P2626

Endomembrane Localization of IFI6/G1P3 in Breast Cancer Cells

A. Davenport[1,2], M. Morris[2], D. Shakya[2], S. Sabti[2], F. Sabti[2], D. Hynds[1], V. Cheriyath[2]; [1]Texas Woman's University, Denton, TX, [2]Texas A&M University-Commerce, Commerce, TX.

Breast cancer remains the second leading cause of cancer-related deaths among U.S women. G1P3 (IFI6/ISG6-16) is an interferon-stimulated gene encoding a 13kD protein with pleotropic functions. Initial studies by us and others characterized G1P3 as an anti-apoptotic protein localized in mitochondria with a role in cancer progression and metastasis. Additionally, G1P3 is a mediator of the antiviral activity of interferons. Based on the pleiotropic functions of G1P3, we hypothesized the multi-organellar localization of G1P3. Using confocal microscopic and biochemical approaches, the subcellular localization of G1P3 was determined in breast cancer cells. Since a cell staining competent antibody for G1P3 was unavailable, confocal studies were carried out using MCF-7 cells expressing a FLAG-tagged G1P3 protein (MCF7/G1P3-Flag). In co-staining studies, ~40% of G1P3 co-occurred with the inner mitochondrial membrane protein COXIV. In agreement with this, protease digestion of affinity purified mitochondria identified that ~30% of G1P3 resides inside the mitochondria. Additionally, G1P3 was found to co-occur with organelles of endomembrane system such as endoplasmic reticulum (16%), *trans*-Golgi (22%), and lysosome (13%). Among endosomes, G1P3 preferentially co-occurred with Rab5 positive endosomes (55%) than with Appl1 endosomes (8.4%) or with EEA1 endosomes (6.9%). Considering the role of Rab5 endosomes in apoptosis resistance and cell migration, inhibiting the association of G1P3 with Rab5 endosomes may induce cancer cell death to improve clinical outcomes in breast cancer patients.

B235/P2627

Suppression of Breast Cancer Cell Proliferation by the Dietary Polyphenols Resveratrol, Ellagic Acid, Fisetin, Luteolin, and Chrysin

B. Clark, K. Whitinger, S. Phipps, H. Waters, E. Brandenburg, **K. Baker**; University of Indianapolis, Indianapolis, IN

Breast cancer is a worldwide health problem that continues to rank as one of the leading causes of death in women. Resveratrol, ellagic acid, fisetin, luteolin, and chrysin, dietary polyphenols found in a variety of fruits and vegetables, have been shown to exhibit anticancer activity; thus, the use of these dietary agents in combination may be effective for the chemoprevention and therapy of breast cancer. In this study we evaluated the antiproliferative effects of resveratrol, ellagic acid, fisetin, luteolin, and chrysin individually and in combination, using MCF-7 breast cancer cells. We found that each of the phytochemicals inhibited MCF-7 cell proliferation in a dose-dependent manner. Furthermore, we found that co-administration of lower doses of resveratrol and ellagic acid, resveratrol and fisetin, or resveratrol and luteolin, resulted in greater inhibition of cell proliferation than either agent alone at the same dose and indicate an additive effect. These results suggest that combinatorial treatments using resveratrol with ellagic acid, fisetin, or luteolin may be an effective chemotherapeutic strategy against breast cancer.

B236/P2628

Structural basis for trafficking and oligomerization defects of a breast cancer-associated mutation in caveolin-1

B. Han[1], A. Gulsevin[2], S. Connolly[3], T. Wang[1], **B. Meyer**[1], J. Porta[3], A. Tiwari[1], A. Deng[2], L. Chang[3], Y. Peskova[1], H. S. Mchaoraub[2], E. Karakas[2], M. D. Ohi[3], J. Meiler[2], A. K. Kenworthy[1]; [1]University of Virginia School of Medicine, Charlottesville, VA, [2]Vanderbilt University, Nashville, TN, [3]University of Michigan, Ann Arbor, MI

Flask-shaped pits in the plasma membrane known as caveolae regulate numerous cellular processes including intracellular trafficking, signaling, lipid homeostasis, and membrane buffering. Caveolae assembly is driven by caveolin-1 (CAV1), a multimeric integral membrane protein. Mutant forms of CAV1 are implicated in a number of diseases, including cancer and pulmonary arterial hypertension. However, the structural bases for how mutations in CAV1 impact caveolae assembly and function remain poorly understood. Here, we study the molecular basis for trafficking and oligomerization defects of a breast cancer-associated mutation of one of the most highly conserved residues in CAV1, P132L using a combination of computational, structural, biochemical, and cell biological approaches. We show P132 is positioned at a major site of protomer-protomer interactions within the CAV1 complex, explaining why the mutant protein fails to homo-oligomerize and traffic to the plasma membrane correctly. Despite its homo-oligomerization defects, P132L, is capable of forming hetero-oligomeric complexes with wild type CAV1 and can even become incorporated into caveolae in this form. These findings provide insights into the fundamental mechanisms that control the formation of homo- and hetero-oligomers of caveolins that are essential for caveolae biogenesis, as well as how these processes are disrupted in human disease.

Microenvironment

LncRNA *LUCAT1* increases the oncogenic properties of gastric cancer cells and macrophages by regulating MIF expression in *H. pylori*-induced gastric cancer.

S. Kim[1,2], S. Lee[1]; [1]Yonsei University, Seoul, KOREA, REPUBLIC OF, [2]Institute of Gastroenterology, Graduate School of Medical Science, Brain Korea 21 Project, Yonsei University College of Medicine, Seoul, KOREA, REPUBLIC OF.

<META NAME="author" CONTENT="김서연(소화기내과)">Long non-coding RNAs (lncRNAs) are proven to play critical roles in cancer biology. Tumor-associated macrophages predominantly induced to be polarized into M2, a pro-tumorigenic type when recruited with the tumor tissue and thereby favoring the tumorigenesis. In our study, we aim the possible mechanisms of the regulatory link between lncRNAs and macrophages in gastric cancer caused by *H. pylori*.Differentially expressed lncRNAs between *H. pylori*-CagA+ infected and control AGS cells, and between cagA vector-transfected and control AGS cells were identified by RNA-seq and validated by qRT-PCR. Next, we built a co-culture system to explore the interaction between THP-1 macrophage cells and AGS cells in the presence of *H. pylori*-CagA+.We validated that the expression of LUCAT1 was significantly up-regulated after of both *H. pylori*-CagA+ infection and cagA transfection. The knock down of LUCAT1 significantly attenuated the proliferation, migration, and invasion of AGS and MKN74 cells. The infection of *H. pylori*-CagA+ increased secretions of inflammatory cytokines which produced a huge chemotactic effect on THP-1 cells. In our study, LUCAT1 up-regulated macrophage migration inhibitory factor (MIF), one of the crucial cytokines involved in cancer and inflammation in AGS and THP-1 cells. We found that LUCAT1 increased by *H. pylori*-CagA+ infection up-regulates MIF in AGS cells and subsequently MIF polarizes surrounding THP-1 macrophages into M2 macrophages. In turn, M2 macrophages activate carcinogenesis in gastric cancer.Our findings provide important insights for the potential development of lncRNA-based targeted approaches for the treatment of *H. pylori*-related gastric cancer.

Expansion of myeloid-derived suppressor cells in pancreatic adenocarcinoma patients is associated with increased epithelial-mesenchymal transition in their tumor microenvironment

A. Aggarwal, V. Sharma, V. Gupta; Post Graduate Institute of Medical Education and Research Chandigarh India, Chandigarh, INDIA.

Introduction: Pancreatic ductal adenocarcinoma (PDAC) is the seventh leading cause of cancer-related deaths worldwide and its incidence is rising continuously due to poor prognosis. An immunosuppressive microenvironment is the characteristic feature of PDAC. The dysregulated immune system leads to suppression of anti-tumor immunity by aberrant production of Myeloid-derived suppressor cells (MDSCs) but the underlying mechanism highlighting their role of tumorigenesis remains inconclusive. Therefore, we aimed to study the net expansion of MDSCs in PDAC patients and their role in promoting invasiveness. **Methods:** We assessed the relative frequencies of MDSCs and chemokines receptors (CCR4 and CCR5) present on their subsets, in the circulation and surgically resected local pancreatic tumor tissue of PDAC patients by flow cytometry. We investigated the status of epithelial-mesenchymal transition (EMT) related markers E-Cadherin, N-Cadherin, Snail, and ZEB1 by qRT-PCR and

immunohistochemistry. **Results:** We found a higher frequency of circulating and tumor infiltrated MDSCs in PDAC patients compared to healthy controls. MDSCs in peripheral blood showed a significant positive correlation with MDSCs burden in cancer tissue. In tumor tissue, expression of E-Cadherin was significantly reduced, while N-Cadherin, Snail, and ZEB1 were markedly raised. The frequency of CCR4+ Monocytic-MDSCs significantly correlated with the expression of mesenchymal transition markers N-Cadherin, Snail, and ZEB1. **Conclusion:** Our results suggest that CCR4+ Monocytic-MDSCs possess significant tumorigenic potential and their expansion might be responsible for higher invasiveness in pancreatic cancer cells. This study sheds light on the tumorigenic role of MDSCs, which can serve as a crucial target of future anti-cancer strategies to inhibit tumor cell invasiveness

Osteoblast regulated autophagy and Wnt/b-catenin signaling in AML cells

K. Shivhare[1,2], N. Satija[3,4]; [1]Developmental Toxicology Division, CSIR-Indian Institute Of Toxicology Research, Lucknow, INDIA, [2]Molecular Neurotoxicology andcell integrity Lab, System toxicology and health risk assesment group, Academy of Scientific & Innovative Research, Lucknow, INDIA, [3]Molecular Neurotoxicology andcell integrity Lab, System toxicology and health risk assesment group, CSIR-Indian Institute Of Toxicology Research, Lucknow, INDIA, [4]Academy of Scientific & Innovative Research, Lucknow, INDIA.

Abnormal proliferation and differentiation is a characteristic feature of Acute Myeloid Leukemia (AML). Relapse is the prime phenomenon associated with the fatal outcomes of AML. These AML cells show metabolic changes in response to chemotherapy or specific treatments. Autophagy is the cellular adaptive response towards the stress and has demonstrated the distinct role in cellular metabolism, involved in the maintenance of cancer condition, resistance to chemotherapy. Autophagy and Wnt/β-catenin signaling are key players involved in regulation of cellular differentiation and proliferation. GSK-3β, one of the main mediator of Wnt/β-catenin signaling is reported to induce autophagy via phosphorylation of ULK-1. Current study explored osteoblast cells regulated autophagy/Wnt/β-catenin axis in AML cells. Different AML cells (KG-1a, U937, HL60) were co-cultured with Osteoblast cells (Saos-2) and were assessed for key autophagy and β-catenin proteins. The three cell lines belong to different subtypes of AML. HL60 and KG-1a in direct contact with Saos-2 consistently showed significant up-regulation in autophagy proteins including p62, LC3, Atg-5, Atg-7, Beclin-1. However, U937 cells showed no significant changes in these autophagy proteins under similar conditions. Upon placing transwell between AML cells and osteoblast cells to restrict their physical contact, expression of autophagy proteins remained unchanged in all 3 AML cell lines. Furthermore, direct contact of AML and osteoblast cells significantly up-regulated levels of β-catenin and GSK-3β in all AML cells which remained unaffected upon physically restricting cell contact. Altogether, the results reveal importance of osteoblast cells in regulation of autophagy and Wnt/β-catenin in AML cells and possible mechanistic insight towards relapse which can be intervened for therapeutics for future perspective.

Spatial transcriptomics reveals mechanically-regulated cell state transitions at the tumor-microenvironment interface

M. V. Hunter[1], R. Moncada[2], I. Yanai[2], R. M. White[1]; [1]Memorial Sloan Kettering Cancer Center, New York, NY, [2]NYU Langone Health, New York, NY.

As tumors grow, they interact with different cells and tissues neighboring the tumor, but it is unclear how these interactions influence tumor cell biology. To investigate this, we applied spatial transcriptomics, single-cell RNA-seq, and single-nucleus RNA-seq to a whole-animal zebrafish model of melanoma. Using spatial transcriptomics, we identified a unique "interface" cell state localized to where the tumor contacts neighboring tissues, suggesting that cell state transitions occur at the tumor boundary. We used single-cell and single-nucleus RNA-seq to find that the interface is composed of specialized tumor and microenvironment cells that upregulate a common gene set. We found evidence of an "interface" population in patient samples, suggesting it is a conserved feature of human melanoma. In both fish and human data, interface cells are characterized by significant upregulation of the chromatin modifier HMGB2, which is prognostic in human melanoma. Loss of HMGB2 impairs invasion of both human melanoma cells *in vitro* and in zebrafish tumors *in vivo*. Paired RNA-seq and ATAC-seq revealed that developmental/pluripotency pathways are enriched in cells overexpressing HMGB2, suggesting developmental gene programs may be hijacked to support tumor invasion. To investigate the mechanism by which HMGB2 may facilitate cell state transitions at the interface, we used confocal microscopy to discover that HMGB2 is preferentially enriched in confined tumor cells under high levels of mechanical force during invasion. When we subjected human melanoma cells to confinement *in vitro*, we discovered that confinement causes HMGB2 to become cytoplasmic, where previous work suggests it may be secreted to be taken up by neighbouring cells. We are currently investigating how mechanical force signals through HMGB2 at the tumor border to induce changes in gene expression, chromatin accessibility, and cell state in both the tumor and surrounding cells. Together, our work suggests that HMGB2 may be a novel mechanosensor of the mechanical microenvironment at the tumor boundary, and demonstrates the power of spatial and single-cell transcriptomics in uncovering the biology underlying tumor cell behavior *in vivo*.

B241/P2633

Vascular endothelial profilin-1 Inhibition suppresses tumor progression in renal cancer

D. Gau[1], A. Allen[1], A. Daoud[1], J. Kunkel[1], A. N. Paranjape[2], F. S. Villanueva[2], P. Roy[1]; [1]Bioengineering, University of Pittsburgh, Pittsburgh, PA, [2]Cardiology, UPMC, Pittsburgh, PA.

Renal cell carcinoma (RCC) is estimated to result in 79,000 new cases and 13,920 deaths in 2022. Clear cell renal cell carcinoma (ccRCC) is the most common subtype of RCC and is characterized by a high vascularized tumor microenvironment (TME). While anti-angiogenic and vascular normalization inducing therapies are initially effective, almost all patients develop resistance to these therapies. Therefore, there is a need to identify alternative fundamental therapies for ccRCC. The goal of the present work was to investigate whether profilin1 (Pfn1), an actin-binding protein that is dramatically upregulated in tumor-associated vascular endothelial cells (VEC) in human ccRCC and linked to advanced disease features and adverse clinical outcome, is a driver of disease progression in RCC. We found that triggering endothelial Pfn1 gene deletion, either globally or restricted to kidney only, dramatically inhibits tumor formation and metastatic dissemination from syngeneic transplants of RCC cells. Loss of endothelial

Pfn1 led to a major suppression of tumor angiogenesis ensuing massive tumor cell death. In a delayed induction setting, loss of endothelial Pfn1 also retarded progression of pre-established tumors. Through small molecule screening, we identified a novel inhibitor of the Pfn1-actin interaction (Pfn1i) and further showed its ability to inhibit aggressiveness of RCC cells *in vitro*, reduce tumor angiogenesis and tumor growth *in vivo*. Furthermore, toward the goal of targeted delivery of Pfn1i in TME, we have successfully encapsulated Pfn1i into lipid microbubbles, and demonstrated prominent anti-angiogenic action by Pfn1i in cell culture setting released by ultrasound-mediated disruption of microbubbles. These findings lay the groundwork for our ongoing efforts that are focused on localized ultrasound-guided delivery of Pfn1i in tumor microenvironment as a therapeutic strategy in mouse model of RCC. Collectively, these findings establish endothelial Pfn1 as a driver of tumor progression as well as a potentially novel therapeutic target in kidney cancer.

Identifying novel INSM1-associated protein networks that drive neuroblastoma differentiation

D. Chakravorty, A. Kelly, A. Saxena; University of Illinois At Chicago, Chicago, IL.

Neuroblastoma (NB), the most common cancer in the first year of life, is sometimes seen to resolve spontaneously by differentiating into neurons. Chemotherapeutic treatments of NB can aid in differentiation but demonstrate varied efficacy and significant side effects. We recently identified several neurogenesis-promoting factors that are necessary but not sufficient for inducing NB differentiation *in vivo*. Meanwhile, we have observed that neuron-like NB cells express higher levels of the transcription factor INSM1, in comparison to progenitor-like NB cells. Although INSM1 has been previously shown to promote human NB cell survival/proliferation, its role in NB differentiation remains uncharacterized. Therefore, to delineate the role of INSM1 in NB survival versus differentiation, we have generated and transfected a 3xFLAG-tagged INSM1 construct to pull down protein complexes for identification via LC-MS/MS. With this approach, we will identify INSM1's interactome in experimental conditions ranging from non-differentiating to differentiating NB cells, with and without induction of differentiation. Furthermore, INSM1 and its candidate interactor proteins will be perturbed in NB cells that will then be injected into distinct zebrafish embryonic microenvironments to evaluate any shift in the balance between NB survival and differentiation. This approach may provide new insights into the mechanisms of NB differentiation *in vivo* and lay the groundwork for pursuing novel therapeutic targets.

MRTF-SRF interaction promotes bone metastasis of breast cancer cells

P. Chawla[1], D. M. Gau[1], Q. Sun[2], D. Boone[3], D. Galson[2,4,5], P. Roy[1,4,5]; [1]Bioengineering, University of Pittsburgh, Pittsburgh, PA, [2]Medicine, Division of Hematology/Oncology, University of Pittsburgh, Pittsburgh, PA, [3]Biomedical Information, University of Pittsburgh, Pittsburgh, PA, [4]UPMC Hillman Cancer Center, Pittsburgh, PA, [5]McGowan Institute for Regenerative Medicine, Pittsburgh, PA.

Bone is a frequent site for breast cancer metastasis. Conditioning of local tumor microenvironment through crosstalk between tumor cells and stromal cells in the metastatic niche is a major driving force for bone colonization of cancer cells. The objective of the present study was to determine the role of Myocardin-related transcription factor (MRTF - a major cofactor for the transcription factor serum-response factor, SRF) in bone colonization of breast cancer cells. We performed experimental metastasis assay to demonstrate that MRTF elevation dramatically increases bone colonization ability of breast

cancer cells *in vivo*. Either genetic disruption of SRF's interaction or small molecule inhibition of MRTF dramatically inhibited bone colonization of breast cancer cells *in vivo*. To gain mechanistic understanding, we next performed RNA-sequencing analyses of 3D cultures of breast cancer cells under genetic and pharmacological perturbations of MRTF, and compared differentially expressed genes in these settings against a 21-gene signature specifically associated with bone metastasis of breast cancer cells. These studies followed by confirmatory qRT-PCR and immunoblot analyses identified connective tissue growth factor (CTGF), a cell-secreted factor known for promoting osteoclastic differentiation/activity and osteolytic lesions by tumor cells, to be transcriptionally upregulated by MRTF in an SRF-dependent manner. These findings were further supported by bioinformatics-based confirmation for MRTF's positive association with CTGF expression in human breast cancer samples, and differential expression of CTGF between isogenic pairs of bone-colonization-competent *vs* incompetent breast cancer cell lines. Inhibition of the MRTF/SRF pathway suppresses osteoclast differentiation of primary bone-marrow derived monocytes in both tumor-intrinsic and -extrinsic manners. Based on these findings, we conclude that MRTF inhibition could be a novel strategy to suppress osteoclastic activity and skeletal involvement in metastatic breast cancer.

B244/P2636

Reprogrammed Schwann cells organize into dynamic tracks that promote pancreatic cancer invasion

S. Deborde[1], L. Gusain[1], A. Powers[1], A. Marcadis[1], Y. Yu[1], C.-H. Chen[1], A. Frants[1], E. Kao[1], L. Tang[1], E. Vakiani[1], M. Amisaki[1], A. Calo[2], V. Balachandran[1], T. Omelchenko[3], B. Reva[4], K. R. Jessen[5], R. J. Wong[1]; [1]Memorial Sloan-Kettering Cancer Center, New York, NY, [2]Institute for Bioengineering of Catalonia, Barcelona, Spain, [3]Rockefeller University, Rockefeller University, NY, [4]Mount Sinai Medical Center, New York, NY, [5]University College London, London, United Kingdom

Nerves are a component of the tumor microenvironment contributing to cancer progression, but the role of cells from nerves in facilitating cancer invasion remains poorly understood. Here we show that Schwann cells (SCs) activated by cancer cells collectively function as Tumor Activated Schwann cell Tracks (TASTs) that promote cancer cell migration and invasion. Non-myelinating SCs form TASTs and have cell gene expression signatures that correlate with diminished survival in patients with pancreatic ductal adenocarcinoma. In TASTs, dynamic SCs form tracks that serve as cancer pathways and apply forces on cancer cells to enhance cancer motility. These SCs are activated by c-Jun, analogous to their reprogramming during nerve repair. This study reveals a mechanism of cancer cell invasion that co-opts a wound repair process and exploits the ability of SCs to collectively organize into tracks. These findings establish a novel paradigm of how cancer cells spread and reveal therapeutic opportunities.

B245/P2637

Study of the adipokine resistin as a mediator of migration, invasion and secretion of extracellular vesicles in PC3 prostate tumor cells

M. Oregel Cortez, O. Galindo Hernandez; Universidad Autonoma De Baja California, Mexicali, B.C., Mexico

Accumulating evidence has reported that physiological levels of resistin increase tumor aggressiveness in prostate cancer (1). On the other hand, the literature presents evidence that cells are capable of secreting extracellular vesicles with various cargo molecules (2). Even tumor cells can secrete extracellular vesicles related to tumor progression in processes such as degradation of the extracellular

matrix, inhibition of apoptosis, angiogenesis and escape from the immune system (3). In this research, we used PC3 prostate cancer cells as a model. The cells were incubated and stimulated with different concentrations of resistin (10, 25, 50, 100 ng/ml). The migration and secretion processes of metalloproteinases were analyzed by wound closure and zymography assays, respectively. The enriched fraction of extracellular vesicles was obtained by differential ultracentrifugation, to later use them as a stimulus in prostate cell cultures. Cell invasion was analyzed using the Boyden chamber technique coated with matrigel. Our results show that resistin induces an increase in the migration and MMP-2 secretion in conditioned media of the PC3 cell line. Additionally, cells that receive treatment with extracellular vesicles obtained from conditioned media of PC3 cells stimulated with resistin, increase the invasive capacity. Thus, the results show that extracellular vesicles from PC3 cells treated with resistin significantly increase prostatic tumor progression in vitro. In summary, our findings demonstrate that extracellular vesicles obtained from resistin-stimulated conditioned media increase cell migration and invasion processes in the PC3 prostate tumor line. These data strongly suggest that extracellular vesicles secreted by PC3 induce migration and invasion. **References**1. Kim, H. J., Lee, Y. S., Won, E. H., Chang, I. H., Kim, T. H., Park, E. Oncogenes and Tumour Suppressors-Signaling

B247/P2638

Caveolin-1 organization and function drive functional plasticity in Ewing Sarcoma

D. Segal[1], D. Rajendran[1], K. Bhatt[1], J. F. Amatruda[2], G. Danuser[1]; [1]Bioinformatics, UT Southwestern Medical Ctr, Dallas, TX, [2]Cancer and Blood Institute, Children's Hospital Los Angeles, Dallas, TX.

While it is widely accepted that plasticity of tumor cells drives cancer disease progression in the form of drug resistance and metastasis, most cellular mechanisms that drive plasticity have yet to be discovered. We uncover the scaffolding protein Caveolin-1 as a putative plasticity factor driving two distinct functional cell states in Ewing Sarcoma, a pediatric cancer of bone and soft tissue. Specifically, single-cell transcriptomics uncovers two transcriptionally distinct cell populations associated with differential expression of the cell surface glycoprotein CD99. Exploiting this CD99 expression level difference for flow-cytometry based isolation of the two cell states, we find distinctions in morphology, proliferation, and gene expression profiles tightly associated with differences in endogenous Caveolin-1 expression levels and spatial organization. Ultrastructure analysis reveals distinctions between the two cell states in presence of caveolae, cholesterol-rich membrane invaginations driven by Caveolin-1. Differences in Caveolin-1 expression and organization are also associated with differences in the oncogenic Receptor Tyrosine Kinase/AKT signaling pathway. Taken together, this work uncovers a link between Caveolin-1 function and organization of oncogenic signaling driving pathogenesis. Since previous work has suggested that mechanical cues trigger changes in Caveolin-1 localization and activity, future

experiments will scrutinize Caveolin-1 as a potential integrator of environmental cues and cell signaling that can drive cellular plasticity in Ewing Sarcoma.

Targeting MAPK/Hippo Pathway Interactions in Metastatic Melanoma

N. K. Aboud, L. García-Gutiérrez, W. Kolch, D. Matallanas; University College Dublin, Dublin, IRELAND.

Background: RAF-1 kinase independent functions were shown to inhibit apoptosis by binding to the Hippo core kinase MST2. We previously identified small compounds that disrupt the RAF-1/MST2 interaction to promote apoptosis. Our current work is aimed at exploring the therapeutic potential of targeting the RAF-1/MST2 interaction in NRAS and BRAF mutant melanoma. Methods: First, we downregulated RAF-1 using siRNAs in various human melanoma cell lines such as the NRAS mutant (SKMEL2), the BRAF mutant (A375) and the BRAF inhibitor resistant (A375R) and levels of apoptosis were measured using flow cytometry. We proceeded to determine the effects of disrupting the RAF-1/MST2 interaction by utilizing the previously identified disruptors, VCC923573:16 and VCC199189:07. Protein-protein interactions were assessed by performing co-immunoprecipitation experiments and western blots. The level of apoptosis induced by treatment was analysed by flow cytometry. Furthermore, to measure pathways activated by the treatment, a time-course experiment was performed and changes in protein phosphorylation levels indicative of activation were detected using western blots. Finally, to test the efficacy of these disruptors in vivo we generated a zebrafish melanoma model with induced skin tumours driven by NRASQ61L or BRAFV600E mutations. Histological analysis of the zebrafish sections was performed after H&E staining, and the proteome of the collected tumours were studied using mass spectrometry. Results: We have found that RAF-1 downregulation is lethal downstream NRASQ61 signalling, while mutations in BRAFV600 overcome this effect. Interestingly, the secondary mutations acquired during BRAF inhibitor resistance seem to resensitize the cells towards RAF-1 downregulation. Consistently, treatment of the NRAS-driven melanoma cell line with RAF-1/MST2 disruptors activates the Hippo pathway and promotes apoptosis in a dose dependent manner. Furthermore, our in vivo results have revealed differential tumour onset and progression in zebrafish dependent on the tumour driver mutation and the proficiency of the Hippo core kinase LATS1. Conclusions: Our work highlights the importance of RAF-1 downstream NRAS and reveals the potential of targeting RAF-1 kinase independent interactions in melanoma. Future work will focus on further deciphering the disruptors' mechanisms of action and testing the effect of disrupting the RAF-1/MST2 interaction in our in vivo model.

Optogenetic investigation into altered signaling code of Oncogenic KRAS by membrane clustering

A. Chandra[1], A. Venkitaraman[2], S. Mayor[1]; [1]National Center for Biological Sciences, Bangalore, INDIA, [2]Cancer Science Institute of Singapore, Singapore, SINGAPORE.

Small GTPase - Kras is a vital mediator of receptor-initiated signal transduction in human cells. Heterozygous activating point mutations that lock KRAS protein in an "active" GTP-bound state are amongst the common oncogenic lesions found in human cancers. How KRAS protein couple to receptor-triggered signals, and how oncogenic KRAS escape this regulation, remains a central unresolved problem in the field. Emerging evidence suggests that the homo- and hetero-typic interaction in nanoscale protein clusters at the plasma membrane drives Ras-mediated signaling. The central aim of this work is

to elucidate the mechanisms that underlie KRAS protein clustering in the plasma membrane, and its role in physiological and oncogenic signaling. Relationship between KRAS membrane clustering and signal output was analyzed using optically activable fluorophore-coupled KRAS proteins. This enabled microscopic analysis of Ras membrane dynamics in oncogenic signaling. Next, we focused on testing the hypothesis that dynamic actin filaments embedded in a more stable cortical actin meshwork organize membrane KRAS to regulate this relationship, and test its implications for the mechanism underlying oncogenic KRAS signaling.

B250/P2641

Trafficking and signaling abnormalities of the epidermal growth factor receptor EGFR variant III

S. Subramanian[1], R. Dey[1], S. Ramadesikan[2], R. C. Aguilar[1]; [1]Department of Biological Sciences, Purdue University, West Lafayette, IN, [2]The Steve and Cindy Rasmussen Institute for Genomic Medicine, Nationwide Children's Hospital, Columbus, OH.

Epidermal Growth Factor Receptor variant III ($EGFR^{viii}$) is found in several cancers such as glioblastomas (GB) (40% cases), head and neck squamous cell carcinoma (30%), prostate cancer (20%), breast cancer (20%) and squamous cell carcinomas (10%). In comparison to wild-type EGFR ($EGFR^{wt}$), $EGFR^{viii}$ lacks amino acids 6-273 due to an in-frame deletion which creates a junction between amino acid 5 and 274 along with the introduction of a novel glycine at the junction. Although this deletion affects a major portion of the extra-cellular domain including the EGF-binding domain, $EGFR^{viii}$ is considered to be constitutively active by a not fully understood molecular mechanism. This EGFR variant is an excellent candidate for targeted therapy since it is found only in tumors and not in normal tissue. All this emphasizes the importance of understanding the basic biology behind the trafficking and signaling pertinent to $EGFR^{viii}$.Here we showed that cells expressing GFP-labeled $EGFR^{viii}$ (and very low levels of $EGFR^{WT}$) exhibited weak binding of tetramethyl-rhodamine labelled EGF. Nevertheless, $EGFR^{viii}$ was efficiently internalized and participated in signal transduction by combined action with other receptor tyrosine kinases (including $EGFR^{wt}$) presumably by forming heterodimers.
Furthermore, $EGFR^{viii}$ triggered the assembly of a unique and previously unnoticed large, intracellular compartment. Immunofluorescence with anti-EEA1 (early endosome marker) and anti PDIA3 (ER marker) revealed nearly 100% colocalization of these markers with GFP-$EGFR^{viii}$, indicating an ER and endosomal mixed nature of the $EGFR^{viii}$ compartment.
To test the potential role of ligand binding in compartment assembly, we treated cells expressing $EGFR^{viii}$ with different growth factors. Our studies showed that these compartments disassembled in the absence of serum/EGF ligand and reassembled when stimulated with growth factors as a function of time and dosage. We showed that as early as 4-8 of stimulation triggered the assembly of $EGFR^{viii}$ containing compartments. We speculate that these large, and unique intracellular $EGFR^{viii}$-positive compartments possessing an early endosomal nature could be sites for endosomal signaling. It has been proposed that $EGFR^{wt}$ can form heterodimers with $EGFR^{viii}$. Thus, it will be crucial to understand the role of co-expressing $EGFR^{wt}$ and characterize the compartment assembly and downstream signaling events.This project will help understanding the molecular mechanism by which the $EGFR^{viii}$ variant subverts intracellular physiology and lay the foundation for future novel cancer therapies.

B251/P2642

Serine/Threonine kinase STK25 negatively regulates mTORC1 activity to suppress tissue overgrowth and tumorigenesis

R. Ho[1], S. Lim[2], N. Ganem[3]; [1]Molecular and Translational Medicine, Boston University School of Medicine, Boston, MA, [2]Mayo Clinic Rochester, Rochester, MN, [3]Pharmacology, Boston University School of Medicine, Boston, MA.

The maintenance of cellular and tissue homeostasis relies on the tight regulation of cell growth and proliferation. These processes are predominantly regulated by two evolutionarily conserved pathways: the mammalian Target of Rapamycin (mTOR) pathway and the Hippo pathway. Dysregulation of both the mTOR and Hippo pathways promotes aberrant cell proliferation, tissue overgrowth and tumorigenesis. Elucidating how the mTOR and Hippo signaling pathways coordinate their activities is therefore a vitally important, yet poorly understood, area of cell cancer biology. Our lab previously demonstrated that STK25, a serine/threonine kinase, functions as an upstream activator of Hippo signaling to limit cell growth. We now demonstrate that STK25 also functions to regulate mTORC1 signaling. We observe that genetic deletion of *STK25* hyperactivates the mTOR pathway, both *in vitro* and *in vivo*. To elucidate the molecular mechanisms of STK25, we utilized the BioID2 proximity labeling system and comparative LC MS/MS analysis to identify a list of proteins that interact significantly with STK25. Based on those findings, we propose that STK25 disrupts the stability of the mTORC1 protein complex by interfering with the CCT/TRiC chaperone protein complex, ultimately attenuating mTOR signaling. Furthermore, using a conditional *STK25* knockout mouse model, we found that deletion of *STK25* alone is sufficient induce tumorigenesis. Taken together, our data suggests that STK25 plays a critical role in modulating cell growth and tumor suppression by negatively regulating the mTORC1 pathway. This would establish STK25 as an upstream regulator of both the Hippo and mTOR pathways, providing further insights to the coordinated regulation of these two crucial pathways.

B252/P2643

GOLPH3 protein controls organ growth by interacting with TOR signaling proteins in Drosophila.

A. Frappaolo, A. Karimpour-Ghahnavieh, S. Sechi, **M. Grazia Giansanti**; Istituto di Biologia e Patologia Molecolari, Italian National Research Council (CNR), Roma, ITALY.

GOLPH3 (Golgi phosphoprotein 3) is an evolutionarily conserved phosphatidylinositol 4-phosphate effector, mainly localized to the Golgi apparatus, where it supports organelle architecture and vesicular trafficking. Overexpression of GOLPH3 correlates with poor prognosis in several cancer types and is associated with enhanced signaling downstream of mTOR (mechanistic target of rapamycin). However, the molecular link between GOLPH3 and mTOR remains elusive. Studies in *Drosophila melanogaster* have shown that Translationally controlled tumor protein (Tctp) and 14-3-3 proteins are required for organ growth by supporting the function of the small GTPase Ras homolog enriched in the brain (Rheb) during mTORC1 (mTOR complex 1) signaling. We show that *Drosophila* GOLPH3 (dGOLPH3) physically interacts with Tctp and 14-3-3ζ. Knockdown of dGOLPH3 reduces wing and eye size and enhances the phenotypes of *Tctp* RNAi. Moreover, the enlargement of the wings caused by Rheb overexpression is suppressed by *dGOLPH3* RNAi. We also show that Golgi localization of Rheb in *Drosophila* cells depends on dGOLPH3. Consistent with dGOLPH3 involvement in mTORC1 activation, depletion of dGOLPH3 reduces levels of phosphorylated ribosomal S6 kinase, a downstream target of mTORC1. Overall, our

data provide the first *in vivo* demonstration that GOLPH3 regulates organ growth by directly associating with mTOR signaling proteins.

B253/P2644

RAI14 Drives Pancreatic Tumorigenesis and Supports Proliferative Mesenchymal Tumor Cells

F. Runa[1], L. Tomaneng[1], Y. Adamian[1], C. Nathan[2], C. Gonzalez[1], J. Hong[1], K. Bhakta[1], M. Boyce[2], J. Kelber[1]; [1]Biology, California State University Northridge, Northridge, CA, [2]Biochemistry, Duke University, Durham, NC.

Pancreatic Ductal Adenocarcinoma (PDAC) accounts for the vast number of malignant tumors in the pancreas. It is a highly lethal solid tumor estimated to be the second-leading cause of cancer-related death in the United States by 2030. Hallmarks of PDAC include post-metastasis diagnosis and therapy resistance. To identify new mechanisms underlying the aggressive nature of this cancer we previously identified roles and mechanisms of action for pseudopodium-enriched atypical kinase 1 (PEAK1) and integrin α1 (ITGA1) as pseudopodium-enriched (PDE) proteins during PDAC progression. Here, we identify a new PDE protein, retinoic acid induced 14 (RAI14, Ankycorbin or NORPEG), that is a constituent of the KRasG12D PDAC cell autonomous phosphoproteome, localizes to cytoskeleton/adhesion domains in PDAC cells and predicts poor patient outcomes. Knockdown or knockout of RAI14 in KRas mutant PDAC cells reduced adhesion-dependent proliferation/survival *in vitro* and abrogated the ability of PDAC cells to form tumors *in vivo.* To identify signaling pathways and potential vulnerabilities that depend upon RAI14, we used cyclic immunofluorescence (CycIF). Interestingly, we discovered that RAI14 is necessary to support a proliferative mesenchymal PDAC cell subpopulation. These data combined with the output of a RAI14-focused bioinformatics pipeline revealed a targetable vulnerability centered around PLK1-mediated mitosis that may be leveraged to sensitize PDAC cells to therapeutic intervention and improve patient outcomes.

B254/P2645

Characterization of gamma-glutamyltransferase 6 protein in breast cancer

G. Peguero Kushner, C. Smith, Z. Li, B. Papp; University of Florida, Gainesville, FL.

Objectives: We recently identified Gamma-glutamyltransferase 6 (GGT6) as a protein required for oncogenic virus lytic reactivation. Once activated, Gamma-Glutamyl-Transpeptidase family (GGT) proteins cleave gamma-glutamyl bonds to maintain intracellular cysteine and glutathione homeostasis. GGT6 was predicted to lack enzymatic activity, and it remains an uncharacterized member of the GGT family. Bioinformatics studies report decreased GGT6 in various subtypes of cancers and this loss is associated with poor survival and increased tumorigenesis markers. Since breast cancer (BC) is one of the leading causes of death in women and GGT6 has not been investigated in this context, we aim to characterize GGT6 and evaluate its potential dysregulation in BC progression by assessing expression levels and protein modifications as well as evaluate its potential as a biomarker. **Methods:** To characterize GGT6 protein we transfected 293T cells with mammalian expression vectors encoding full length GGT6 open reading frame or cDNA derived GGT6 isoforms. To study the half-life of GGT6, GGT6 positive cells were treated with the protein synthesis inhibitor cycloheximide. To evaluate our predicted N-linked glycosylation, enzymatic treatment was used for removal of N-linked oligosaccharide chains. We used bioinformatics, RT-qPCR, and immunoblot analysis to compare GGT6 expression with epithelial or mesenchymal markers across mammary tissues, breast cancer subtypes and BC lines. Kaplan-Meier

survival plots were generated to assess whether GGT6 expression correlates with survival in subtypes of BC. **Results:** GGT6 has a shorter half-life compared to the other GGT proteins and endogenous GGT6 is glycosylated in T47D and MDAMB468 BC cells. High GGT6 expression positively correlated with epithelial markers (such as EpCAM1) but negatively correlated with mesenchymal markers (such as ZEB1) at the mRNA and protein level, suggesting GGT6 was expressed in epithelial-like cells but decreased in mesenchymal subtypes. Immunoblots revealed a smaller GGT6 derived N-terminal fragment in the cells suggesting that GGT6 protein might be processed. Data mining revealed GGT6 to be significantly downregulated in the more aggressive mesenchymal subtypes compared to normal tissue. High GGT6 transcript levels correlate with increased survival in Luminal A and estrogen receptor positive subtypes which have better prognostic outcomes. **Conclusion:** GGT6 is a N-linked glycosylated protein with a short half-life and high expression in mammary cells with epithelial features, and associates with better prognosis in breast cancer.

B255/P2646

Optimization of M13 bacteriophage-mediated gene delivery for cancer therapy

C.-Y. Kao, Y.-C. Pan, Y.-H. Hsiao, K. Mou; Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan

Gene therapy based on viral vectors is a promising modality to treat a variety of diseases, including cancers. Current limitations of viral vectors include pre-existing neutralization antibodies in patients; the high cost of clinical-grade production; and poor cell-type specificity. Here, we aim to engineer the M13 bacteriophage as an efficient gene delivery vehicle. We displayed various epidermal growth factor receptor (EGFR) ligands on the M13 pIII capsids and encapsulated the green fluorescent protein gene for the measurement of transduction efficiency in human cells with different levels of EGFR expression. The M13 bacteriophages displaying high-affinity EGFR ligands showed the binary transduction efficiency depending on the EGFR levels in cells. Additionally, we hypothesized that the human protein PrimPol might facilitate the conversion of single-stranded DNA to double-stranded DNA and enhance transgene expression. Indeed, the M13 bacteriophage resulted in higher transgene expression in the human cells over-expressing PrimPol. To investigate other possible cellular determinants for bacteriophage transduction, we performed the transcriptome analysis between two cell populations with high and low transduction efficiencies. The data revealed a skewed distribution with many transcripts down-regulated in high-transduction cells, including many viral defending proteins. Furthermore, we hypothesized that the M13 bacteriophage size might influence transduction efficiency. We generated a series of M13 bacteriophages from 300 nm to 1000 nm. We observed an anti-correlation between the M13 bacteriophage length and the transgene transduction efficiency. With properly re-structuring the M13 origin, we designed an optimal M13 bacteriophage, which dramatically improved the transduction efficiency to the levels comparable to the adeno-associated viral vectors. On the basis of our optimal bacteriophage design, we delivered several therapeutic genes, such as N-terminal gasdermin D (GSDMD) and membrane-anchored fragment crystallizable region (Fc), to test their anti-tumor activities. Delivery of the N-terminal GSDMD greatly induced pyroptosis in cancer cells. The membrane-anchored Fc gene delivered by the bacteriophage successfully enable the cell killing by natural killer cells. Overall, our engineered M13 bacteriophage achieved an unprecedented transduction efficiency in human cells and holds a great potential for the next-generation gene therapy.

The Drosophila Accessory Gland: a model for the study of tumor-promoting features in non-dividing multinucleated polyploid cells.

S. Church, A. Box, L. Buttitta; University of Michigan, Ann Arbor, MI

Polyploid multinucleated tumor cells are believed to be a main source of tumor recurrence and resistance against chemotherapy and irradiation in numerous cancers. Here we describe a Drosophila-based model for the study of polyploid multinucleated cells. The accessory glands of male Drosophila are the fly functional analog of the human prostate. The cells of the accessory gland are post-mitotic, binucleated, and polyploid. Using this model, we examined how activating fly versions of oncogenes associated with prostate cancer, such as Myc and Yki, the fly homolog of YAP, affect the accessory gland epithelium. We find that overexpression of these oncogenes induces cellular hypertrophy, nuclear anaplasia, loss of proper epithelial polarity, and endocycling in the Drosophila accessory gland. Additionally, oncogene activation recapitulated features of cancer such as upregulation of beta-integrin, expression of matrix metalloproteinases 1 (MMP1), upregulation of phosphorylated MAPK, as well as apical and basal extrusions, and alterations to glandular morphology, all in the absence of mitosis. We also observe non-autonomous effects of oncogene activation in neighboring cells, demonstrating the power of this model for examining complex tumor vs. non-tumor heterogeneity in cancer development. Our work provides a novel model to study tumor-promoting features of non-dividing polyploid multinucleated cells under oncogenic conditions.

GGPPS as a therapeutic target in cancer

S. Mitra, P. Devreotes; Johns Hopkins University Sch Med, Baltimore, MD

Cancer cells have unique metabolic demands that can be harnessed to provide novel therapeutic approaches. Recently, the mevalonate pathway has been implicated in supporting tumorigenesis. Statins target this pathway and are typically used for lowering cholesterol. But these drugs target the entire mevalonate pathway and the effects on cancer cells have been traced to depletion of GGPP, a downstream intermediate. GGPP is required to geranylgeranylate a network of signal transduction proteins, like small GTPases, which are essential for macropinocytosis and cell motility. These processes are upregulated in cells with oncogenic mutations, making such cells selectively sensitive to GGPP depletion. The goal of this proposal is to identify the enzyme that synthesizes GGPP in cells, geranylgeranyl transferase synthase (GGPPS), as a therapeutic target in cancer. Towards this goal, I will investigate the significance of the enzyme in cell survival and transformation, explore the structure-function relation of the enzyme to identify key residues for enzyme function, and explore the mechanism of its localization, regulation, and dynamics in cells

“Altering FAK-paxillin interaction: a potential therapeutic strategy to target tumor growth and metastasis”

M. Christoforou, A. Charalambous, P. Skourides; University of Cyprus, Nicosia, Cyprus

Focal adhesion kinase (FAK) is a cytoplasmic tyrosine kinase that is implicated in several cellular functions including cellular adhesion, motility, proliferation and survival. Interestingly, FAK is

overexpressed and activated in primary or metastatic cancers and both its kinase-dependent and kinase-independent scaffolding functions facilitate cancer progression and metastasis. Therefore, FAK is considered an attractive drug target for cancer therapy. Several small FAK inhibitors are currently undergoing clinical trials, but so far these have been met with limited success and none of them has been approved and launched in the market. Our group has developed a new strategy for the inhibition of FAK, successfully targeting both kinase dependent and independent functions of FAK at the same time. The strategy relies on the displacement of FAK from Focal Adhesions (FAs), using a small peptide to compete with interactions taking place between the LD motifs of paxillin and the hydrophobic pockets of the FAK FAT domain, shown to be necessary and sufficient for FAK´s FA targeting. We have previously shown that a short peptide dimer containing the LD2 and LD4 motifs of paxillin is sufficient to mask interactions taking place at the HPs on FAK's FAT domain and lead to the elimination of endogenous FAK from FAs. *In vitro* experiments demonstrate that the LD2-LD4 peptide inhibits FAK/Src signaling at FAs and results in the dramatic reduction of tumor cell migration and invasion. We now show that LD2-LD4 also targets proline-rich tyrosine kinase 2 (PYK2), that is also overexpressed in cancerous tissues and stimulates multiple oncogenic signaling pathways. This further enhances its anti-metastatic potential as a dual FAK/PYK2 inhibitor. We have examined the efficacy of this newly developed strategy for the inhibition of FAK and PYK2 by exploring the impact of LD2-LD4 on tumor growth and progression in mice. Collectively, data from our pre-clinical experiments validate the *in vitro* results and indicate that LD2-LD4 expression can inhibit tumor growth. Most importantly, LD2-LD4 had a dramatic impact on tumor progression and metastasis nearly abolishing the appearance of metastatic tumors, highlighting the potential of this newly developed strategy as a therapeutic approach against cancer and metastasis.

B259/P2650

Characterizing Variants of Undetermined Significance in the BRCA Repair Pathway

K. Anglin; Prairie View A&M University, Prairie View, TX.

"Pathogenic" or "Likely Pathogenic" germline mutations in DNA repair genes such as Brca1, Brca2, and Palb2 in the BRCA repair pathway can lead to an increased risk of developing breast, pancreatic, and ovarian cancers. Other mutations may be found in the patient population, yet whether they play a role in increasing the risk of developing cancer is unknown; these are called Variants of Undetermined Significance (VUS). The impact of these variants' expression on cell proliferation, apoptosis, oxidative stress factors, and internalization in certain cell types are unclear. Further, several questions remain about the prevalence and impact of DNA repair gene variants in certain tissues. Characterizing the phenotypic impacts of these variants in different cell-based models will provide more information about relevant molecular targets. The aim of this project is to investigate the role of DNA repair gene variants using cell-based and functional assays. We hypothesize that knockdown of the DNA repair gene *Palb2* will lead to a decline in homologous recombination in a cervical cancer cell line. To test the hypothesis, DOTC2-4510 cells were grown in complete culture medium at 37°C. Following expansion, $2.5x10^5$ cells were plated onto culture well-plates. Brca2 and/or Palb2 were overexpressed using an expression vector, or Palb2 was silenced using siRNAs. Cells were maintained for 48 hours and extracted lysates were assessed for expression of wild type Palb2, Brca2, and gamma H_2ax. Knockdown of Palb2 in DOTC2-4510 cells will lead to a decrease in genomic stability, as observed with gamma H_2ax expression. We will carry out additional cell-based assays in the presence of clinical variants of DNA repair genes,

including *Brca1*, *Brca2* and *Palb2* in DOTC2-4510 cells. We will also perform co-immunoprecipitations to look for resultant binding partners of Palb2 in DOTC2-4510 cells.

Expression of oxidative stress-related genes in triple negative breast cancer cell lines derived from African American and European American women

Z. Robinson, J. Francois, C. Jeun, R. Minter, A. Mazza, K. E. Miletti-Gonzalez; Delaware State University, Dover, DE

Breast cancer is the most frequently diagnosed cancer among African American (AA) women and among the different types of this cancer, triple negative breast cancer (TNBC) is an aggressive breast cancer with the worst prognosis due to the absence of three key therapeutic targets, estrogen receptor (ER), progesterone receptor (PR) and human epidermal growth factor receptor 2 (HER2). TNBC, which comprises 15-20% of all breast cancers, is disproportionately higher in AA women compared to European American (EA) women. For this reason, we compared the gene expression of oxidative stress-related genes in two groups of TNBC cell lines, one group derived from AA (group AA, cell lines HCC70 and HCC1806) and the other group derived from EA women (group EA, cell lines HCC38 and HCC1143), before (control) and after treating the cells with hydrogen peroxide. We hypothesize that these two groups of TNBC cell lines will have a differential cellular response to oxidative stress caused by hydrogen peroxide as well as a differential gene expression in oxidative stress-related genes. These four cell lines were treated with hydrogen peroxide from 2 mM to 0.0078 mM. MTS cell viability assays were performed after 24 hours of treatment and total RNA was extracted, sequenced (RNA-seq) and bioinformatically analyzed. The group AA TNBC cell lines resulted to be more resistant to oxidative stress caused by hydrogen peroxide than the group EA TNBC cell lines. The RNA-seq generated gene expression profile revealed several differentially expressed genes involved in glutathione synthesis (e.g., GLS2, SLC7A11), reactive oxygen species scavenging (e.g., CAT, GPX2) and xenobiotics detoxification (e.g., ALDH3A1, UGT1A6). Among them, glutathione peroxidase 2 (GPX2) was the highest differentially expressed gene with a fold change of 274 times higher in untreated group AA compared to group EA TNBC cell lines. These results suggest a correlation between the origin of the TNBC cell lines used and their response to oxidative stress caused by hydrogen peroxide. Because CD44 is highly expressed in TNBC cells and has been reported to have a prognostic role in TNBC, we propose future experiments to investigate the expression of CD44 in these cell lines and a potential role in oxidative stress-related gene regulation.

B261/P2652

Annotation of BARD1, A Familial Ovarian Cancer Gene?

D. Holmes, G. Regisford; Prairie View A&M University, Prairie View, TX.

Familial ovarian cancer is a genetic phenomenon in which a family lineage is genetically predisposed to ovarian cancer. Ovarian cancer is the 4th most deadly cancer-related gynecological disease mainly because it is detected during the latter stages of disease progression. The main signifiers of ovarian cancer are the mutations of the BRCA1 and BRCA2 genes. However, a less characterized gene called BRCA1 Associated RING Domain 1 (BARD1) has been implicated to predict predisposition to hereditary forms of this deadly cancer. Therefore, the objective of this study was to annotate and characterize the BARD1 gene in silico. We hypothesized that the BARD1 gene is a functional protein-coding gene that

may lead to familial ovarian cancer when mutated. In testing this hypothesis, we used the GeneCards and National Center of Biotechnology Information (NCBI), University of California Santa Cruz (UCSC) and Ensembl bioinformatics databases, as well as the Basic Local Alignment Search Tool (BLAST) to investigate the location, structure, expression pattern, and function of the BARD1 gene. According to the GeneCards and UCSC bioinformatics database, the BARD1 gene is located on chromosome 2q35, is approximately 84kb in length, and has a minus-strand orientation. BARD1 is expressed in several tissues, including reproductive tissues such as the testis, prostate, breast, uterus, and ovaries. The NCBI and Ensembl databases and BLAST indicated that orthologs of BARD1 are found in mice (Mus musculus), chickens (Gallus gallus), lizards (Anolis carolinensis), African clawed frogs (Xenopus laevis), and Zebrafish (Danio rerio). However, there are no known paralogs of BARD1. Diseases associated with mutations of the BARD1 gene are breast cancer along with hereditary breast and ovarian cancer syndrome. These results indicate that BARD1 is a functional protein-coding gene, and its mutations may be associated with familial ovarian cancer. Future studies will determine the effect of photothermal therapy (PTT) and radiation on the expression of BARD1 in several ovarian cancer cell lines, in vitro.

B262/P2653

Assessing cancer cell senescence as a novel anti-cancer therapy for pancreatic cancer

K. Morris, S. Cole, P. Vaughan, K. Vaughan; University of Notre Dame, Notre Dame, IN

Pancreatic ductal adenocarcinoma (PDAC) has the lowest 5-year survival rate of any major cancer; just 10% in 2022. Gemcitabine (GEM) is the current standard of care for the treatment of PDAC, however, it is a cytotoxic chemotherapy that is relatively ineffective and comes with harsh side effects such as fever, nausea, and extreme fatigue due to the cytotoxic nature of the drug. **Alternative approaches are desperately needed to increase overall survival and reduce the suffering of PDAC patients**. In recent years, there has been a surge of interest in immune activation for the treatment of cancer, however, thus far no such treatments have been discovered for PDAC. Recently, our lab discovered a novel treatment pathway for PDAC that works through induction of nuclear blebbing and cellular senescence, opening the door to a completely new therapeutic approach. The combination (EpoAurorin) of EpoB and an Aurora B Kinase inhibitor, prevents phosphorylation of lamin A by Aurora B. When de-phosphorylated, lamin A can no longer bind to phospho-Barrier-to-autointegration factor (pBAF), causing to nuclear blebbing. As nuclear blebbing often leads to micronuclei and DNA in the cytosol, a treatment with this approach could activate the cGAS-cGAMP-STING pathway to bring the innate immune system to fight the cancer. Targeting cancer by inducing cellular senescence and activating the immune system provides many benefits over current treatment regimens including growth prevention without the harsh side effects common for cytotoxic chemotherapies. While further investigating the mechanism, we became interested in the BAF half of the pathway and identified vaccinia-related kinase 1 (VRK1) as the BAF kinase responsible for the association of phospho-BAF and phospho-lamin A. Luteolin, a natural flavonoid, has been identified as a VRK1 inhibitor, however, its potency and absorption are very low. Through the synthesis of a library of luteolin analogues, we have been searching for a novel compound that has the same effects as luteolin at lower dosages. This compound can then be used a lead compound for the therapeutic development of a VRK1 inhibitor for the treatment of PDAC.

Single-molecule tracking reveals two low-mobility states for chromatin and transcriptional regulators within the nucleus

K. Wagh*[1,2], D. A. Stavreva*[1], R. A. M. Jensen[1,3], V. Paakinaho[1,4], G. Fettweis[1], R. Schiltz[1], D. Wüstner[3], S. Mandrup[3], D. M. Presman[1,5], A. Upadhyaya[2,6], G. L. Hager[1]; [1]Lab of Receptor Biology and Gene Expression, National Cancer Institute, NIH, Bethesda, MD, [2]Department of Physics, University of Maryland, College Park, MD, [3]Department of Biochemistry and Molecular Biology, University of Southern Denmark, Odense, DENMARK, [4]Institute of Biomedicine, University of Eastern Finland, Kuopio, FINLAND, [5]Instituto de Fisiología, Biología Molecular y Neurociencias (IFIBYNE), CONICET-Universidad de Buenos Aires, Buenos Aires, ARGENTINA, [6]Institute for Physical Science and Technology, University of Maryland, College Park, MD.

Transcription factors (TFs) scan the nucleus in search of their consensus binding motifs located within enhancers or promoter-proximal regions. The mechanism by which TFs navigate the complex nuclear environment to assemble the transcriptional machinery at specific genomic loci remains elusive. Using single-molecule tracking, coupled with machine learning, we examined the mobility of multiple transcription factors and coregulators. We show that chromatin (labeled by histone H2B), steroid hormone receptors, as well as other transcriptional coregulators, architectural proteins, and remodelers, all display two distinct low-mobility states. Our results indicate that both low-mobility states are intimately coupled with mobile chromatin. Ligand activation results in a dramatic increase in the proportion of steroid receptors in the lowest mobility state. Mutational analysis revealed that chromatin interactions in the lower mobility state require an intact DNA-binding domain as well as domains important for forming protein complexes with other binding partners. These domains are not necessary for engagement with the higher mobility fraction of chromatin. Importantly, these states are not spatially separated as previously believed but in fact, individual H2B and TF molecules can dynamically switch between them. Together, our results identify two unique and distinct low-mobility states of transcriptional regulators that appear to represent common pathways for transcription activation in mammalian cells.

Dynamic mechanisms of the Notch transcriptional response

J. M. Rogers[1], B. Guo[1], E. D. Egan[1], J. C. Aster[2], K. Adelman[1], S. C. Blacklow[1]; [1]BCMP, Harvard Medical School, Boston, MA, [2]Department of Pathology, Brigham and Women's Hospital, Boston, MA.

Cells must enact specific gene expression programs in response to signal activation in order to establish and maintain identity. The transcriptional response to Notch signaling relies on co-activators of the MAML family, which are thought to recruit additional co-activators (e.g. p300, chromatin remodelers) to stimulate transcription. In previous work, I showed that different Notch responsive genes depend on different portions of MAML1 for transcription in Jurkat T-ALL cells (Rogers, Guo et al 2020). In particular, HES4 is dependent only on TAD1 of MAML1, which is thought to recruit p300, whereas DTX1 requires both TAD1 and TAD2. Additionally, Notch dependent HES4 expression can be supported by direct fusion of the p300 HAT domain to the NTC-binding portion of MAML1, but DTX1 expression cannot, indicating

the need for recruitment of other co-factors. The differences between these two model target genes motivate the importance of expanding mechanistic studies to a genome-wide context.
To that end, I used a recently developed cellular system for Notch activation, in which a mutated and truncated form of Notch1 (ΔEGF-L1596H) is expressed in a squamous cell carcinoma cell line that lacks endogenous Notch1 (Pan et al 2020). Because nuclear access of this Notch protein is ligand-independent and gamma-secretase dependent, the cells can be maintained in a Notch-naïve state with a gamma-secretase inhibitor (GSI) and activated by GSI washout, allowing for time resolved investigation of how the genome responds to the introduction of Notch. In this system, I have performed Precision Run-on sequencing (PRO-seq) over a fine time course to identify the transcriptional response to Notch activation. Analyses of these data reveal clusters of genes with distinct temporal responses to Notch activation - genes that respond quickly, those that respond slowly, genes that are transiently expressed, and even genes that are downregulated - highlighting the heterogeneity in the dynamic responses to signal induction. PRO-seq data also enables identification of active enhancers that regulate gene expression. Further integration of ChIP-seq and ATAC-seq datasets will enable a more high- resolution mechanistic understanding of the Notch transcriptional response.

B266/P2656

Transcription is a key regulator of nuclear bleb formation, stabilization, and rupture, but not nuclear mechanics

I. K. Oder[1], M. L. Currey[2], S. Gupta[3], Y. Berrada[2], B. Nguyen[1], J. M. Schwarz[3,4], E. J. Banigan[5,6], **A. D. Stephens**[2,1]; [1]Molecular and Cellular Biology, University of Massachusetts Amherst, Amherst, MA, [2]Biology Department, University of Massachusetts Amherst, Amherst, MA, [3]Department of Physics and BioInspired Syracuse, Syracuse University, Syracuse, NY, [4]Indian Creek Farm, Ithaca, NY, [5]Department of Physics, Massachusetts Institute of Technology, Boston, MA, [6]Institute of Medical Engineering & Science, Massachusetts Institute of Technology, Boston, MA.

Chromatin is an essential component of nuclear mechanics and shape that maintains nuclear compartmentalization and function. It is well established that the biophysical properties of chromatin alter nuclear shape stability, but little is known about whether and how major genomic functions can impact the integrity of the nucleus. We hypothesized that transcription might affect the physical properties of the cell nucleus through its effects on chromatin structure and dynamics. To test the effects of transcription, we inhibited transcription with the RNA Pol II inhibitor alpha amanitin in wild-type cells and cells treated with valproic acid (VPA), which decompacts and softens chromatin and increases nuclear blebbing and rupture. We observed that transcription inhibition suppresses nuclear blebbing for several cell types, histone modification profiles (drug treatments), and transcription inhibitors. However, transcription inhibition does not alter chromatin histone modification state or nuclear rigidity, which are mechanisms for nuclear blebbing. Instead, transcription appears to be necessary for nuclear bleb formation, stabilization, and bleb-based nuclear ruptures. Our data reveal that active/phosphorylated RNA Pol II ser5, marking transcription initiation, is enriched in nuclear blebs

relative to DNA and the transcription elongation marker RNA Pol II phosphorylated at ser2 . Thus, transcription initiation is a structural hallmark of nuclear blebs, and it is vital to forming a nuclear bleb. Polymer simulations suggest that motor activity, such as that of RNA Pol II, within chromatin can generate active forces that deform the nuclear lamina, and that nuclear deformations depend on motor dynamics. Our data provide evidence that the genomic function of transcription impacts nuclear shape stability, and suggests a novel mechanism, separate and distinct from chromatin rigidity, for regulating large-scale nuclear shape and function.

B267/P2657

Enhancer and promoter coordination of transcription bursting and heterogeneity

F. Chapus[1,2], C. Day[3,2], J. Rodriguez[4,2]; [1]Fleur Chapus, Durham, NC, [2]Escbl, NIEHS, NIH, Durham, NC, [3]Christopher Day, Durham, NC, [4]Joseph Rodriguez, Durham, NC.

Intra-tumoral gene expression heterogeneity is a roadblock toward effective cancer treatment due to subpopulations acquiring resistance and metastatic ability. This expression heterogeneity can be explained by the stochastic nature of transcription. Transcriptional initiation is coordinated through distal elements known as enhancers. These elements function *via* proximity which aids in recruitment of cofactors and chromatin remodelers. During transcriptional activation, genes are transcribed in episodic bursts of nascent RNA synthesis. Moreover, heterogeneously expressed genes exhibit variably long periods of transcriptional inactivity. Given that enhancers are key elements of transcriptional activation, how they coordinate transcriptional bursting of target genes remains unclear. Here, we use single molecule RNA FISH and live cell imaging to decipher the coordination between enhancer activity and transcription burst initiation. We observe coupling between the transcription of the estrogen-responsive gene TFF1 and its enhancer transcription upon estrogen stimulation. Moreover, TFF1 enhancer RNA sporadically form condensates correlated with an increase of TFF1 mRNA content. To accurately dissect the temporal relationship between enhancer and promoter activity, we are using 2-color live cell RNA imaging to monitor endogenous enhancer and promoter activity of several enhancer-gene pairs. Our work highlights the dynamic coupling of enhancer and promoter regulation of estrogen responsive genes and its implications on expression heterogeneity.

B268/P2658

Defining nanoscale genetic interactions of bacteria with engineered nanoparticles

T. Noussi, D. Lajeunesse PhD; Nanoscience, UNC Greensboro, Greensboro, NC.

Engineered nanoparticles have distinct physicochemical properties which enable their utilization in a variety of sectors from Biomedicine to Environmental remediation. Engineered nanoparticles interact with biological systems potentially changing the behavior of these systems by inducing specific physiological and metabolic modifications within the exposed organisms; furthermore, these responses to engineered nanoparticles may also differ from one organism to another. While a great deal of work has been done to identify lethal/antimicrobial nanomaterials to control pathogenic microbial biofilm formation, little work has been done to study non-lethal impact of nanomaterials of microbes. Moreover, the genetic impact of this cell-nanoparticle interaction is not well understood. We have defined the transcriptional genetic response of the gram-negative bacterium Escherichia coli (E. coli) to three different engineered silica, gold, and polystyrene nanoparticles. Screening an E. coli reporter gene library that covers 70% of the E. coli genome, we have identified eights genes that are upregulated in

response to nanoparticle exposure and possibly represent a common nanoparticle response mechanism. These eight genes have been verified using qRTPCR and include previously identified stress response genes (rssB, evgA, sodC,) genes encoding transports (yhdY, yhhT) and several genes with unknown function (glcC, vacJ/MlaA, cysQ). The gene ontology of the eight genes shows that metabolic pathways, signal transduction pathways, oxidative stress and protein transport systems are significantly affected in response to the three nanoparticle exposures. These results demonstrate that there is specific common response of E. coli to round-shaped metal oxide, metal, and polymeric nanoparticles. Overall, this research will provide a better understanding of bacteria stress response as well as bacterial resistance to nanoparticle-based antibiotics and identify potential new targets for drugs given that the bacteria-nanoparticle interactions have crucial implications in public health and the environment.

B269/P2659

Each individual promoter has a small region with a distinctive physical property

K. UEMURA, I. Hattori, T. Ohyama; Waseda University, Tokyo, JAPAN.

We previously reported that TATA box and initiator (Inr) sequences comprise distinctively flexible and rigid sequences when compared with the other parts of the promoter region (Fukue *et al*., *Nucl. Acids Res*., 2004). Interestingly, the same physical property lies in the transcription start site (TSS) in the case of "core-less" promoters that do not contain any known promoter elements (Fukue *et al*., *Nucl. Acids Res*., 2005). In addition, recently we found that the same is true for non-coding RNA promoters (Uemura *et al*., ASCB/EMBO meeting 2019). However, these findings were based on the averaged physical properties of promoters. Thus, it remains unsolved whether each individual gene has and uses such a distinctive physical property for transcription. The current study examined this issue. Using the data set on "high-confidence TSSs" defined by the FANTOM5 consortium, we classified human pol. II promoters into several groups. Those were largely divided into *cis*-element-containing promoters and core-less promoters. The former was further sub-grouped into 67 according to the species of *cis*-element. Interestingly, core-less promoters accounted for more than 60% of the total. We confirmed that in most cases even each individual gene has some distinctive physical property on or adjacent vicinity of the TSS, irrespective of the promoter type. Thus, regarding physical properties of promoter DNA, we could finally succeed to link average profiles to each individual profile. Here, we discuss genetic information written in not DNA sequence but physical properties of DNA.

B270/P2660

RNA G-Quadruplexes in PE/PPE genes of *Mycobacterium* regulate transcription

A. Kumar, P. Vivekanandan; Kusuma School of Biological Sciences, Insitute Institute of Technology Delhi, New Delhi, INDIA.

G-quadruplex structures play a crucial role in many cellular processes like transcription, translation, and replication. The RNA G-quadruplexes are thermodynamically more stable and can readily form due to their single-stranded configuration. The role of RNA G-quadruplexes in the prokaryotes remains poorly understood. In this study, we analysed 1624 complete bacterial genomes and coding sequences for putative quadruplex sequences (PQS). We found that the mycobacteria have significantly higher PQS densities in their genomes and the CDS. Interestingly, PQS enriched in the CDS was observed only in slow-growing pathogenic mycobacteria but not fast-growing or non-pathogenic mycobacteria. Of note, a majority (over 50%) of the PQS in the CDS of pathogenic mycobacteria mapped to PE/PPE gene family,

an essential class of *Mycobacterium* genes involved in pathogenesis and host immunity evasion. This is particularly important as the PE/PPE gene family is unique to pathogenic mycobacteria, and it represents an expanding family of genes (~10% of the CDS) in mycobacterial genomes, which are well-known for their genomic down-sizing during evolution. The PQS in the CDS of the PE/PPE gene family will also be present in the mRNA of the PE/PPE genes. Using RNA oligos for a selected subset of PQS from PE/PPE genes, we demonstrate their ability to form RNA G-quadruplexes in vitro using standard biophysical methods. The addition of BRACO-19, a G-quadruplex binding ligand, stabilized the quadruplexes. Further, BRACO-19 significantly inhibits the growth of pathogenic mycobacteria at low micromolar concentrations. This effect was less pronounced on non-pathogenic mycobacteria, suggesting a role for RNA G-quadruplexes in regulating mycobacterial growth. To understand the biological role of RNA G-quadruplex in mycobacteria, we used BRACO-19 in log phase cultures of *Mycobacterium tuberculosis* H37Ra, in vitro transcription and heterologous expression in *E. coli*. Our results suggest that the stabilization of RNA G-quadruplexes in the PE/PPE genes of pathogenic mycobacteria inhibits transcription resulting in reduced levels of PE/PPE protein expression. Taken together, our findings suggest that RNA G-quadruplexes in mycobacterial genomes may regulate transcription and growth dynamics among pathogenic mycobacteria. In sum, this work highlights how RNA G-quadruplex containing genes may contribute to pathogenesis and virulence of mycobacteria and lays the groundwork for understanding the biological role of RNA G-quadruplexes in prokaryotes.

B271/P2661

Carnivory of the protocarnivorous plant *Roridula*

N. Arai[1], T. Ochiai[2], H. Doi[3], T. Ohyama[2]; [1]Kanagawa University, Yokohama, JAPAN, [2]Waseda University, Tokyo, JAPAN, [3]Hyogo Prefectural Flower Center, Hyogo, JAPAN.

Carnivorous plants have adapted themselves to the nutrient-deficient habitats. They can obtain nitrogen and phosphate from insects for amino acid and nucleotide syntheses. Many studies have been performed to clarify the mechanisms underlying formation of trap leaves and nutrient absorption, repertoire of the enzymes in the digestive fluid, and expression specificity of the corresponding genes. However, it is still enigma how carnivorous plants have evolved from non-carnivorous plants. We focused on a protocarnivorous plant *Roridula* to elucidate the evolutionary process of carnivorous plants. Most carnivorous plants use their own systems to break down their prey and absorb the degradation products. On the other hand, *Roridula* depends on symbiontic bugs of the genus *Pameridea* to get nutrients from the prey: *Pameridea* eats the prey trapped on the *Roridula* leaves and its feces dropped on the ground help the plant to grow. Using glandular tentacles on the trap leaves of *R*. *dentata* and *R. gorgonias* and mucus secreted from them, we performed transcriptome and proteome analyses. Contrary to the preceding reports, we found that the mucus of each plant contains a few digestive enzymes that are commonly found in the digestive fluid of carnivorous plants. Furthermore, the genes encoding hydrolytic enzymes and transporters were found to be highly expressed in the glandular tentacles. These results may strongly suggest that *Roridula* is a carnivorous plant, though further studies are still required to clearly substantiate its carnivory. In this meeting, we will compare *Roridula* with canonical carnivorous plants and discuss how plants have evolutionary acquired carnivory.

B272/P2662

Polyploidy is essential for high rates of biosynthesis in the *C. elegans* intestine

A. Lessenger, J. Feldman; Biology, Stanford University, Stanford, CA.

The maximum production of biological molecules in a system, called its biosynthetic capacity, increases as cells proliferate and organisms grow, but how this capacity is determined is poorly studied outside of unicellular contexts. RNA and protein become more dilute when cells expand in volume without proportional replication of DNA, indicating that the biosynthetic capacity of cells is ultimately limited by the number of genomes. Proliferating cells can maintain the ratio between DNA and cytoplasm by coupling cell cycle entry to an increase in cell volume. However, many cells types in multicellular organisms can increase their biosynthetic capacity without cell division by becoming polyploid, a condition where cells have many copies of the genome. Using the multicellular model, *C. elegans,* we show that **polyploidy is critical to maintaining normal levels of organ growth and biosynthesis.** Artificially lowering the DNA/cytoplasm ratio by reducing polyploidization in the intestine causes these cells to become smaller and have more dilute RNA. This limitation does not appear to affect the growth of other tissues, but severely impairs fitness by reducing brood size and causing a developmental delay in the F1 generation. We performed RNA sequencing to understand whether DNA content was equally limiting to the production of all transcripts. Instead, we found that the most highly expressed genes are most severely limited by reduced DNA content, suggesting that their promoters may be near maximum occupancy by polymerase under normal conditions. In contrast, most other genes increase the number of transcripts produced by each genome. Surprisingly, we did not find evidence for upregulated production of transcriptional machinery, but do observe a significant upregulation of the production of translational machinery. Together, these data support a model where total transcription of most genes is limited to maintain balance with the most highly expressed genes. Future work will investigate whether these transcriptional changes translate to the protein level, and how these changes mechanistically reduce fitness.

B273/P2663

Annotation of Genes and Genomic Elements in Contig 48 of *Drosophila kikkawai*

N. Connolly[1], T. Sadikot[2]; [1]Biology Department, Washburn University, Topeka, KS, [2]Biology, Washburn University, Topeka, KS.

The genome of *Drosophila melanogaster* has been a highly studied genome in biology for the past twenty years. *D. melanogaster* is a model organism for studying the developmental and cellular processes common in other eukaryotes. This project will use *D. melanogaster* genome as a reference for identifying genes and genomic elements in other *Drosophila* species. The analysis of the sequences and data collection will be done using open-source computational genomic tools for sequencing, gene-prediction, and genome browsing. The resources used during this project have been obtained through the Genomic Education Partnership (GEP). GEP is a bioinformatics program that is sponsored by Washington University, in St. Louis. The analysis and interpretation of the *Drosophila* genome requires screening of the sequence of interest, gene markers, and a comparison of predicted gene features using *D*. *melanogaster* as a reference. This project focuses on annotating an approximately 62,000 bp region of the *Drosophila kikkawai* genome which is predicated to have nine protein-coding genes. The validity of these predictions is tested using bioinformatics analysis.

Transcriptional heterogeneity in the giant, multinucleated placenta syncytiotrophoblast cell

M. M. Keenen, A. Thulluru, A. Skinkle, A. S. Gladfelter; UNC Chapel Hill, Chapel Hill, NC

During pregnancy, the placenta facilitates the transport of nutrients, oxygen, and hormones between the pregnant person and fetus. The cellular interface between the maternal and fetal vasculature is the multinucleated syncytiotrophoblast (STB), a giant tissue-sized single cell. The STB wraps around the entire surface of the placenta encasing it with one common cytoplasm containing billions of nuclei. This giant cell must not only facilitate the exchange of nutrients, but is essential for fetal immunosuppression, is the primary producer of pregnancy peptide and steroid hormones and performs essential metabolic functions. To accomplish these diverse functions in a single cell, the STB appears to spatially organizes its cytoplasm for specific and distinct local functions. For instance, hormones are produced in cytoplasmic regions that exhibit high rates of translation and secretion and contain many transcriptionally active nuclei. In contrast, areas adjacent to the fetal vasculature have a narrower cytosol to facilitate diffusion and express vasculature growth factors. We hypothesize neighboring nuclei can express differential gene expression programs despite being bathed in a common cytoplasm, enabling distinct spatial organization of the STB cytosol. To test this, we utilize single molecule RNA FISH of primary human placenta tissue. We find that the RNA of pregnancy peptide hormones (hCG, hPL) and vasculature receptors (FLT, PLGF) are all heterogeneously expressed in syncytial nuclei, with high expressing nuclei adjacent to nuclei with little or no expression. Further, the transcription factors involved in STB hormone expression, including GCM1 and CREB, also exhibit differential enrichment in STB nuclei implicating their localization with heterogenous hormone transcription. Finally, we apply single nucleus RNA sequencing to measure the degree of transcriptional heterogeneity at a genomic scale within the STB. This work provides mechanistic, molecular insights into how this essential and massive multinucleate cell is functionally organized to support human life.

Bioinformatic prediction revealed the potential effects of *THBS1* mutation on liver fibrosis and inflammation

Q. Lin[1], C. S. Tang[1], P. H. Chung[1], V. C. Lui[1], P. K. Tam[1,2]; [1]Department of Surgery, Li Ka Shing Faculty of Medicine, The University Of Hong Kong, Hong Kong, HONG KONG, [2]Faculty of Medicine, Macau University of Science and Technology, Macao, MACAO.

Biliary atresia (BA) is a rare, life-threatening inflammatory disease of the liver and bile ducts that occurs in newborns. Patients with BA may develop profound liver fibrosis, leading to liver transplantation. We performed whole genome sequencing on the patients with BA and their unaffected parents. Bioinformatic analysis, including protein-protein interaction network and hub genes analysis, identified *THBS1* (Thrombospondin 1) as the most vital hub gene of the candidate disease-causing genes of BA. Here, we identified a compound heterozygous variant in one BA trio. Protein structure perdition using AlphaFold and SWISS-MODEL suggested that the compound heterozygous variant on *THBS1* could affect the tertiary structure, stability, or calcium ions environment of THBS1. From the RNA-seq data, we observed differential expression between BA patients and normal controls of *THBS1* in the human liver (Luo et al. 2019). Moreover, we also observed abnormal expression of *THBS1* in the murine model of biliary atresia from a previously published paper (Bessho et al. 2014). To investigate the potential mechanism of cell activities on BA, we applied the gene deconvolution method to impute cell type-

specific expression from bulk RNA-seq data of BA and normal controls. Notably, *THBS1* showed dysregulation in BA samples in hepatocytes and inflammatory macrophages. Together with a literature review on *THBS1*, we hypothesized that dysregulation of *THBS1* and its associated pathways would promote liver fibrosis and inflammation, contributing to the etiology and progression of BA.

Variability of Human rDNA and Transcription Activity of Ribosomal Genes

N. Chmurciakova[1], E. Smirnov[1], J. Kurfurst[2], F. Liska[1], D. Cmarko[1]; [1]Institute of Biology and Medical Genetics, First Faculty of Medicine, Charles University, Prague, CZECH REPUBLIC, [2]Institute of Organic Chemistry and Biochemistry of the CAS, Prague, CZECH REPUBLIC.

Human ribosomal DNA (rDNA) is represented by multiple repeats in each cell. Every repeat consists of a 13 kb long part with genes encoding 18S, 5.8S and 28S rRNAs as well as a 30 kb long intergenic spacer (IGS). However, transcription does not take place in all repeats. The transcriptionally active genes are characterized by the epigenetic marks of the active chromatin, including hypomethylation of the promoter and adjacent IGS areas. But it is still unknown what causes the differentiation of the genes into active and silent. In this study we examine whether this differentiation is related to the nucleotide sequence of IGS. We isolated rDNA from nucleoli of human fibrosarcoma cells (HT1080) and separated methylated and non-methylated DNA by chromatin immunoprecipitation. Then we used PCR to amplify a 2 kb long region upstream of the transcription start and sequenced the product. We found a significant sequence variability represented by single nucleotide variations (SNV), short insertions and deletions. Six SNVs correlated with the DNA methylation status. Additionally, there was significant correlation between the methylation status and the number of certain simple (tetrameric) repeats, favourable for the formation of G-quadruplexes. These data indicate that IGS structure is involved in the differentiation of ribosomal genes into active and silent. Moreover, one of the discovered SNVs belongs to a known micro-RNA (miR) gene involved in cancer related pathways. Two other SNVs are situated in the regions well matched with miRs produced in other parts of genome. Thus, our data suggest a number of pathways that may connect variations of rDNA sequence with its transcription activity.
This work was supported by the Grant Agency of Czech Republic (19-21715S) and by the Charles University (program Cooperatio - Oncology and Haematologhy).

Comparing Neuronal Splicing Events in Spinocerebellar Ataxias and Myotonic Dystrophy

C. E. Pritchard[1], A. Aliyeva[2,3], C. D. Lennon[2], E. E. Davey[2], C. C. DeMeo[2], J. M. Velez[2], A. Mascorro[2], J. D. Cleary[2], H. K. Shorrock[2], J. A. Berglund[2,3]; [1]Department of Biological Sciences, Lehigh University, Bethlehem, PA, [2]RNA Institute, University at Albany, Albany, NY, [3]Department of Biological Sciences, University at Albany, Albany, NY.

Spinocerebellar ataxias (SCA) are autosomal dominant neurodegenerative diseases defined by cerebellar degeneration and movement issues, notably balance and coordination, but also muscle spasticity, weakness and peripheral neuropathy. SCAs are genetically heterogeneous with several types caused by CAG repeat expansion mutations in different genes (e.g., SCAs 1-3, 6, 7 & 12). In many of these disorders, the CAG expansion is translated into polyglutamine (Q) expansion proteins, although the pathogenic role of these polyQ proteins is not well understood. In contrast, the mechanism of disease pathogenesis is relatively well understood for the CTG repeat expansion disease myotonic dystrophy

type 1 (DM1). DM1 is an autosomal dominant neurodegenerative disease defined by myotonia, muscle weakness and wasting as well as multisystemic complications. In DM1, CTG expansions within the *dystrophia myotonica protein kinase* (DMPK) gene are transcribed into CUG repeats, which sequester RNA binding proteins (RBPs), leading to mis-regulation of alternative splicing and other RNA processing defects. While widespread alternative splicing dysregulation has also recently been reported in Huntington's disease (another CAG repeat expansion disorder), similar alternative splicing defects have not been widely investigated in CAG expansion SCAs. In this study, we used conserved neuronal splicing events as a metric to assess potential interplay between these CAG/CTG repeat expansion disorders. Using data from both cellular and animal models of DM1 and CAG expansion SCAs, we identified widespread dysregulation of alternative splicing in each dataset. Skipped cassette exon events represented the majority of all alternative splicing events and accounted for over 50% of all event types in each dataset. Pairwise gene ontology analysis and interaction network visualization revealed interaction groups that shared enriched terms related to neuron development and function. Overall, this work supports neuronal spliceopathy as a common feature between these CAG/CTG repeat expansion disorders.

B278/P2668

Chromatin-mediated hypoxic stress response by Set4 in *S. cerevisiae*

W. Sun[1,2], Y. Jethmalani[1], M. Negesse[1], I. Justice[1], S. Amos[1], E. Green[1,2]; [1]Biological Sciences, University of Maryland-Baltimore County, Baltimore, MD, [2]Biochemistry and Molecular Biology, University of Maryland, Baltimore, Baltimore, MD.

Stress responses in yeast are often mediated by changes in gene expression that allow the cells to adapt to the new environment. This dynamic signaling occurs through changes in transcriptional regulation, often dependent on chromatin. Set4 is a chromatin-associated protein that is protective in oxidative and hypoxic stresses. Set4 protein is lowly expressed under normal conditions, but under hypoxic conditions its expression is induced. Set4 is part of the SET domain family of lysine methyltransferases but appears to lack catalytic activity. Besides its paralog Set3 in yeast, there are other orthologs that share this feature: Set-9 and Set-26 in *C. elegans*, UpSET in *D. melanogaster*, and MLL5 and SETD5 in mammals. The mechanism by which Set4 promotes survival under hypoxic stress has yet to be determined. Set4 regulates expression of subtelomeric genes, including stress response genes and cell wall components such as the *PAU* family, which are known to be highly induced under hypoxia. We have shown that loss of *SET4* leads to changes in local chromatin environment in hypoxia, including an increase in H3K9ac in regions where Set4 localizes during hypoxic stress. This correlates with our observation that loss of *SET4* affects the localization of the histone deacetylase Rpd3 and chromatin-associated component of the SIR complex, Sir3, at stress-induced genes. Set4 appears to work, at least in part, through regulating the activity of the transcription factor Upc2. Interestingly, Upc2 controls Set4 expression, suggesting a feedback loop regulating stress response gene expression. Here, we will present our current model on Set4 interactions with other chromatin modifiers and transcription regulators at stress response genes. Altogether, this work provides insight into potential players that may be involved in the role of Set4 during hypoxic stress and identifies new chromatin regulatory pathways that may be controlled by related proteins in other organisms.

Analysis of Genes in the Initial Interaction of Global Genomic Nucleotide Excision Repairin Zebrafish

J. Sanchez, N. Goerner, E. E. Gestl; Biology, West Chester University, West Chester, PA.

DNA replication occurs in all living organisms and is essential for the passing down of genetic information. As a complex mechanism, it is prone to errors that the cell must be able to fix to stay alive. The Global Genome-Nucleotide Excision Repair (GG-NER) pathway works to fix bulky damage such as those caused by UV light. The GG-NER pathway consists of proteins that are recruited and interact with the damaged DNA site including DDB1, DDB2, CETN2, HR23B, XPA, and XPC the were studied in zebrafish. The zebrafish's genome contains all the NER genes, similar to humans that were studied. RNA samples were collected from 1 to 24 hours after treatment with UV light as well as untreated RNA. The highest amount of was used for further experiments utilizing zebrafish that were either treated with UV light, caffeine, or both in combination. Developmental expression of the genes was also analyzed throughout the zebrafish lifetime of 2 hours to 10 years of age.

B280/P2670

Analysis of Transcription-Coupled Nucleotide Excision Repair Genes in Zebrafish

B. Hanson, N. Detweiler, E. Gestl; Biology, West Chester University, West Chester, PA.

This project was designed to examine the expression of genes involved in the process of Transcribed-Coupled Nucleotide Excision Repair in zebrafish. The RNA levels of CSA, CSB, XAB2, MMS19, UVSSA, and USP were measured via qPCR at various time increments after the completion of the UV treatment up to 24 hours following treatment. Treatments involving both UV light and caffeine were also carried out. In addition, RNA was collected from zebrafish from 2 hours to 10 years of age and the expression levels analyzed to determine correlation with age. Zebrafish were utilized as a model system since they have all the counterparts to the human NER process. The embryos are transparent, making it easier to observe their internal structures and can be isolated in large numbers necessary for this type of experiment.

Chromatin and Chromosome Organization

Oncogenic lncRNAs alter epigenetic memory at a fragile chromosomal site in human cancer cells

G. Arunkumar, S. Baek, D. Sturgill, M. Bui, Y. Dalal; Center for Cancer Research, National Cancer Institute/NIH, Bethesda, MD.

Chromosome instability is a key event in cancer progression. The essential histone H3 variant CENP-A plays a fundamental role in defining centromere identity, structure, and function, but is innately overexpressed in several types of solid cancers. In the cancer background, excess CENP-A is deposited ectopically on chromosome arms, including at the 8q24/*cMYC* locus, by invading transcription-coupled H3.3 chaperone pathways. Intriguingly, in many cancers, transcription of lncRNAs is upregulated and correlates with poor prognosis, therapeutic resistance, and cancer recurrence in patients. Here, we report that the transcription of chromosome 8q24-derived oncogenic lncRNAs plays an unanticipated role in altering the chromatin landscape of the 8q24 locus. We report that transcription of oncogenic ncRNAs and associated R-loop formation at the 8q24 genomic locus results in the recruitment of H3.3

chaperone-CENP-A histone variant complexes to 8q24. Finally, we demonstrate that a transgene cassette which encodes a specific oncogenic lncRNA from the 8q24 region integrated into a naïve chromosome locus, recruits CENP-A to the new location specifically in a *cis*-acting manner. These data provide a plausible mechanistic link between locus-specific oncogenic lncRNAs, aberrant local chromatin structure, and the generation of new epigenetic memory in human cancer cells.

Super-silencers regulated by chromatin interactions control apoptotic genes

Y. Zhang[1], K. Chen[2], Y. Cai[1], A. Nambu[1], Y. See[2], C. Fu[3], A. Raju[4], M. Lakshmanan[4], M. Osato[1], V. Tergaonkar[4], **M. J. Fullwood**[2]; [1]Cancer Science Institute of Singapore, Singapore, SINGAPORE, [2]School of Biological Sciences, Nanyang Technological University, Singapore, SINGAPORE, [3]Mechanobiology Institute, Singapore, SINGAPORE, [4]Institute of Molecular and Cell Biology, Singapore, SINGAPORE.

Human silencers have been shown to exist and regulate developmental gene expression. However, the functional importance of human silencers needs to be elucidated such as the working mechanism and whether they can form “super-silencers”. Here, through interrogating two putative silencer components of *FGF18* gene, we found that two silencers can cooperate via compensated chromatin interactions to form a “super-silencer”. Furthermore, double knock-out of two silencers exhibited synergistic upregulation of *FGF18* expression and changes of cell identity. To disturb the “super-silencers”, we applied combinational treatment of an EZH2 inhibitor GSK343, and a REST inhibitor, X5050 (“GR”). We found that GR led to severe loss of TADs and loops, while the use of just one inhibitor by itself only showed mild changes. Such changes of TADs and loops may due to reduced CTCF protein level observed upon GR treatment. Moreover, GSK343 and X5050 worked together synergistically to upregulate the apoptotic genes controlled by super-silencers, and thus gave rise to antitumor effects including apoptosis, cell cycle arrest and tumor growth inhibition. Overall, our data demonstrated the first example of a “super-silencer” and showed that combinational usage of GSK343 and X5050 could potentially lead to cancer ablation through disruption of “super-silencers”. Taken together, our results suggest that the usage of combination treatment to target super-silencers and 3D genome organization should be further researched as a potential future cancer therapy.

***In situ* 3-D analysis of transcriptionally repressed yeast nuclei by cryo-ET**

C. Y. Y. Chong, J. K. Chen, S. Cai, J. Shi, **L. Gan**; National University of Singapore, Singapore, SINGAPORE.

The relationship between 3-D chromatin structure and transcription is poorly understood *in situ*. Recent advances in both imaging and acute perturbation make it possible to study changes in transcription and large-scale changes in chromatin packing at the molecular (~ 4 nm) level inside cells. Namely, cryo-electron tomography (cryo-ET) of cryogenically thinned frozen-hydrated cells can reveal the 3-D organization of macromolecular complexes inside cell nuclei in a minimally perturbed life-like state without the artifacts associated with fixation and staining. Inducible knockdowns by the anchor-away and auxin-inducible-degron systems can rapidly perturb the function of essential genes of yeasts. Using cryo-ET, we recently found that in unperturbed budding yeast *S. cerevisiae*, less than 10% of the nucleosomes have the canonical form (146 base pairs of DNA wrapped in ~ 1.7 left-handed turns in a 10 x 6 nm particle) *in situ*. The majority of the nucleosome-like particles are so heterogeneous that they cannot be classified into a canonical structure. This heterogeneity is consistent with other studies and

with the notion that the yeast genome is largely “open” in a euchromatic state. In contrast, canonical nucleosomes are abundant and therefore easily located *ex vivo* in lysed nuclei. Here we use cryo-ET to test the hypothesis that transcription by the highly abundant RNA polymerase II (RNAPII) is responsible for the low abundance of canonical nucleosomes *in situ*. We imaged the 3-D organization chromatin in a temperature-sensitive strain, an anchor-away strain, and an auxin-inducible-degron strain - all of which allow rapid inactivation of RNAPII function. In all three strains, non-canonical nucleosomes remained the majority species after RNAPII knockdown. Furthermore, comparison with unperturbed cells shows that the 3-D packing of nucleosome-like particles does not undergo large changes after transcription shutoff. Our work shows that RNAPII transcription does not radically alter yeast chromatin organization at the mono- or oligonucleosome level *in situ*. Future work that combines genetic perturbation and *in situ* cryo-ET will be done systematically to reveal the factors responsible for the highly open state of yeast chromatin.

B284/P2674

SUMOylation-mediated phase separation drives APB formation and telomere clustering in parallel in ALT cancer cells

R. Zhao[1], D. Chenoweth[2], H. Zhang[1]; [1]Department of Biological Sciences, Mellon College of Science, Carnegie Mellon University, Pittsburgh, PA, [2]Department of Chemistry, School of Arts and Sciences, University of Pennsylvania, Philadelphia, PA.

In telomerase-free cancer cells that employ an alternative lengthening of telomeres (ALT) pathway for telomere maintenance, PML bodies are mislocalized to telomeres to form ALT telomere-associated PML bodies (APBs). APBs contain DNA repair factors and telomere clusters to promote homology-directed telomere DNA synthesis and are potential therapeutic targets. We previously reported that mimicking SUMOylation on ALT telomeres with a chemical dimerization system drives phase separation to form APBs and cluster telomeres. However, how APBs are formed by SUMOylation mediated phase separation and whether enrichment of DNA repair factors and telomere clustering depends on APB formation is not clear yet. To answer these questions, we followed PML bodies in live cells after recruiting SUMOs to telomeres with our dimerization system. We found APBs can form through two pathways: nucleation of de novo PML bodies on SUMOs coated telomeres or fusion of existing PML bodies with SUMO coated telomeres. In addition, we observed three types of telomere clustering: SUMO-coated telomeres fuse, SUMO-coated telomeres fuse with APBs, and APBs fuse. The ability of SUMO-coated telomeres to fuse without APB formation implies PML independent phase separation after SUMOylation. Indeed, recruiting SUMOs to telomeres in PML knock-out cells enriched DNA repair factors such as BLM to promote PML-independent phase separation and telomere clustering. In addition, telomere clustering is not affected by PML deletion when telomere-fused nuclease is used to trigger the ALT pathway. However, in the endogenous ALT cancer cells, when only a small number of telomeres are SUMOylated, PML is required for both enrichment of SUMOs on telomeres and telomere clustering. Our results show that SUMOylation-mediated phase separation drives APB formation and telomere clustering in parallel rather than sequentially, though the former can promote the latter. Supporting the importance of SUMOylation in ALT, we observe that SUMO inhibition leads to less telomere DNA synthesis, more telomere shortening, and less colony formation in ALT cells but not non-ALT cells, suggesting SUMOylation can be a potential target for ALT cancer therapy.

B285/P2675

Role of Hox Gene *Ultrabithorax* in Wing Differentiation in Butterflies and Moths

A. Tendolkar, K. van Horne, C. Heryanto, A. Mazo-Vargas, A. Martin; The George Washington University, Washington, DC.

The origin and evolution of *Hox* genes were key for the diversification of animal body plans.These deeply conserved developmental genes are organized in the genomes as serial homologs in bilateral animals. *Hox* genes trigger segment-specific signaling networks that establish the fate of the different regions of the embryo. Mutations in these genes result in homeosis - loss of one body identity and gain of another. Our research focuses on the *Hox* gene *Ultrabithorax* (*Ubx*)and its role in insect wing diversification. Fore and hind wings show morphological differences among insect orders - balancing halteres in flies, protective hardened shells in beetles and intricate patterns in butterflies. In insects, *Ubx* is expressed in the third thoracic segment and is responsible for the ontogenesis of the hindwing. Role of *Ubx* in hindwing differentiation has been studied in flies, beetles and planthoppers; however,description of its role in butterflies and moths is limited. We used CRISPR targeted mutagenesis to generate *Ubx* loss-of-function somatic mutations in two nymphalid butterflies (*Junonia coenia*,*Vanessa cardui*)and a pyralid moth (*Plodia interpunctella*). The resulting mosaic clones yielded hindwing-to-forewing transformations in scale shape and size, color patterns, and wing venation and structure. Additionally, in the moth *P. interpunctella*, loss of *Ubx* generated ectopic forewing secondary sexual traits on the hindwing, showing that *Ubx* is necessary for specifying many aspects of hindwing-specific identities. Our study establishes *Ubx* as the micromanager of hindwing identity, a result that parallels observations in other insects. To tease apart the different functions of *Ubx* in hindwing differentiation, we used ATAC-seq to identify putative regulators of *Ubx* and used CRISPR-Cas9 for functional testing. We are currently attempting to generate enhancer knock-out lines to characterize *Ubx* expression in mutants. Taken together, our study will provide insight into the different aspects of lepidopteran hindwing that Ubx controls and contribute knowledge to compare lepidopteran hindwing development with other insects.

B286/P2676

Computational predictions of 3D hubs of chromatin many-body interactions uncover physical scaffolds for regulation of gene expression

H. Farooq, L. Du, A. Perez-Rathke, K. Chronis, J. Liang; University of Illinois At Chicago, Chicago, IL.

Chromatin 3D organization plays important roles in the regulation of gene expression. However, Hi-C captures only population-averaged pairwise contact frequencies and does not detect higher-order many-body interactions. Here we use CHROMATIX, a computational method which reconstructs ensemble of single-cell chromatin conformations by deconvolving Hi-C data to detect enrichment of many-body interactions. We generate large ensembles (2x104) of independent 3D single-cell chromatin conformations using population Hi-C data. Our single-cell models reproduce imaging, Dip-C, and 3D FISH single cell measurements. In addition, the aggregations of single-cell chromatin models are also in strong agreement with population Hi-C measurements. The reconstructed ensembles of single-cell chromatin structures enable us to discover 3D hubs of higher-order many-body interactions across hundreds of loci in B-lymphocyte cells. We illustrate the functional roles of 3D hubs of many-body interactions in regulating gene expression using the example of eQTL associated genes. We show higher- order 3D hubs of gene and eQTLs provide the physical basis of differential gene expression, with examples of hubs of 1-gene-to-many-variants and many-genes-to-1-variant. Overall, our results show 3D chromatin many-body

hubs are important for gene expression, and they can be discovered through computational modeling of ensembles of single-cell 3D chromatin conformations using population Hi-C data

B287/P2677

Live cell quantification of telomere length in single cell using CRISPR-based imaging

K. Lanning, L. Bowling, K. Bellingham-Johnstun, B. Levesque, C. Laplante; MBS, North Carolina State University, Raleigh, NC.

Telomeres are heterochromatin regions of repetitive DNA sequences that protect the ends of chromosomes. Therefore their length and structure are critical for cellular functions. However, the local structural organization of telomeres remains mostly unknown owing to the lack of methods to measure chromatin organization in living cells. We developed a quantitative platform to measure the length of telomeres in live cells using a combination of fluorescence microscopy and a nuclease-deficient Cas9 (dCas9) chromatin labeling method. Our approach is based on a calibration method developed to measure the concentration of proteins in living fission yeast cells. We modified this method to measure the local concentration of dCas9-3xmEGFP bound to guide RNAs (gRNAs) that recognize repeats of the TTAGGG telomeric sequences of U2OS and HeLa cells. Binding of dCas9-3xmEGFP to gRNAs tiled along telomeres resulted in dozens of bright fluorescent foci across the nuclei of both types of cells. In single U2OS cell, the fluorescence intensity and the size of telomeric foci varied greatly. In contrast, in HeLa cells, the foci were smaller and their fluorescence intensity more consistent. Using our quantification method, we measured a broad rage in the local concentration of dCas9-3XmEGFP (0.1 to 5.1 μM, with a mean of 1.3 ± 0.9 μM) per telomere In U2OS cells. Consistent with our observations, we measured a narrower range of dCas9-3XmEGFP concentration (0.3 to 1.0 μM, with a mean of 0.5 ± 0.2 μM) per telomere in HeLa cells. We converted these local concentration values to number of dCas9 polypeptides per telomeric foci. Assuming non-overlapping binding of the gRNAs along the DNA sequences, these numbers of dCas9 per telomere represent a length of DNA of 5.8 to 296.1 Kb (mean of 72.5 ± 50.4 Kb) for telomeres in U2OS cells. These values agree with current estimations of telomere lengths of 5 to 150 kB for U2OS cells. In HeLa cells, our calculated numbers of dCas9 per telomere represent lengths of DNA ranging from 7.2 to 24.9 Kb (mean of 12.3 ± 5.6 Kb). Therefore, U2OS cells show a wide range in the length of telomeres while HeLa cells have more consistent and shorter telomeres. We applied our image analysis platform to the study of repetitive chromatin sequences in living cells. With appropriate adaptations, this system could also be used for investigating unique DNA sequences within the genome thus opening the door to understanding dynamics of chromatin state and compartmentalization in single cell.

B288/P2678

Functional Chromatin Spatial Interactions Provide 3D Basis for Gene Expression and Their Discovery through Integrated Analysis of 3D Single-cell Chromatin Ensemble Modeling and Epigenetic Marks

L. Du[1], H. Farooq[1], K. Chronis[2], J. Liang[1]; [1]Richard and Loan Hill Department of Biomedical Engineering, University of Illinois Chicago, Chicago, IL, [2]Department of Biochemistry and Molecular Genetics, University of Illinois Chicago, Chicago, IL.

Three-dimensional structures of chromatin play important roles in gene regulation and in nuclear function. Hi-C measurements have provided a wealth of information on chromatin interactions. Emerging evidence suggests functional chromatin interactions, including promoter-enhancer

interaction, are related to gene expression. However, gene promoters and their regulatory elements can be separated by 10^3-10^6 base pairs apart. Therefore, examining 3D chromatin conformations and identifying functionally important spatial long-range interactions are important for deciphering the structure-function relationship of 3D genome. Our recent work of the CHROMATIX deep sampling algorithms can identify non-random chromatin polymer interactions. Despite being 5-7% of total Hi-C counts, they can be used for 3D chromatin folding. The large ensembles (5.0×10^4) of 3D single-cell chromatin conformations deconvolved from population Hi-C heatmap accurately reproduce both single-cell capture and imaging studies, as well as population Hi-C measurements. In this study, we examine predicted ensembles of single-cell 3D chromatin conformations of loci containing differentially expressed genes between myelogenous leukemia cancer cells K562 and normal lymphoblastoid cells GM12878. We have identified subsets of non-random chromatin interactions based on large random ensembles of 3D chromatin chains folded in confined nuclear volume using publicly available Hi-C data. These non-random interactions are used to generate folded ensembles of 5.0×10^4 single-cell 3D conformations for individual loci. We have further quantified the heterogeneity of 3D chromatin conformations by clustering, with each spatial cluster and its proportion defined. In addition, we have carried out integrated analysis of patterns of RNA-seq, ATAC-seq, and epigenetic data of these loci in K562 and GM12878 cells. Results from analysis of 33 gene-active loci show that functional chromatin spatial interactions provide 3D basis for gene expression, and subpopulations 3D chromatin conformations with larger radius of gyration are generally more active. Overall, functional interactions can be identified through integrated analysis of 3D single-cell chromatin ensemble modeling and patterns of epigenetic marks. Our results show that there are well-defined signatures of 3D subpopulations of chromatin conformations involving distinctive patterns of epigenetic marks, and these signatures are strongly associated with differentially expressed genes.

A targeted, transposase-mediated, RNA-DNA proximity-ligation sequencing technique to identify centromeric chromatin associated RNAs

K. A. Fryer, C. Limouse, A. F. Straight; Stanford University, Stanford, CA.

Establishing and maintaining chromatin organization is essential for genome stability and gene regulation. The tight control of this organization is mediated by interaction between proteins, the DNA sequence, and RNA. Mounting evidence suggests a crucial role for non-coding RNAs in regulating various aspects of chromatin architecture. To identify and map chromatin associated RNAs in a targeted manner, we have developed a transposase mediated RNA-DNA proximity ligation sequencing method. To link the genomic localization, and associated RNAs at a region of interest, we designed a biotinylated bridge sequence that allows for transposition into the genome at the 5' end and ligation of a nearby RNA to the 3' end. Transposition of the bridge is targeted via binding of the protein-A fused to the N-terminus of Tn5 transposase to an antibody bound to a protein of interest. Once transposed, nearby RNAs are then ligated to the 3' end of the bridge. Sequences containing the transposed bridge are selected via streptavidin bead binding and the RNA side is converted to cDNA resulting in a cDNA-bridge-DNA molecule that can then be sequenced using both NextGen sequencing and long read sequencing. We have implemented this method to identify RNAs associated with the centromere, a specialized chromatin domain that serves as the attachment site for microtubules during cell division. Centromeric chromatin is defined by the presence of nucleosomes containing the histone H3 variant, CENP-A. Assembly of CENP-A is orchestrated by several multi-protein complexes, many of which have been

shown to bind nucleic acid. CENP-A assembly is also influenced by neighboring heterochromatin environments. Previous studies have demonstrated a critical role for RNA binding by the histone methyltransferase, SUV39H1, which is responsible for depositing H3K9me3 at pericentromeric regions. However, the role of RNA at the centromere is not fully understood, in part due to the highly repetitive DNA sequence which precludes unique mapping of short read sequencing data. The method we have developed utilizes long read sequencing to allow for unique mapping of highly repetitive sequences and interrogation at the individual chromatin-RNA interaction level. Using this technique, we will be able to identify centromere associated RNAs and map their spatial organization within individual centromeres.

Resolving Cellular Heterogeneity through 3D Ensemble Models of Single-Cell Chromatin Conformations for Understanding Genome Structure-Function Relationship

J. Liang, H. Farooq, L. Du, P. Delafrouze, A. Perez-Rathke; Richard and Loan Hill Department of Biomedical Engineering, University of Illinois at Chicago, Chicago, IL.

Computational modeling of 3D chromatin plays important roles in understanding the principles of genome organization. We discuss a minimalistic approach towards polymer modeling and how it can be used to invert population Hi-C into high-resolution, high-coverage single-cell chromatin conformations. Utilizing only basic physical properties such as nuclear volume and no adjustable parameters, this model reveals that a few specific Hi-C interactions (15-35 for enhancer-rich loci in human cells) can fold chromatin into individual conformations consistent with single-cell imaging, Dip-C, and FISH-measured genomic distance distributions. Aggregating individual conformations also reproduces population Hi-C frequencies. Furthermore, this single-cell modeling approach allows quantification of structural heterogeneity and discovery of specific higher-order many-body units of spatial physical interactions. This minimalistic 3D chromatin model has revealed a number additional insights: 1) chromatin scaling rules are a result of volume-confined polymers; 2) TADs form as a byproduct of 3D chromatin folding driven by a few specific interactions; 3) cell subpopulations equipped with different chromatin structural scaffolds are developmental stage-dependent; and 4) quantification of the functional landscape and epigenetic marks of many-body units which are simultaneously spatially co-interacting within enhancer-rich, euchromatic regions. We also discuss the implications of these findings in understanding the genome structure-function relationship.

The SUN-family protein Sad1 interacts with the histone H2A-H2B dimer to mediate the spatial organization of heterochromatin through phase separation

Q. Dong[1], W. Sun[2], J. Gao[1], Y. Chen[3], **F. Li**[1]; [1]Department of Biology, New York University, New York, NY, [2]Shanghai Institute of Biochemistry and Cell Biology, Chinese Academy of Sciences,, Shanghai, China, [3]Shanghai Institute of Biochemistry and Cell Biology, Chinese Academy of Sciences, Shanghai, China

Heterochromatin generally associates with the nuclear periphery, but how the spatial organization of heterochromatin is regulated to ensure epigenetic silencing remains unclear. Heterochromatin in fission yeast preferentially assembles at peri-centromeres, telomeres, and the mating-type locus. Sad1, a conserved SUN (Sad1-UNC-84) family protein, associates with spindle pole body (SPB), responsible for tethering centromeres to SPB in fission yeast vegetative cells. Here, we demonstrated that Sad1 directly interacts with the histone H2A-H2B heterodimer. To our surprise, we found that in addition to its SPB

localization, Sad1 is also distributed throughout the nuclear envelope in a dynamic manner. The nuclear envelope distribution of Sad1 depends on its interactions with histone H2A-H2B. We further showed that the Sad1-H2A-H2B complex plays a critical role in the attachment of telomeres and the mating-type locus to the nuclear envelope by interacting with the inner membrane protein Bqt4. Our results demonstrated that Sad1 uses two different motifs at its N-terminus to regulate centromere clustering and the spatial positioning of telomeres and the *mat* locus. In addition, the complex is essential for heterochromatin silencing. We identified that Sad1-H2A-H2B interacts with HDACs, including Clr3 and Sir2, to mediate heterochromatin assembly. Interestingly, histone binding to Sad1 robustly induced the formation of liquid-like condensates, which facilitate recruitment of factors important for heterochromatin localization and assembly. We solved the crystal structure of the Sad1-histone complex, revealing the intimate contacts between H2B and an acidic motif of Sad1. Finally, we demonstrated that Sad1 can serve as a histone chaperone to promote nucleosome assembly. Our results revealed that the conserved SUN-domain protein Sad1 together with histone H2A-H2B serves as a previously unrecognized regulatory module to mediate the organization of heterochromatin at the nuclear periphery. Our results also indicated a nucleosome-independent role of histone H2A-H2B. Importantly, this study provides insight into how LLPS of proteins on the nuclear envelope impacts the spatial organization of chromatin domains.

B292/P2682

Nuclear Position Modulates Long-Range Chromatin Interactions

E. H. Finn[1], T. Misteli[2]; [1]Oklahoma Medical Research Foundation, Oklahoma City, OK, [2]National Cancer Institute, NIH, Bethesda, MD

The human genome is non-randomly organized within the cell nucleus. Spatial mapping of genome folding by biochemical methods and imaging has revealed extensive variation in locus interaction frequencies between cells in a population and between homologs within an individual cell. Commonly used mapping approaches typically examine either the relative position of genomic sites to each other or the position of individual loci relative to nuclear landmarks. Whether the frequency of specific chromatin-chromatin interactions is affected by where in the nuclear space a locus is located is unknown. We simultaneously mapped at the single cell level the interaction frequencies and radial position of more than a hundred locus pairs using high-throughput imaging to ask whether the location within the nucleus affects interactions frequency. We find strong enrichment of many interactions at specific radial positions. Position-dependency of interactions was cell-type specific, correlated with local chromatin type, and cell-type-specific enriched associations were marked by increased variability, sometimes without a significant decrease in mean spatial distance. These observations demonstrate that genome organization relative to itself and relative to nuclear landmarks are closely interwoven.

B293/P2683

Linker Histone condensates wet chromatid surface to modulate its nuclear amount

V. Murugesan[1,2], M. Rinaldin[1,2], T. Quail[1,2], M. Elsner[1,2], J. Brugues[1,2]; [1]Max Planck Institute for Molecular Cell biology and Genetics(MPI-CBG), Dresden, GERMANY, [2]Max Planck Institute for Physics and Complex Systems (MPI-PKS), Dresden, GERMANY.

Nuclear composition dictates nuclear function. However, controlling nuclear composition is challenging particularly in early development as the Nuclear-to-Cytoplasmic(N/C) ratio reduces exponentially. By

studying H1.8 incorporation in the nucleus in X. laevis extract, we uncovered an alternative mechanism to import that leads to nuclear enrichment. We observe that the linker histone H1.8 forms phase-separated condensates in the cytoplasm and the nucleus. Despite the enrichment inside the nucleus, we find that H1.8 is not imported across the nuclear membrane. Using live imaging, we demonstrate that H1.8 nucleates and forms condensates on the mitotic chromatids, prior to the formation of the nuclear envelope. These condensates wet the chromatids and are then sequestered into the interphase nucleus as the cell cycle progresses, resulting in the observed enrichment. We further show that cytoplasmic droplets help maintain a steady nucleation rate by buffering the soluble amount in the cytoplasm. Our findings show that the properties of droplet wetting on chromatid surfaces provide a robust mechanism to regulate nuclear composition independently of the N/C ratio.

B294/P2684

Coarsening of nuclear condensates is governed by the interplay between chromatin stiffness and condensate intermolecular interaction strength

D. Sankar Banerjee[1], **T. Chigumira**[1], J. Kratz[1], D. M. Chenoweth[2], S. Banerjee[1], H. Zhang[1]; [1]Carnegie Mellon University, Pittsburgh, PA, [2]University of Pennsylvania, Philadelphia, PA

Biomolecular condensates are implicated in many cellular processes. Growth dynamics and size control of condensates within the complex cellular environment and at time scales relevant to biological processes are therefore of great importance but are not well understood. To characterize the long-term growth dynamics of condensates in the nucleus, we used chemical tools to induce protein condensate formation and followed their growth for up to eight hours. Contrary to previous reports of mainly coalescence-based condensate coarsening due to suppression by the chromatin network, we observed ripening and continuous diffusion-based growth at long timescales. To explain these surprising observations, we developed a quantitative physical model and found that in addition to chromatin stiffness, condensate protein intermolecular interaction strength, which determines condensate properties such as fluidity, surface tension and partition coefficient, controls condensate growth. To test the model prediction that protein intermolecular interactions affect growth, we tracked the growth of condensates comprised of proteins with weaker intermolecular interaction strength. We observed a significant increase in the ripening fractions and rates, agreeing with model predictions. To test that condensate ripening is governed by the interplay between protein interaction strength and chromatin stiffness, we followed the growth dynamics of the two types of condensates in perturbed chromatin environments. We found that smaller variance in the chromatin stiffness within cells results in narrower condensate size distribution for both condensates and the effect is greater for condensates with weaker molecular interactions. This confirms that chromatin stiffness affects condensate growth, but that the extent of the effect depends on the strength of the protein interactions within the condensates. By combining theoretical modeling and experimental validation, our findings provide a new mechanism for condensate growth and size control in the nucleus to aid the understanding of condensate functionality and regulation.

B295/P2685

Condensation dynamics of sticky chromatin

A. R. Lamson[1], O. Troyanskya[1,2], M. Shelley[1,3]; [1]Flatiron Institute, New York, NY, [2]Princeton University, Princeton, NJ, [3]New York University, New York, NY

Multicellular organisms require cells to differentiate to perform specific tasks and functions even though every cell contains the information necessary to produce all cell types of that organism. Cells differentiate by regulating gene expression in various ways. One way is by forming DNA-protein condensates inside the nucleus. Certain condensates, such as heterochromatin, suppress gene expression while others, like transcription hubs, up-regulate gene expression in the surrounding nuclear region. Current biomolecular condensate models explain equilibrium properties, like size and stability, but lack dynamics. For example, rheological properties and collapse times for large lengths of chromatin remain poorly characterized or explained. To study such dynamics, we use a mixture of coarse-grained 3D Brownian dynamics and kinetic Monte-Carlo algorithms to model DNA and associated binding proteins. Our simulations reveal two ways 'sticky' filaments go from being uncondensed, to condensed at multiple locations, to having a single condensate populating the filament. The conformational path taken is determined by the protein-DNA binding kinetics, the protein density, and the filament slack. This work sheds light on DNA and chromatin fibers reorganization on time-scales physically relevant to the cell cycle and crucial for proper gene expression during events like cell division.

B296/P2686

Short-range chromatin structure in linker histone depleted cells

I. Duba, A. Clerkin, V. Risca; Rockefeller University, New York, NY

Chromatin structure is known to be a key regulator of gene expression and cellular function. Linker histone H1, a chromatin-binding protein known to condense chromatin in vitro, is essential in mammals and has profound effects on cellular function upon knockdown, ranging from compromised ability to differentiate in embryonic stem cells to an increase in malignant transformation of B cells. In embryonic stem cells, H1 depletion produces modest changes in gene expression, primarily at repeats. In B and T cells, it impacts genomic compartments and accessibility in heterochromatin. Extensive *in vitro* work shows that H1 causes nucleosome arrays to adopt more compact conformations, but how this translates to locus- and epigenetic state-specific regulation of sub-kilobase chromatin structure in cells has not been fully characterized. To probe the role of H1 in shaping short-range chromatin structure, we performed Micro-C, a nucleosome-resolution proximity ligation-based assay, in the human leukemia cell line K562 with and without depletion of H1. We find that, genome-wide, the contact probability curve of control (WT) cells exhibits enriched contacts between a nucleosome and its third nearest neighbor and fifth nearest neighbor. This pattern is lacking in the H1-depleted cells, which instead show a monotonic decrease of nucleosome contact probability with genomic distance. Within each sample, comparing heterochromatin (enriched for H1) and promoter regions (depleted of H1), a similar pattern of contact probability is observable. This H1-dependent contact probability pattern is likely indicative of an underlying chromatin folding motif promoted by H1 in which N/N+3 and N/N+5 contacts are favored. We are currently investigating how these changes relate to chromatin's accessibility to the nuclease and what contact patterns would be predicted from simulated chromatin structures. The finding that H1 promotes a chromatin fiber structure across multiple contexts represents a step toward understanding the structural impact H1 has on chromatin *in situ*.

B297/P2687

Imaging-based CRISPR Knockout Screen Identifies Regulators of Centromere Clustering

K. Guin, A. Keikhosravi, L. Ozbun, G. Pegoraro, T. Misteli; National Cancer Institute, National Institutes of Health, Bethesda, MD

Centromeres are specialized genomic loci that assemble the multi-protein kinetochore complex, which interacts with the spindle apparatus and ensures faithful chromosome segregation during cell division. Centromere function is highly conserved in most eukaryotes although centromere DNA sequences and the structure of kinetochores can be diverse across species. Centromeres appear non-randomly localized in the 3D space of the cell nucleus. While in most yeasts all centromeres form a single cluster at the nuclear periphery, multiple heterochromatin embedded clusters of centromeres, known as chromocenters, are observed in *Drosophila* and mice. In human cells clustering is less pronounced, but some centromeres tend to cluster near the nucleolus. The molecular mechanisms that determine the location and extent of clustering of centromeres in 3D space are largely unknown. By quantitatively measuring the degree of centromere clustering, we find cell-type specific differences in the localization patterns of human centromeres. For example, HCT116 colon cancer epithelial cells tend to have a central arrangement of centromeres while centromeres are well distributed in hTERT-RPE1 retinal epithelial cells. To address the molecular mechanisms of cell-type specific centromere clustering patterns, we performed an arrayed high-throughput CRISPR knockout screen for 1068 chromatin associated proteins in HCT116 and hTERT-RPE1 cells. Our data suggest cell-type specific as well as conserved role of chromatin-associated proteins regulating centromere clustering. These experiments are providing novel insights into mechanisms of higher order genome organization.

B298/P2688

Polymer modeling reveals interplay between physical property of DNA and the size and distribution of condensin-based chromatin loops

D. Kolbin[1], B. Walker[2], C. Hult[3], D. Adalsteinsson[1], G. Forest[1], K. Bloom[1]; [1]UNC Chapel Hill, Chapel Hill, NC, [2]UC Irvine, Irvine, CA, [3]Gettysburg College, Gettysburg, PA

Condensin and cohesin have profound effects on the higher order organization of chromatin. Through their ability to extrude loops, the genome can be compartmentalized into subdomains that are topologically isolated, condensed into a bottlebrush for tension sensing between sister kinetochores and packaging in cell division. How the size, distribution and duration of loops is regulated is an emerging question in the field. To understand this regulation, we have turned to bead-spring polymer models of the chromatin. Such polymer models have been critical in gaining insight into a number of DNA metabolic processes including nucleolar function, transcription and DNA repair. DNA loops are constantly formed and dissolved through thermal fluctuations of a highly flexible DNA polymer. Loop-extrusion provides a mechanism to regulate this process and mold specific regions of the genome, depending on cell cycle stage, cell type, or environmental perturbations. We have found that the **stiffness of the polymer** substrate (DNA chain), the **spring properties** of condensin, and the distribution of attachment sites (hard or soft, i.e. centromeres or nuclear pores) have disproportionate effects on the properties of chromatin loops. Constraining the ends of DNA will result in regulation of loops by types of condensin (strong, moderate, or weak) and diminishes the role of the chromatin type (stiff or floppy) forming the loops. Biologically such regulation can be achieved by swapping out members of the

condensin complex or by modifying its subunits by PTM. However, when the ends of DNA are unconstrained (free ends) chromatin's polymer property (stiffness) will overwhelmingly dictate loop sizes formed by condensins. In this regime the control over loop sizes is relegated toward the substrate itself and can be actuated by chromatin modifiers and nucleosome remodelers. Through modeling experiments and theory, this study formulates the critical physical inputs into how chromatin loops can be regulated in vivo. We show that regulation can be achieved via the complexes like condensin and dictated by local chromatin properties like tethering or its stiffness (persistence length), leading us to propose a **multimodal control** of higher order chromatin looping.

B299/P2689

Active hydrodynamic theory of chromatin dynamics

A. S. Rautu[1], D. Saintillan[2], M. J. Shelley[1,3]; [1]Simons Foundation Flatiron Institute, New York City, NY, [2]University of California San Diego, San Diego, CA, [3]New York University Courant Institute, New York City, NY

The organization of chromatin inside the cell nucleus is crucial for the proper functioning of many nuclear processes in eukaryotes. In differentiated cells, chromatin is spatially segregated into euchromatin and heterochromatin compartments. The former is loosely packed and transcriptionally active, while the latter is compacted and mostly consists of transcriptionally silent genes. Here we describe a hydrodynamic model of chromatin and nucleoplasm at micron scales. The chromatin is modeled as a viscous, compressible fluid, as informed by microrheology experiments and their response at long time. Heterochromatin is distinguished by the presence of contractile stresses due to HP1 crosslinking. This stress induces density instabilities and large-scale flows of the chromatin fluid and nucleoplasm. Simulations reveal coarsening of heterochromatic components, which in an open system lead to a finite-size droplet, whereas in a confining domain we observe a redistribution at the boundaries, resembling a wetting phenomenon. Hence these mechanical processes may play an important role in the spatial organization of heterochromatin which is usually enriched near the nuclear periphery.

B300/P2690

Targeted degradation of macroH2A to investigate its role in chromatin compaction and organization

A. Ou, J. Rendleman, J. Soroczynski, V. Risca; The Rockefeller University, New York, NY

Non-canonical histones play also an important role in regulating and organizing the genome. One such histone of interest is macroH2A, a variant of H2A with an unusually large molecular weight and tripartite structure consisting of the histone folding region, positively charged linker, and a macrodomain. The two subtypes of macroH2A (macroH2A1 and macroH2A2) are encoded by two genes; however, exon switching in macroH2A1 can give two isoforms (1.1 and 1.2) which seem to play opposing roles in gene activation.

The macroH2A family of histones can have a wide range of roles related to their regulation of gene expression including maintaining cell states, X-chromosome inactivation and senescence, as well as functioning in DNA damage repair. MacroH2A1.1 has been implicated in transcriptional activation through the regulation of nucleosome acetylation, while the other isoforms play a repressive role. Mechanistically, the function of macroH2A is not yet well understood, especially with respect to how they repress transcription and has been proposed to be maintaining and organizing higher-order

chromatin organization or interfering with transcription factor binding.To study macroH2A, we utilized a proteolysis targeting chimera (PROTAC) against an endogenously tagged macroH2A to allow for acute protein degradation. Our preliminary results showed that acute loss of macroH2A1 did not drastically alter chromatin accessibility.

B301/P2691

Cooperation of condensin, histone modifications, and nuclear architecture in dosage compensation

J. Trombley, A. Rakozy, L. E. Tushman, G. Csankovszki; University of Michigan, Ann Arbor, MI

In organisms with differing numbers of sex chromosomes between sexes, the process of dosage compensation balances X chromosome gene expression. In *C. elegans* hermaphrodites (XX), X chromosomes are bound by a dosage compensation complex (DCC) to down-regulate gene expression on both X's to cause expression levels comparable to males (XO). The DCC is a multi-subunit protein complex composed of Condensin I^{DC} and additional X chromosome-associated proteins. The DCC on the hermaphrodite X mediates three known mechanisms of dosage compensation. The binding of the DCC specifically to both of the hermaphrodite X chromosomes causes X-specific enrichment of histone 4 lysine 20 monomethylation (H4K20me1). The DCC also, via an unknown mechanism, influences the tethering of the X to the nuclear lamina. In addition, the *C. elegans* specific SMC complex, Condensin I^{DC} restructures the hermaphrodite X's to reduce transcription. However, it is unknown if Condensin I^{DC} is needed for the maintenance of dosage compensation in mature *C. elegans*. Previous studies in our lab showed that these processes individually make significant contributions to X chromosome structure and gene expression. Strong null mutations in the DCC lead to varying degrees of hermaphrodite-specific lethality. Yet, the hermaphrodite mutants with defects for both the H4K20me1 and nuclear lamina tethering pathways are viable. We are testing whether the combination of defects from the three known pathways will increase dosage compensation defects, or destabilize repression during the maintenance phase, to a greater degree than what was seen in previous studies.

B302/P2692

Heavy Ion Damage on Chromatin; Break Mapping Across Genomic Compartments

H. Canaj[1], A. Scortea[1], D. W. West[1], I. Plante[2], V. Risca[1]; [1]Rockefeller University, New York, NY, [2]KBR, NASA, Houston, TX

Space radiation, including gamma rays and galactic cosmic ray ions traveling at relativistic speeds, presents a challenge to the health of astronauts engaged in long-term space travel. Although chromatin is generally thought to protect DNA from a range of insults, including ionizing radiation, the relationship of chromatin local organization to the sensitivity of the underlying genomic locus to damage is not yet well understood. Breaks that span across genomic compartments could cause rearrangements that are highly mutagenic. Understanding how different kinds of radiation drive damage patterns across genomic compartments can help us understand the nature of the damage events and to what extent chromatin protects against deleterious outcomes. To investigate how chromatin structure shapes patterns of DNA damage caused by ionizing radiation, we measured the density of breaks in DNA across different functional genomic compartments after irradiation of human fibroblast and umbilical vein endothelial cells with gamma rays, X-rays and heavy ions. We irradiated cells with O_{18} and Fe_{56} at the NASA space radiation laboratory at Brookhaven National Lab, and measured cell proliferation and DNA repair dynamics by immunofluorescence at various timepoints after irradiation. We also used RICC-seq and

End-seq, two DNA sequencing-based methods, to measure genome-wide single stranded DNA and double stranded DNA breaks, respectively, in ice-chilled cells immediately after irradiation. By chilling the cells, we sought to reduce the impact of the DNA damage response on the DNA break landscape. We compared break densities across genomic compartments defined by histone marks, nuclear localization, or accessibility. Under X-ray irradiation, we see that heterochromatic regions, like lamina-associated domains and H3K9me3 marked chromatin, show a lower break density compared to a genomic control, whereas regions associated with euchromatic, ATAC-seq accessible regions or H3K27ac-marked chromatin have higher break density for both ssDNA and dsDNA breaks. These data will provide the basis for future chromatin state-specific nanodosimetry and evaluation of explicit simulations of DNA damage events by packages such as NASA'S RITRACKS.

B303/P2693

OpenTn5 Project: Open-source resource for robust and scalable Tn5 transposase purification and characterization.

J. Soroczynski, D. A. Oren, L. J. Anderson, J. Yeung, J. Rendleman, V. Risca; The Rockefeller University, New York, NY

Tn5 is a bacterial cut-and-paste transposase, which can simultaneously fragment target DNA and append its ends with custom DNA sequences, in a process referred to as tagmentation. This property of Tn5 has been leveraged over the last decade to develop an ever-increasing number of technologies for generating high-throughput sequencing DNA libraries. Despite the versatility and widespread adoption of tagmentation, a persistent challenge in the development of Tn5-based technologies has been lack of a recombinant expression and storage protocol that robustly maintains enzyme activity, and of standardized activity assays. We describe a robust protocol for high-yield Protein G-Tn5 fusion (pG-Tn5) expression and purification, as well as detailed quality control assays. We benchmarked our pG-Tn5 fusion against commercial enzymes across a variety of applications, including both bulk and single-cell ATAC-seq, as well as Cut&Tag, showing it is functionally identical. The protocol we developed is short, affordable and scalable, allowing one to obtain usable quantities of Tn5 from as little as 50 mL E. coli culture using only bench-top equipment. The pG-Tn5 produced is highly pure and stable in -20 °C for at least 1 year. We provide the expression plasmid and protocol as open-source resources, and as a platform for development of new applications of tagmentation.

B304/P2694

Optimization of the Trim-Away system for rapid degradation of endogenous proteins from *Xenopus* egg extract for the study of cellular dynamics

A. Jevitt, J. Chen, S. Rankin; OKLAHOMA MEDICAL RESEARCH FOUNDATION, Oklahoma City, OK

Extracts made from the eggs of *Xenopus laevis* have provided a valuable model for studying subcellular events, including chromosome dynamics, DNA replication, mitochondria assembly, cell cycle progression, and many others. In this system, protein depletions are often used to analyze the requirement for endogenous proteins, and rescue experiments with recombinant proteins are often used to confirm activities and map function. Here we show that the TRIM21 ubiquitin ligase can be effectively used to deplete proteins from egg extracts rapidly. The advantage of this approach is that it requires far less antibody than is typically required for immunodepletions, making it more cost-effective. We provide several examples of antibodies against *Xenopus* proteins that can be used in combination

with the TRIM21 ligase to cause efficient protein depletion, suggesting this approach's general usefulness and applicability in egg extracts. We demonstrate that TRIM-away depletions occur efficiently in both interphase and meiotically arrested extracts. The simplicity with which TRIM-away can be applied to *Xenopus* egg extracts suggests that it is uniquely powerful and useful in this system.

B305/P2695

Characterizing ESCO1's Interaction with Chromatin

J. Schoen[1,2], A. Poss[1], E. Lima da Silva[1], J. Chen[1], E. Floyd[1], S. Rankin[1,2]; [1]OKLAHOMA MEDICAL RESEARCH FOUNDATION, Oklahoma City, OK, [2]University of Oklahoma Health Sciences Center, Oklahoma City, OK

ESCO1 is an acetyltransferase enzyme that regulates chromosome organization and gene expression by modifying Cohesin, a key regulator of genome architecture. Cohesin organizes DNA into loops and is critical for normal chromosome structure and function. Acetylation of the SMC3 subunit of Cohesin by ESCO1 stabilizes Cohesin on DNA, promoting long residence time at functional sites. Factors that shape when, where, or how ESCO1 stabilizes Cohesin are not understood.

We have found that tethering ESCO1 to a specific location in the nucleus results in gross local rearrangement of chromatin. Strikingly, this local chromatin rearrangement occurs independently of ESCO1's acetyltransferase activity and does not occur through Cohesin. We have mapped this activity to a 35 amino acid motif within ESCO1 and shown that this region of ESCO1 binds directly to DNA, with a likely preference for single stranded DNA. Deletion of this DNA binding domain (DBD) leads to a reduction in chromatin-bound ESCO1.

We hypothesize that the ESCO1 DBD directs it to preferred binding sites where it regulates Cohesin and gene expression. Experiments are ongoing to complete the characterization of the DBD, define how it is regulated, and characterize its impact on Cohesin localization and gene expression. With these experiments, we will define the biological impact of ESCO1's DNA binding activity.

B306/P2696

The Effect of Nuclear Compartmentalization on DNA Repair

A. Laffitte, M. King; Yale University, New Haven, CT

DNA double-stranded breaks (DSBs) represent a danger to genome stability. DSBs are repaired primarily through canonical non-homologous end-joining (NHEJ) or homologous recombination (HR). Repair pathway choice is critical because failure to choose the most faithful repair mechanism can lead to loss of genome integrity. HR is the more error-free repair pathway, using the sister chromatid as a template for repair. In line with previous work, I found that nuclear compartmentalization impacts repair pathway choice, specifically in regulating the loading of repair factors onto resected ssDNA, which arises as a consequence of nucleolytic processing of the DSB. My results show that Rad52, which remodels RPA to Rad51 loading in fission yeast, is efficiently recruited to resected DSBs and is retained there during repair in the nuclear interior. By contrast, in DSBs tethered to the nuclear periphery, Rad52 loading is transient. The mechanism behind this observation is still unknown. I hypothesize that HR is disfavored at the nuclear periphery due to factors residing there that compete with Rad52 for loading onto resected DNA. It is possible that one of these factors is DNA-damage induced RNA (ddRNA) that hybridizes with resected ssDNA to form RNA-DNA hybrids. Consistent with such a model, RNaseH overexpression partially rescues persistent Rad52 loading at the nuclear periphery. This led me to investigate ddRNA as a possible source of RNA that could contribute to the RNA-DNA hybrids that antagonize Rad52 loading.

Accordingly, after a DSB, I observed a temporary upregulation of transcripts in the surrounding genomic region. This upregulation was only detectable in a Dicer-deficient background, where processing into small RNA is perturbed. One model to explain these observations is that damage-induced bidirectional transcription flanking a DSB produces dsRNA that is then a substrate for Dicer. This leaves open the possibility that these damage-induced transcripts are the form of RNA that hybridizes with resected ssDNA, thereby antagonizing Rad52 loading. These initial findings support the idea that repair by HR proceeds differently in the nuclear interior and periphery. Ongoing work will continue to shed light on the relationship between nuclear compartments and DNA repair mechanism choice and efficiency.

B307/P2697

Phosphorylation-Dependent Regulation of ESCO2

B. Rankin[1,2], J. Chen[1], D. Flavors[1], V. Moore[1], S. Rankin[1,2]; [1]Oklahoma Medical Research Foundation, Oklahoma City, OK, [2]University of Oklahoma Health Science Center, Oklahoma City, OK

Tethering of sister chromatids by the cohesin complex following DNA replication ensures accurate alignment and segregation of chromosomes during the subsequent cell division. Sister chromatid cohesion is promoted by acetylation of the SMC3 subunit of cohesin by the ESCO2 acetyltransferase. This is coordinated by interactions between ESCO2 and DNA replication machinery. Through conserved motifs in its intrinsically disordered N-terminal tail, ESCO2 interacts with PCNA and the MCM2-7 helicase complex.
Several proteomic reports suggest that ESCO2 is phosphorylated, though the impact of these modifications on ESCO2 function are not known. We have engineered mutations in potentially modified residues in ESCO2 and tested their impact on cohesion establishment and interactions of ESCO2 with the replication machinery. Using a knockdown and replacement strategy we have found that one phosphorylation site, strongly impacts sister chromatid cohesion. We also found that this mutation had significant impact on the ability of ESCO2 to interact with the replication machinery.
We conclude from these experiments that phosphorylation of ESCO2 plays a critical role in sister chromatid cohesion establishment during DNA replication. This regulation provides novel insight about the cell cycle-dependent regulation of this essential mediator of sister chromatid cohesion.

Nuclear speckles are non-membrane bound organelles known as storage sites for mRNA processing and splicing factors. In addition, nuclear speckles have also been implicated in splicing and export of a subset of mRNAs, including the influenza virus M mRNA that encodes proteins required for viral entry, trafficking, and budding. However, little is known about how nuclear speckles are assembled or regulated. Here we uncovered a role for the cellular protein kinase TAO2 as a constituent of nuclear speckles and as a factor required for the integrity of these nuclear bodies and for their functions in pre-mRNA splicing and trafficking. We found that a nuclear pool of TAO2 is localized at nuclear speckles and interacts with nuclear speckle factors involved in RNA splicing and nuclear export, including SRSF1 and Aly/Ref. Depletion of TAO2 or inhibition of its kinase activity disrupts nuclear speckle structure, decreasing the levels of several proteins involved in nuclear speckle assembly and splicing, including SC35 and SON. Consequently, splicing and nuclear export of influenza virus M mRNA were severely compromised and caused a disruption in the virus life cycle. In fact, low levels of TAO2 led to a decrease in viral protein levels and inhibited viral replication. Additionally, depletion or inhibition of TAO2 also resulted in abnormal expression of a subset of mRNAs with key roles in viral replication and immunity. More recently, we performed RNA-seq analysis of nuclear and cytoplasmic fractions of cells depleted of TAO2 and of control cells. We found that decreased levels of TAO2 inhibited nuclear export of a subset of cellular mRNAs whereas their total levels were not significantly altered. Among this group are mRNAs that encode key enzymes involved in post-translational modifications and transcription factors that regulate gene expression. Together, these findings uncovered a role for TAO2 in nuclear speckle formation and function and revealed host requirements and vulnerabilities for influenza infection.

Novel role of Translesion DNA synthesis polymerase kappa in the nucleolus and in nucleolar stress response recovery

S. Paul[1], A. Heinbaugh[1], A. Paul[1], P. Cifani[2], D. Pappin[2], T. Spratt[1]; [1]Penn State University College of Medicine, Hershey, PA, [2]Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.

Translesion DNA synthesis (TLS) polymerases evolved to tolerate DNA damage that bypasses DNA lesions. Multiple TLS polymerases exist with different damage tolerance capabilities. A major knowledge-gap in elucidating the roles of these polymerases is that it is difficult to identify which polymerase is active in a specific situation. We synthesized a novel nucleotide analog N^2-benzyl-2'-deoxyguanosine (EBndG) that is highly selective toward DNA polymerase kappa (PolK), a Y-family TLS polymerase. PolK can bypass bulky lesions generated by benzo[*a*]pyrene diolepoxide (BPDE), an environmental carcinogen. Although PolK has been identified to have multiple cellular roles such as protection of stalled replication forks and non-B DNA synthesis, the mechanisms regulating its different cellular activities are unknown. To interrogate the identity of proteins surrounding the PolK active sites, we performed an extensive study using modified aniPOND (accelerated native isolation of proteins on nascent DNA), called iPoKD (isolation of proteins on Pol kappa synthesized DNA). Human cell-lines were treated with BPDE, subsequently 5-ethynyl-2'-deoxyuridine (EdU) or EBndG was added and proteins bound to the DNA containing EdU and EBndG were analyzed by mass-spectrometry (MS). Our data identified DNA replication and repair proteins previously identified with EdU pull-downs; and

interestingly enrichment of ribosome biogenesis and nucleolar proteins associated with EBndG pull-downs. Using super-resolution confocal microscopy, our data suggest, that PolK is active in the nucleolus after BPDE damage, inserts EBndG in the nucleolar DNA, and it's activity is regulated by the canonical polycomb complex recruited by the PARylation by PARP1. We noted that BPDE lead to nucleolar stress and PolK is essential in recovering cells from nucleolar stress. Surprisingly, we also discovered that in PolK compromised cells 5-ethynyl uridine (EU) incorporation and transcription of pre-rRNA was significantly reduced. PolK active site interactome identified RNA polymerase I subunits and ribosome biogenesis proteins. We are now further exploring PolK's role in maintaining ribosomal biogenesis and ribosomal DNA integrity after BPDE damage. This study will provide first insight into the novel of TLS DNA synthesis polymerase in the nucleolus.

Nuclear speckle proteins drive neurodegenerative tauopathy

R. Eck, **B. Kraemer**; University of Washington, Seattle, WA.

Pathological accumulation of the microtubule binding protein tau drives age-related neurodegeneration in a variety of disorders, collectively called tauopathies. In the most common tauopathy, Alzheimer's disease (AD), the accumulation of pathological tau strongly correlates with cognitive decline. The underlying molecular mechanisms that drive neurodegeneration in tauopathies remain unknown**.** We employed classical forward genetic approaches and identified multiple loss of function alleles in the *C. elegans spop-1 g*ene that ameliorate tauopathy, suggesting SPOP is required for tau mediated neurodegeneration. CRISPR based genome editing methodology enabled the generation of customized *SPOP-1* loss of function and null alleles. Molecular genetics, behavioral, neuronal reporter assays, and biochemical analyses were also employed to characterize the consequences of *spop-1* loss of function on tauopathy related phenotypes in model systems. Knockout of SPOP-1 rescues tau mediated behavioral deficits caused by neuronal dysfunction in tau transgenic *C. elegans.* Biochemical analysis revealed that SPOP-1 loss of function promotes clearance of phosphorylated and total tau species from *C. elegans* neurons, but no change in tau transgene mRNA levels. Tau transgenic animals exhibit obvious neurodegeneration of GABAergic neurons, but loss of *spop-1* rescues neurodegeneration. While SPOP functions as an CUL3 E3 ligase adaptor protein, CUL3 function is not required for SPOP loss of function rescue of tauopathy. Genetic epistasis analysis suggests the nuclear speckle resident poly(A) RNA binding protein *sut-2* and *spop-1* function in a parallel molecular pathway. SPOP is a novel modifier of tauopathy phenotypes. Combined with previous findings investigating ALYREF, PARN/TOE1, SUT-1 and SUT-2/MSUT2, this work suggests phase-separated nuclear speckles are an important cellular site controlling susceptibility to pathological tau. Recent work showing SPOP modification of PR dipeptides derived from C9orf72 expansion suggests common pathways may be at work in the neurodegenerative molecular mechanisms of tauopathy, repeat dipeptides, and perhaps other proteinopathy disorders.

Zinc Finger 692 (ZNF692) regulates nucleolar shape and activity through its interaction with nucleophosmin 1 (NPM1)

I. N. Brown[1], M. Lafita Navarro[2], M. Conacci-Sorrell[2]; [1]UT Southwestern Medical Center, Dallas, TX, [2]UT Southwestern, Dallas, TX.

Nucleolar function and ribosome biogenesis are essential for protein synthesis and cellular growth. Therefore, aberrant increase in nucleolar size and number are hallmarks of many cancers and have been associated with poor prognosis; nucleolar size is one of the most frequently used parameters by pathologists to grade solid tumors. While basic components and general molecular functions of the nucleolus have been studied, fundamental information on the mechanisms and molecules involved in the increased nucleolar size and activity specifically in cancer cells is missing. In an unbiased screen designed to identify growth promoting pathways in MYC-transformed cells, our lab identified a novel and critical nucleolar regulator, the Zinc finger protein 692 (ZNF692) (manuscript submitted). Our data has shown that ZNF692 downregulation interferes with protein synthesis and nucleolar function, and overexpression promotes nucleolar activity and protein synthesis. Moreover, we found that ZNF692 expression is dramatically increased in nearly all solid tumors deposited in the TGCA and is correlated with poor patient outcome. On a molecular level, our lab has shown that ZNF692 facilitates small ribosome subunit assembly and the final steps of 18S rRNA processing in the nucleolus. Through this project, we have unexpectedly discovered that ZNF692 also interacts with nucleophosmin 1 (NPM1) to assemble the granular component of the nucleolus. In the absence of ZNF692, NPM1 aberrantly localizes as ring-like structures. This unexpected distribution of NPM1 resembles the liquid condensates formed *in vitro* by purified NPM1. Therefore, we propose a working model that ZNF692 regulates nucleolar architecture and activity to accommodate the demands for ribosome biogenesis, directly controlling the biosynthetic capabilities of hyper-proliferative cells.

Sequence Determinants of 53BP1 Phase Separation

M. Garabedian, M. C. Good; University of Pennsylvania, Philadelphia, PA.

DNA double strand breaks (DSBs) are among the most deleterious events that cells encounter. As such, elegant and complex systems exist to address these breaks, primarily in one of two pathways: non-homologous end joining (NHEJ) and homologous recombination (HR). High fidelity repair of breaks and proper balance between these pathways is essential for maintaining genomic integrity and preventing tumorigenesis. While many aspects and players involved in DNA repair and repair pathway selection have been characterized, our understanding of the complex interplay between different tumor suppressors, their ligands, and other downstream factors remains incomplete. Recently, 53BP1, along with many other disordered proteins found in the nucleus, was found to phase separate into biomolecular condensates during DNA damage response. We hypothesize that liquid-liquid phase separation (LLPS) of 53BP1 is driven by π-π and/or cation-π interactions and is required for stimulating NHEJ. Here, using in vitro condensation experiments and imaging in live cells, we show that specific disruption of π-π and/or cation-π interactions disrupt phase separation of 53BP1. Loss of these interactions leads to reduction of NHEJ components at break sites, consistent with the role of 53BP1 as a disordered protein that acts as a scaffold. Further, point mutants are unable to suppress HR at break

sites. Collectively, we propose that the degree of 53BP1 phase separation at DSBs can influence cellular decision making between NHEJ and HR to resolve broken DNA.

B314/P2703

Fission yeast nuclear pore protein nup211 regulates the transcriptome

D. Kamel[1,2], A. Sookdeo[1,2], W.-G. Qiu[1,2], H. Zhong[1,2]; [1]Hunter College, The City University of New York, New York, NY, [2]The Graduate Center, The City University of New York, New York, NY

While nuclear pore proteins primarily mediate nucleocytoplasmic transport, they are also involved in other activities like transcription, chromatin organization, and cell cycle regulation. The fission yeast nucleoporin nup211 localizes to the nuclear basket and is known to play important roles in regulating RNA quality and mRNA export. Interestingly, several orthologs of nup211 have been shown to regulate transcription in addition to their roles in nucleocytoplasmic transport. Although nup211 preferentially associates with heterochromatin, it is unclear whether it also modulates transcription. To better understand the full scope of nup211 function, we examined how cells are affected when nup211 protein level is reduced. Since *nup211* is an essential gene, we constructed a conditional mutant strain (*nup211-so*) in which *nup211* expression is controlled by a thiamine-repressible promoter. RNA-Seq analysis revealed that reducing *nup211* expression significantly affected the transcript abundance of ~1,600 genes. Among the upregulated genes are transcription factors (e.g., *atf1*, *pcr1* and *mbx1*) , cell cycle regulators (e.g., *wee1*), and genes involved in histone modification. Consistent with septation and cytokinesis defects observed by microscopy, several genes known to play important roles in septation and cell wall synthesis (e.g., *pom1*, *bgs1*, *pxl1* and *knh1*) were also upregulated. RT-qPCR results confirmed the upregulation of these genes. Furthermore, through domain analysis we determined that the first 655 residues of nup211 are sufficient for cell viability as exogenous expression of this domain in *nup211-so* cells was able to rescue cell growth and morphology. Finally, RT-qPCR results showed that ectopically expressing either full-length nup211 or nup211$_{1\text{-}655}$ was able to partially or fully restore the transcript levels of the subset of genes examined in *nup211-so* cells. Our findings reveal a novel function of nup211 in regulating the transcriptome in addition to its role in nuclear transport. Further studies will be carried out to determine the underlying mechanism(s) of nup211 in regulating gene expression.

Functions of Nuclear Envelope Proteins

B315/P2704

The Inner Nuclear Membrane Protein NEMP1 is Required for Proper Erythropoiesis and Supports Nuclear Envelope Openings in Erythroblasts

D. Hodzic; Washington University School of Medicine, St. Louis, MO.

Nuclear Envelope Membrane Proteins (NEMP) are a conserved family of nuclear envelope proteins that reside within the inner nuclear membrane. Even though *Nemp1* knockout (KO) mice are overtly normal, they display a pronounced splenomegaly. This phenotype and recent reports describing a requirement for nuclear envelope openings during erythroblasts terminal maturation led us to examine a potential role for Nemp1 in erythropoiesis. Here, we report that *Nemp1* knockout (KO) mice show peripheral blood defects, anemia in neonates, ineffective erythropoiesis, splenomegaly and stress erythropoiesis. The erythroid lineage of *Nemp1* KO mice is overrepresented until the pronounced apoptosis of polychromatophilic erythroblasts. We show that NEMP1 localizes to the nuclear envelope of

erythroblasts and their progenitors. Mechanistically, we discovered that NEMP1 accumulates into aggregates that localize near or at the edge of nuclear envelope openings and *Nemp1* deficiency leads to a marked decrease of both nuclear envelope openings and ensuing enucleation. Together, our results for the first time demonstrate that NEMP1 is essential for nuclear envelope openings and erythropoietic maturation *in vivo* and provide the first mouse model of defective erythropoiesis directly linked to the loss of an inner nuclear membrane protein.

B316/P2705

Chromatin-based membrane remodeling and bilayer lipid metabolism enable spindle disassembly to seal nuclear envelope holes

S. Barger, H. Yang, S. Lee, S. Bahmanyar; Yale University, New Haven, CT

After open mitosis, spindle microtubule disassembly coordinates with closure of nuclear envelope holes. The nuclear envelope protein, LEM-2, and CHMP-7 serve as adaptors for ESCRT membrane remodeling machinery to execute sealing. The transient accumulation of LEM-2/CHMP-7 to nuclear envelope holes is conserved across multiple organisms; however, loss of CHMP-7 gives rise to subtle or no defects in nuclear permeability suggesting redundant mechanisms are responsible for sealing holes. Using the stereotypical divisions of early *C. elegans* embryos, we found that CNEP-1, the nuclear envelope-associated regulator of the phosphatidic acid phosphatase lipin, contributes to nuclear closure by controlling metabolic changes in bilayer ER/nuclear envelope lipids. Here, we show that spindle disassembly requires membrane remodeling via CNEP-1 control of lipin and chromatin-LEM-2 binding to ensure sealing of holes. Using endogenous CRISPR-mediated mutagenesis, we show that the interaction between LEM-2 and the DNA crosslinking protein BAF prevents membranes from transiently enwrapping mitotic chromosomes, frequently at sites adjoining the mitotic spindle. Ectopic membranes around sealing sites can also result from loss of *cnep-1/*lipin suggesting a role for lipid metabolism in remodeling membranes around chromatin. Strikingly, enwrapped mitotic chromosomes persist when both *lem-2*-BAF binding and *cnep-1/*lipin are absent causing enhanced nuclear leakiness. In some cases, abnormal membrane enwrapping prevents disassembly of chromosome-associated spindle microtubules leading to severe spindle and nuclear morphology defects. Importantly, nuclear formation defects resulting from disrupted lipid metabolism are specific to loss of the LEM-2-BAF interaction - deletion of *chmp-7* or the domain of LEM-2 that binds CHMP-7 results in comparatively subtle defects. We also provide evidence suggesting regulation of lipid metabolism through the human CNEP-1 homologue, CTDNEP1, and lipin 1 is also coupled to chromatin-mediated nuclear envelope remodeling in U2OS cells. Together, our data suggest a conserved mechanism in which membrane remodeling mediated by chromatin-LEM-2 interactions and bilayer lipid metabolism prevent abnormal membrane enwrapping of chromosomes to allow timely spindle disassembly and proper sealing. We are currently testing whether global or local changes in lipid metabolism are required to cooperate with chromatin-based membrane remodeling for hole closure.

B317/P2706

A mechanosensitive checkpoint at the meiotic nuclear envelope revealed by chemically-induced proximity

C. Liu, A. F. Dernburg; University of California, Berkeley/HHMI, Berkeley, CA

A variety of surveillance mechanisms help to ensure accurate transmission of genetic information during mitosis and meiosis. While certain pathways respond to unrepaired DNA damage, additional checkpoints monitor meiosis-specific events such as synapsis, the assembly of the synaptonemal complex (SC) between homologous chromosomes. During *C. elegans* oogenesis, defects in synapsis lead to a cell cycle delay and eventually trigger apoptosis. Previous work revealed that this "synapsis checkpoint" depends on functional pairing centers (PCs), special regions on each chromosome that mediate nuclear envelope attachment and promote homolog pairing and synapsis. However, how cells monitor and respond to defects in SC assembly remains unclear. In early meiotic prophase, the Polo-like kinase PLK-2 normally relocalizes from PCs to the SC as chromosomes synapse. Synapsis defects result in prolonged association of PLK-2 with PCs and extended phosphorylation of nuclear envelope proteins. To test whether the presence of PLK-2 at PCs confers a signal that promotes apoptosis, I repurposed the auxin-inducible degradation (AID) into a chemically-induced proximity (CIP) system that enables inducible and ectopic targeting of TIR1-tagged PLK-2 to degron-tagged HIM-8, a protein that specifically binds to X-chromosome PCs through meiotic prophase.

I found that ectopic targeting of PLK-2 to X-chromosome PCs was sufficient to induce elevated germline apoptosis that is uncoupled from synapsis defects and does not require HUS-1, an essential component of the DNA damage checkpoint. Using a kinase-dead PLK-2::TIR1 fusion, I found that the kinase activity of PLK-2 is required for CIP-triggered apoptosis. Intriguingly, targeting PLK-2 to PCs also greatly extends the phosphorylation of Lamin/LMN-1 at Ser32, an established PLK-2 target associated with labile nuclear lamina at meiotic entry. Indeed, targeting PLK-2 directly to the nuclear lamina, or ectopic depletion of the nuclear lamina, also induces HUS-1 independent germline apoptosis, even in the absence of functional PCs. Live imaging shows elevated deformation of the meiotic nuclear envelope upon weakening the nuclear lamina, suggesting mechanical stress. Unexpectedly, I found that a mechanosensitive Piezo1/PEZO-1 channel localizes to the nuclear envelope of meiotic nuclei and is required for elevated germline apoptosis triggered by either ectopic PLK-2 recruitment to the nuclear lamina or asynapsis. To our knowledge, this is the first evidence of a role for mechanosensitive channels in detecting nuclear events or contributing to quality control during gamete production. Thus, in response to unsynapsed chromosomes, modification of the nuclear lamina by PLK-2 is likely a direct trigger for apoptosis through mechanosensation.

B318/P2707

Loss of SUN2 is protective against injury-induced lung fibrosis

E. Carley[1], X. Peng[2], E. Kocak[1], E. L. Herzog[2], M. C. King[1,3]; [1]Department of Cell Biology, Yale University, New Haven, CT, [2]Department of Pulmonary, Critical Care and Sleep Medicine, Yale University, New Haven, CT, [3]Department of Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT.

Fibrosis is the excessive excretion of extracellular matrix proteins and tissue stiffening that leads to a decrease in organ function. Both biochemical and mechanical signals are integrated into the progression of fibrosis, however the mechanisms by which the mechanical arm of this pathway exerts its effect

remain to be fully defined. The expression level of mechanosensitive A-type lamins, a key component of the nuclear lamina, is increased in Idiopathic Pulmonary Fibrosis across multiple cell types, suggesting that mechanotransduction to the nuclear envelope could play a role in fibrotic progression. Mechanical forces can be transmitted from the extracellular matrix, through the cytoskeleton, to the nucleus via Linker of Nucleoskeleton and Cytoskeleton (LINC) complexes, which mechanically couple the cytoskeleton to the nuclear lamina. To investigate the role of mechanotransduction via LINC complexes in the progression of fibrosis we turned to mouse models of LINC complex ablation. We discovered that loss of SUN2 leads to protection from injury-induced lung fibrosis, suggesting that force transduction through the LINC complex is a driver of extracellular matrix production in this context. We also observed an intriguing dependence on gender, with loss of SUN2 in male mice delaying, but not preventing ECM deposition and loss of SUN2 in female mice completely preventing ECM deposition after lung injury. To define the underlying mechanisms of these observations, we have probed the impact of SUN2 loss on the cell populations present in the lung at various time points after lung injury and found that while loss of SUN2 does not appear to impact the initial injury of the tissue, it does lead to higher levels of epithelial cells at 14 days post injury. These observations suggest that SUN2 may impact epithelial regeneration after injury, a function that could be mechanistically related to our recent work demonstrating that LINC complexes control epithelial differentiation in the epidermis. This work highlights the possibility that intervening in a SUN2-dependent mechanotransduction pathway could short-circuit fibrotic progression, in part by promoting greater regeneration of the epithelia.

B319/P2708

Functional and Domain Analysis of the Inner Nuclear Membrane Protein Csa1 in Budding Yeast

L. Carson, H. Yu; Florida State University, Tallahassee, FL.

The nucleus is surrounded by the nuclear envelope, a double membrane structure composed of the inner nuclear membrane (INM) and the outer nuclear membrane (ONM). Embedded within the nuclear envelope, the nuclear pore complex (NPC) controls trafficking between the nucleus and the cytoplasm. The nucleolus, a large crescent shaped membraneless suborganelle within the nucleus, forms around the ribosomal DNA (rDNA) and functions in the production of ribosomes. In budding yeast, rDNA, and therefore the nucleolus, is tethered to the nuclear periphery during interphase. Due to the highly repetitive nature of rDNA, recombination at the rDNA is suppressed. Aberrant rDNA recombination can result in the formation of extrachromosomal rDNA circles (ERCs). The accumulation of ERCs and aged NPCs have been shown to advance cellular senescence. Although these aging factors are known to decrease the replicative lifespan, the mechanism of how they arise inside the nucleus remains to be further elucidated. We show here that the INM protein Csa1 plays a critical role in regulating rDNA recombination, as well as potentially controlling ERC formation and NPC biogenesis. Using point and deletional yeast mutants, we have found that the N-terminus of Csa1 is essential for its localization to the INM. Using a gene reporter assay, we show that Csa1 suppresses rDNA recombination. We propose that Csa1 functions in the tethering of rDNA/nucleolus to the INM, thereby inhibiting rDNA recombination and ERC formation. Consistent with this idea, Csa1 interacts with the LEM domain protein Heh1, which is required for tethering rDNA/nucleolus to the nuclear periphery. We also show that Csa1 interacts genetically with the TREX-2 complex, known to function in the asymmetric retention of ERCs to the mother cell. This unexpected role of Csa1 as a regulator of rDNA recombination and nuclear envelope architecture provides a foundation for further studies on the mechanism of replicative cell aging in budding yeast.

B320/P2709

Emerin Interacts with Histone Methyltransferases to Regulate Repressive Chromatin at the Nuclear Periphery

N. Marano, J. M. Holaska; Cooper Medical School of Rowan University, Camden, NJ.

X-Linked Emery-Dreifuss muscular dystrophy is caused by mutations in the gene encoding emerin. Emerin is an inner nuclear membrane protein important for repressive chromatin organization at the nuclear periphery. Myogenic differentiation is a tightly regulated process characterized by genomic reorganization leading to coordinated temporal expression of key transcription factors, including MyoD, Pax7, and Myf5. Emerin was shown to interact with repressive histone modification machinery, including HDAC3 and EZH2. Using emerin-null myogenic progenitor cells we established several EDMD-causing emerin mutant lines in the effort to understand how the functional interaction of emerin with HDAC3 regulates histone methyltransferase localization or function to organize repressive chromatin at the nuclear periphery. We found that, in addition to its interaction with HDAC3, emerin interacts with the histone methyltransferases EZH2 and G9a in myogenic progenitor cells. Further, we show enhanced binding of emerin HDAC3-binding mutants S54F and Q133H to EZH2 and G9a. Treatment with small molecule inhibitors of EZH2 and G9a reduced H3K9me2 or H3K27me3 throughout differentiation. EZH2 and G9a inhibitors impaired cell cycle withdrawal, differentiation commitment, and myotube formation in wildtype progenitors, while they had no effect on emerin-null progenitors. Interestingly, these inhibitors exacerbated the impaired differentiation of emerin S54F and Q133H mutant progenitors. Collectively, these results suggest the functional interaction between emerin and HDAC3, EZH2, and G9a are important for myogenic differentiation.

B321/P2710

Characterization of 1700029J07RIK, a Novel Nuclear Membrane Associated Protein that is Induced During Skeletal Muscle Atrophy

D. Waddell, S. Lynch; Department of Biology, University of North Florida, Jacksonville, FL.

Skeletal muscle atrophy results from myriad physiological conditions including denervation, corticosteroid exposure, and aging. The objective of this study is to characterize the novel 1700029J07RIK gene, which is induced during neurogenic skeletal muscle atrophy and is differentially expressed in Muscle RING Finger 1 (MuRF1) knockout mice compared to wild-type mice. Muscle tissue isolated from wild-type control mice and MuRF1 knockout mice revealed that the expression of 1700029J07RIK is unchanged at 3 days post-denervation, while expression is significantly induced in wild-type mice at 14 days post-denervation but remains unchanged in the MuRF1-null animals. It has been well established that muscle cells go through a distinct developmental timeline in which they proliferate as single cell myoblasts and then differentiate and fuse into multinucleated myotubes. Quantitative PCR was used to determine that the 1700029J07RIK gene is expressed in proliferating cells and increases in expression as muscle cells differentiate. In addition, the 1700029J07RIK cDNA was cloned from muscle cells and fused with green fluorescent protein and visualized by confocal fluorescent microscopy revealing a cytoplasmic and nuclear membrane localization pattern of the 1700029J07RIK protein in proliferating muscle cells that is distinct from differentiated muscle cells. Utilizing cellular fractionation, it was determined that 1700029J07RIK is localized to both the cytoplasmic and nuclear fractions in proliferating cells, but then appears to translocate into the nucleus as muscle cells differentiate. Moreover, ectopic expression of 1700029J07RIK resulted in elevated levels of Nesprin-1

protein but did not affect Sun2 or Emerin protein levels. Interestingly, the 1700029J07RIK protein appears to undergo post-translational modification as relocation to the nuclear compartment progresses and overexpression leads to a decrease in intermediate filament proteins Desmin and Vimentin. Finally, it was observed that overexpression of 1700029J07RIK resulted in inhibition of muscle cell differentiation and attenuation of the ERK1/2 branch of the MAP Kinase signaling pathway. While there is virtually nothing known about this novel gene in the context of skeletal muscle, the results presented here suggest 1700029J07RIK may play a role in muscle cell differentiation and in skeletal muscle atrophy.

B322/P2711

The Nuclear Envelope Protein NEMP1 is Specifically Required for Female Mouse Fertility and Forms Novel Nuclear Envelope Structures in Maturing Oocytes

D. Hodzic[1], A. Ganguly[1], B. Hakim[1], C. Potter[1], W. Ha[2], Y. Tsatskis[2], A. Jurisicova[2], H. McNeill[1];
[1]Washington University School of Medicine, St. Louis, MO, [2]Lunenfeld-Tanenbaum Research Institute, Toronto, ON, Canada

Nemp1 is an inner nuclear membrane protein of the nuclear envelope (NE) that is required for fertility of in worms, fishes and flies. Even though Nemp1 KO mice are overtly normal, females are subfertile with a significant decrease of the ovarian reserve and a loss of chromatin compaction during folliculogenesis. In ovary slices, endogenous Nemp1 expression levels are markedly higher in the germline by comparison to the somatic cells. As expected for a NE protein, Nemp1 formed homogenous nuclear rim-like pattern in primordial follicles. However, upon the transition from primordial to primary follicles, Nemp1 progressively accumulates into NE foci we named Nuclear Envelope Clusters (NECs). Remarkably, NECs numbers progressively increases during folliculogenesis from about ~5 to about ~150 in primary and antral follicles, respectively. With sizes up to 700 nm, NECs remain present at the NE of ovulated germinal vesicles. To get more insight into the dynamics of these novel NE structures, we developed a mouse model allowing for the conditional expression of Nemp1-GFP in the germline using Zp3-Cre. In this system, Nemp1-GFP faithfully reflects the localization of endogenous Nemp1 at the NE of the germline as well as its accumulation into NECs. Time-lapse video microscopy of Nemp1-GFP in GVs revealed an astoundingly dynamic NE with infolds and protrusions of the NE that form at a scale of seconds. The same dynamics was also observed in antral follicles within acute ovary slices. Our proteomic analyses of Nemp1-GFP fibroblasts have emphasized the interaction between Nemp1 and Ran. Accordingly, Ran colocalizes with Nemp1 in NECs. Finally, we also show that the conditional expression of Nemp1-GFP partially rescues the loss of fertility of Nemp1KO females. Taken together, our results show that Nemp1 is essential to mouse female fertility, that it is highly expressed at the NE of maturing oocytes where it progressively accumulates along with Ran into NECs. The latter correspond to novel structures of the female germline NE. Because the timing of NECs formation corresponds to the onset of chromatin condensation in the germline and that chromatin is decondensed in the Nemp1KO germline, we currently hypothesize that Nemp1 plays a central role in chromatin condensation during folliculogenesis.

B323/P2712

Lamin A/C proteomes from heart, muscle and brain in an IL10-KO model of human frailty

K. L. Wilson; Johns Hopkins School of Medicine, Baltimore, MD

Clinical frailty affects 5-11% of people over age 65 and involves significantly higher risk of morbidity and mortality. Frailty phenotypes include muscle weakening, inflammation and perturbed metabolism, which overlap the spectrum of phenotypes ('laminopathies') caused by mutations in *LMNA*. *LMNA* encodes nuclear intermediate filament proteins, lamin A and lamin C, with shared and distinct roles in mitosis and tissue-specific 3D genome organization and signaling. We hypothesized that wildtype lamins A & C are functionally perturbed in frailty, potentially contributing to tissue dysfunction. We tested this hypothesis by identifying native lamin A/C proteomes from skeletal muscle, heart and brain in an aged (21-22 month) chronic-inflammation (interleukin-10 knockout, IL10-KO) mouse model of frailty. We used lamin A/C antibodies to immunoprecipitate lamins and associated proteins from heart, skeletal muscle and brain lysates of ten female mice (five IL10-KO and five controls), then used Tandem Mass Tags to uniquely label each sample, and pooled each set of same-tissue samples for quantitative mass spectrometry analysis. We identified a native lamin A/C proteome in each tissue— novel for heart and brain— including two candidates (Perm1, Fam210a) previously linked to human frailty phenotypes in genome-wide studies. A subset of proteins in each tissue showed significantly increased or decreased association with lamin A/C in the IL10-KO. After filtering and considering known functions of 502 candidate lamin-associated proteins in muscle, 340 candidates in heart, and >2,200 candidates in brain, we selected twelve for further study. Candidate lamin-binding proteins were arrayed as a series of synthetic 20-mer peptides (staggered by 7 residues) and probed sequentially with either recombinant mature lamin A 'tail' (residues 385-646) or lamin C 'tail' (residues 385-572). As positive controls we included prelamin A, emerin and the peptide unique to lamin C. These results validated direct binding of one or both recombinant lamins to ten candidates. Plausibility was evaluated using PyMol, which showed that putative binding site(s) mapped to surface-exposed residues in novel partners including three affected in IL10-KO skeletal muscle (Ppme-1, Lmcd1, Fabp4) and two affected in heart (Gins3, AldoA). Since little-to-nothing is known about native lamin A/C proteomes in most tissues and organs, including brain, these proteomes provide foundations to study the mechanisms of human frailty and laminopathies based on understanding both conserved and tissue-specific functions of lamin A and lamin C.

Differential interactomes of lamin A & lamin C in early G1

J. Sobo[1], A. Rendon-Jonguitud[1], X. Wong[2], K. Reddy[1]; [1]Johns Hopkins University Sch Med, Baltimore, MD, [2]A*STAR, Immunos, Singapore

The nuclear lamina comprises a network of type V intermediate filaments called lamins that form a meshwork that underlies the inner nuclear membrane (INM). Lamins have been implicated in numerous cellular functions including structural integrity and positioning as well as genome organization and regulation. Large regions of heterochromatin associate with the nuclear lamina in lamin associated domains (LADs). There are two general classes of somatic lamins: B-type (lamin B1 and B2; laB), which are expressed in all cell types and developmental stages, and A-type, which are developmentally regulated and display cell-type specific differences in expression levels. A-type lamins are comprised of two isotypes, lamin A (laA) and lamin C (laC), that are derived through alternative splicing of the *LMNA*

gene. We have recently shown that laC is uniquely important for proper LAD organization, with a potentially important role in reorganizing LADs to the lamina at mitotic exit. Intriguingly, both LADs and laC are in the nucleoplasm in early G1, while laB and most of laA are already polymerized at the nuclear periphery. Given the unique roles and disposition of laA and laC at mitotic exit, we have employed Turbo-ID, a derivative of the biotin-ligase proximity labeling method Bio-ID, to detect their differential proteomes during mitotic exit in synchronized cell populations. Using mass spectrometry analysis on biotin enriched peptides, we hope to identify dynamic differential proteome networks of laA and laC and uncover partners and regulators involved in LAD organization dynamics.

Endocytic Trafficking

Phosphatidylinositol 4,5-Bisphosphate Is Required for Cargo Sorting of Epidermal Growth Factor Receptor to the Lysosome

S. Chu[1], J. Hsu[1,2]; [1]Institute of Biochemical Sciences, National Taiwan University, Taipei, TAIWAN, [2]Institute of Biological Chemistry, Academia Sinica, Taipei, TAIWAN.

Phosphatidylinositol 4,5-bisphosphate (PI(4,5)P2) is a lipid messenger at the plasma membrane to control the endocytosis of several membrane receptors such as epidermal growth factor receptor (EGFR). Most of PI(4,5)P2 is generated by type I phosphatidylinositol phosphate kinase (PIPKI) from the substrate phosphatidylinositol-4-bisphosphate (PI4P) to support intracellular PI(4,5)P2 signaling. Recently, PI(4,5)P2 also has been found on endosomal and lysosomal membranes to facilitate endocytic protein transport. PIP5K1A, a type I phosphatidylinositol phosphate kinase, plays important roles in a variety of cellular functions including protein transport. How lipid kinase coordinates phospholipid signaling and membrane recruitment of downstream effector has been unclear. Here, we show that PIP5K1A regulates the lysosomal transport of EGFR for protein degradation. We also demonstrate that EGF stimulation promotes PIP5K1A to form a complex with EGFR for the cargo sorting to the lysosome. PI(4,5)P2-containing membrane compartment is also required to recruit cargo adaptors to promote EGFR lysosomal targeting for protein degradation. These findings identify a new aspect of endosome-to-lysosome trafficking by realizing how lipid membranes directly participate in regulating protein transport.

UHRF1BP1 and UHRF1BP1L (SHIP164) are Chorein Motif Containing Lipid Transport Proteins that Control Membrane Dynamics in the endo-lysosome system

M. G. Hanna[1,1,2,1], P. De Camilli[1,1,2,1,3]; [1]Yale University, New Haven, CT, [2]Howard Hughes Medical Institute, Chevy Chase, MD, [3]Aligning Science Across Parkinson's (ASAP) Collaborative Research Network, Chevy Chase, MD

Chorein motif proteins are a family of putative lipid transport proteins localized at intracellular membrane contacts sites. They have a rod-like shape and contain a hydrophobic groove running along their length which is thought to function as a conduit for lipid transfer between bilayers by a bridge-like mechanism. Recently, in collaboration with the Reinisch lab (Hanna, Suen, Wu, Reinisch & De Camilli; J. Cell Biol. 2022, PMID: 35499567), we reported a systematic structural and functional characterization of SHIP164 (UHRF1BP1L), another member of this family, previously shown to be a Rab5 effector. In such

study we have 1) confirmed lipid transport properties of this protein, 2) found that endogenous SHIP164 is localized to clusters of small early endocytic vesicles positive for the mannose-6-phosphate receptor (CI-MPR), 3) shown that SHIP164 over-expression expands the size of these clusters and 4) determined that loss of SHIP164 results in the abnormal traffic of CI-MPR. SHIP164 has a paralogue called UHRF1BP1, previously suggested to be a Rab7 effector. Accordingly, 5) we have also found that although exogenous UHRF1BP1 also induced large vesicle assemblies, such assemblies were associated with the lysosome marker LAMP1, rather than early endosomal markers, pointing to a role downstream of SHIP164. We have now further investigated the properties of UHRF1BP1 and SHIP164. We have corroborated evidence for their distinct subcellular localization along the endocytic pathway, in spite of their remarkable predicted structural similarity. We have investigated the physical properties of the vesicle assemblies where they accumulate, utilizing optogenetic and thermodynamic assays in live cells. We have found that both paralogues are enriched in brain, a finding of special interest as SHIP164 was reported to be a candidate Parkinson's disease susceptibility gene. In ongoing studies, we are exploring the impact of the combined loss-of-function of both proteins on the endocytic pathway. An attractive working hypothesis is that UHRF1BP1 and SHIP164, via their lipid transport properties, may help fine tune to protein-lipid ratio of membrane of the endocytic pathway.

Apolipoprotein C3 facilitates endocytosis of cationic lipid nanoparticles via apolipoprotein receptor 2 and the peroxisome proliferator-activated receptor gamma pathway

M. Kulka[1], S. Alam[2], F. Wang[2], H. Qian[2]; [1]Medical Microbiology and Immunology, University of Alberta, Nanotechnology Research Center, NRC, Edmonton, AB, CANADA, [2]Nanotechnology Research Center, NRC, Edmonton, AB, CANADA.

Mast cells (MCs), are hematopoetically-derived secretory immune cells that release preformed as well as de novo synthesized inflammatory mediators in response to activation by several stimuli. Based on their role in inflammatory responses, particularly in the lung and skin, MCs provide a convenient and effective target for anti-inflammatory therapeutic strategies. Drug-delivery of lipophilic payloads to MCs can be challenging due to their functionally distinct intracellular structures. In the present study, pH-sensitive cationic lipid-based nanoparticles (LNPs) composed of DODMA, DODAP or DOTAP lipids that encapsulated a GFP or eGFP plasmid were constructed using non-turbulent microfluidic mixing. This approach achieved up to 75-92% encapsulation efficiency. Dynamic light scattering revealed a uniform and homogeneous size distribution of LNPs. To promote cellular internalization, LNPs were complexed with apolipoproteins, amphipathic proteins capable of binding lipids and facilitating their transport in the bloodstream and into cells. LNP preparations made up of DODMA or DODMA, DODAP and DOTAP lipids were coated with one of seven apolipoproteins (A1, B, C3, D, E2, E4 and H). Terminally differentiated bone-marrow derived mouse mast cells (BMMCs) were treated with Apo-LNP and internalization was measured using flow cytometry. Out of all the apolipoproteins tested, LNP coated with apolipoprotein C3 (ApoC3) most efficiently facilitated cellular internalization of the LNP into BMMCs as determined by GFP fluorescence using flow cytometry. These effects were confirmed in a less differentiated but also interleukin-3-dependent model of mouse mast cells, MC/9. ApoC3-LNP enhanced internalization by BMMC in a concentration-dependent manner and this was significantly increased when BMMC were pre-treated with inhibitors of actin polymerization, suggesting a dependence on intracellular shuttling. Activation of peroxisome proliferator-activated receptor gamma (PPARgamma) decreased ApoC3-LNP internalization and reduced the expression of apolipoprotein E receptor 2

(ApoER2) , suggesting that ApoC3-LNP binding to ApoER2 may be responsible for its enhanced internalization. Altogether, our studies reveal an important role of ApoC3 in facilitating internalization of cationic LNPs into MCs.

B329/P2717

Rab3 regulates microdomain-mediated plasma membrane recycling

K. R. Levental[1], B. Diaz-Rohrer[2], I. Castello-Serrano[1], H.-Y. Wang[1], I. Levental[1]; [1]University of Virginia, Charlottesville, VA, [2]University of Texas Health Science Center at Houston, Houston, TX

The composition of the plasma membrane (PM) must be tightly controlled despite constant, rapid endocytosis, requiring active, selective recycling of endocytosed membrane components. For most proteins, the mechanisms and pathways of recycling to the PM remain unknown. We report that association with ordered, lipid-driven membrane microdomains (i.e. rafts) is sufficient for PM localization of a subset of transmembrane proteins and that abrogation of raft association disrupts their trafficking and leads to their degradation in lysosomes. Using orthogonal, genetically encoded probes with defined, tunable raft affinity, we screened for trafficking mediators required for efficient recycling of microdomain-associated cargo from endosomes to the PM. Among a set of specific mediators, we identified Rab3 as an important mediator of plasma membrane localization of microdomain-associated proteins. Disruption of Rab3 reduced the localization of raft probes on the PM and led to their accumulation in Rab7-positive endosomes, suggesting inefficient recycling. Rab3 itself is palmitoylated and may associate with microdomains on Rab7-positive endosomes to facilitate sorting and subsequent recycling to the PM. Abrogation of Rab3 function mis-localized the endogenous raft-associated protein Linker for Activation of T-cells, leading to its intracellular accumulation and reduced T cell activation. These findings reveal a fundamental role for lipid-driven microdomains in endocytic traffic and suggest Rab3 as a central regulator of PM composition.

B330/P2718

P4-ATPases Require Retromer for their Localization

M. Jimenez, J. T. Best, C. Kyoung, T. R. Graham; Vanderbilt University, Nashville, TN.

The transport of proteins and lipids throughout the cell is crucial for diverse cellular processes including vesicular transport, signal transduction and apoptosis. One important aspect of cell functionality is an asymmetric membrane composition established by type-IV P-type ATPases (P4-ATPase), which uses the energy from ATP hydrolysis to transport lipids from the exofacial to the cytofacial leaflet of membranes. P4-ATPase deficiency disrupts vesicle-mediated protein transport from Golgi and endosomal membranes and can lead to a number of severe neurological defects. For proper P4-ATPase function, correct localization to appropriate membranes is essential. Of the five P4-ATPases in *Saccharomyces cerevisiae*, Dnf1 and Dnf2 are known to localize to the plasma membrane (PM) while Neo1, Drs2, and Dnf3 localize to the Golgi and each travels through the endocytic pathway as part of their trafficking itineraries. In this study, I seek to determine the recycling and retrograde trafficking pathways traveled by P4-ATPases, and how these flippases interact with components of those pathways. Key components of four major trafficking pathways between endosomes and the Golgi including Drs2/Rcy1/COPI, Snx4, retromer and AP-1/Clathrin, were deleted to determine the routes required for Dnf1/Dnf2 PM localization and Drs2 Golgi localization. Deletion of retromer components including Vps35, Vps5, Vps17, and Snx3 led to mislocalization of Dnf1, Dnf2, and Drs2 to the vacuole, as similarly described previously

for Neo1. These data suggest a primary role for retromer in proper localization of P4-ATPases although a minor role for Rcy1 and Snx4 was detected. In dissecting the interactions between retromer and the P4-ATPases, it was found that Dnf1 contains retromer recognition motifs in the N-terminal tail and both Dnf1 and Dnf2 have a novel C-terminal tail motif. **Together these results would suggest the loss of retromer leads to a substantial loss of P4-ATPases at their primary membrane and should therefore cause major changes in membrane organization.** Deficiencies in the human orthologs of Dnf1/Dnf2 and retromer have been linked to endosomal dysfunction leading to Parkinson's Disease. This study could help elucidate why mutations in these proteins cause the disease.

B331/P2719

Acute and reversible modulation of kidney proximal tubule endocytic capacity by fluid shear stress

E. Lackner[1], K. E. Shipman[1], K. R. Long[1], I. A. Cowan[1], O. A. Weisz[1,2]; [1]Department of Medicine Renal-Electrolyte Division, University of Pittsburgh, Pittsburgh, PA, [2]School of Medicine Department of Cell Biology, University of Pittsburgh, Pittsburgh, PA.

The proximal tubule (PT) of the kidney is comprised of cells that are uniquely specialized for efficient apical uptake of albumin and other proteins that escape the glomerular filtration barrier. These proteins bind to the multiligand receptors megalin and cubilin and are internalized via clathrin-dependent endocytosis into small apical early endosomes that rapidly mature into larger apical vacuoles. Dissociated ligands are delivered from vacuoles to lysosomes for degradation, while receptors are collected into dense apical tubules for recycling to the cell surface. We have optimized a proximal tubule cell model cultured under orbital shear stress that recapitulates the essential morphologic and functional features of the PT *in vivo*, including high megalin and cubilin expression and robust apical endocytic capacity. Using this model, we found that acute changes in orbital speed trigger rapid changes in the endocytosis of albumin. We hypothesize that *in vivo*, this modulation of endocytic capacity enables PT cells to preserve uptake efficiency in response to changes in glomerular filtration rate. We are using biochemical and imaging approaches combined with mathematical modeling to identify the trafficking step(s) modulated by fluid shear stress. Using cell surface biotinylation to quantify the fraction of receptors at the apical membrane, we consistently observed an increase in surface megalin and cubilin at the apical membrane upon removal of shear stress. To determine the contributions of endocytic vs recycling rates to this altered profile, we are quantifying the endocytic rate of megalin and also measuring the colocalization with known markers of apical endocytic compartments. These data will be used to adapt our recently developed kinetic model of megalin trafficking in PT cells to determine effects shear stress changes on individual trafficking rates. This approach allows us to integrate effects of small changes in a single round of trafficking over multiple iterations, and will enable us to identify potential signaling pathways impacted by shear stress that modulate alterations in membrane traffic.

Insulin Signaling Attenuates GLUT4 Endocytosis in Muscle Cells via GSK3α-Dyn2-Bin1 Interplay

J. Laiman[1], Y. Hsu[1], J. Loh[1], W. Tang[2], M. Chuang[1], H. Liu[3,4], W. Yang[5], B. Chen[6], L. Chuang[1,7], Y. Chang[7,8,9], Y. Liu[1,10]; [1]Institute of Molecular Medicine, College of Medicine, National Taiwan University, Taipei, TAIWAN, [2]ResearchCenter for Applied Sciences, Academia Sinica, Taipei, TAIWAN, [3]National Research Institute of Chinese Medicine, Ministry of Health and Welfare, Taipei, TAIWAN, [4]Program in the Clinical Drug Development of Herbal Medicine, Taipei Medical University, Taipei, TAIWAN, [5]Division of Nephrology, Department of Internal Medicine, National Taiwan University Hospital, Hsin-Chu Branch,

Hsin-Chu, TAIWAN, [6]2ResearchCenter for Applied Sciences, Academia Sinica, Taipei, TAIWAN, [7]Department of Internal Medicine, National Taiwan University Hospital, Taipei, TAIWAN, [8]Institute of Medical Genomics and Proteomics, College of Medicine, National Taiwan University, Taipei, TAIWAN, [9]Institute of Biomedical Sciences, Academia Sinica, Taipei, TAIWAN, [10]Center of Precision Medicine, College of Medicine, National Taiwan University, Taipei, TAIWAN.

Skeletal muscle is the main tissue where insulin-stimulated glucose uptake occurs to maintain blood glucose. Glucose transporter 4 (GLUT4), is translocated from intracellular membrane compartments to muscle surface upon insulin signaling to facilitate glucose uptake and internalized back in the absence of insulin. Despite its role in promoting GLUT4 exocytosis, little is known about the role of the insulin signaling pathway in GLUT4 endocytosis. Here, we showed that the mechanoenzyme catalyzing GLUT4 internalization, dynamin-2 (Dyn2), is negatively regulated by insulin signaling in muscle cells. Bin1, a membrane remodeling protein highly expressed in muscle, inhibits Dyn2 via direct interaction of its SRC Homology 3 (SH3) domain with the proline-rich domain (PRD) of Dyn2. GSK3α, but not GSK3β, in turn phosphorylates Dyn2 to relieve its inhibition by Bin1. Conversely, insulin signaling inactivates GSK3α, suppressing Dyn2-mediated GLUT4 endocytosis to boost glucose uptake. In addition, the pharmacological inhibition of GSK3α in diet-induced obese mice leads to enhanced insulin sensitivity and glucose tolerance. Collectively, we demonstrated the attenuation of GLUT4 endocytosis by insulin signaling through GSK3α-Dyn2-Bin1 interplay in muscle cells.

The Fragile X Messenger Ribonucleoprotein (FMRP) Negatively Regulates Clathrin-associated Adaptor Complex Protein 2 (AP2) and Endocytosis

L. Shi, A. Valdez-Sinon, N. Raj, A. Kosti, V. Faundez, G. Bassell; Department of Cell Biology, Emory University School of Medicine, Atlanta, GA.

FXS is a neurodevelopmental brain disorder caused by the loss of FMRP, known to regulate mRNA translation and local protein synthesis important for synapse development and function. A number of studies have shown that FMRP deficient neurons have impaired trafficking of receptors and ion channels, but the role of specific FMRP targets and their translational dysregulation are not well understood. Using RIP, we confirmed that FMRP was associated with *Ap2a1* and *Ap2b1* mRNAs. Increased expression of AP2 subunits were detected in synaptoneurosome fractions of *Fmr1* KO mouse, although no significant change in mRNA levels were found. Increased rate of newly synthesized AP2B1 was observed in *Fmr1* KO neurons. DHPG stimulation increased AP2 levels at postsynaptic sites in WT but not *Fmr1* KO cortical neurons. Importantly, smiFISH showed AP2 subunit mRNAs localized to dendrites. Taken together, these results suggest that FMRP regulates the postsynaptic expression of AP2 subunits, perhaps via local translation. To obtain further insight into how FMRP may regulate components involved in membrane trafficking, we performed a proteomics study of FMRP interactome in N2A cells. While major gene ontology categories were linked to translation and posttranscriptional regulation, three subunits of AP2 were identified. Co-IP and immunofluorescence further demonstrated that AP2 subunits were associated and colocalized with FMRP in dendrites. Because of the important functions of AP2 in membrane trafficking, transferrin was used as a reporter to study clathrin-mediated endocytosis and endosomal trafficking. Quantitative imaging analysis revealed that *Fmr1* KO neurons showed a delayed, but significant increase of transferrin positive puncta numbers, which suggests that *Fmr1* depletion may lead to increased rate of endocytosis. Compared to WT neurons, the early

endosomes in *Fmr1* KO neurons showed increased numbers and enlarged size after transferrin feeding. In this study, we uncovered impairments in the expression and synaptic localization of AP2 subunits that may be due to loss of FMRP mediated local translation regulation as well as FMRP interacting with AP2 subunits at synapses. Further work is underway to determine if dysregulated AP2 is responsible for the observed abnormal neuronal endocytosis and to identify the specific surface proteins adversely affected in FXS.

B334/P2722

Evolutionary cell biology of clathrin-mediated endocytosis in yeasts

A. Picco, C. P. Toret, A. Rivier-Cordey, M. Kaksonen; University of Geneva, Geneva, SWITZERLAND.

Clathrin-mediated endocytosis is a core, eukaryotic membrane trafficking pathway at the interface between the cell and its environment. Endocytosis requires biophysical events to occur sequentially: first, the endocytic coat proteins define the site of endocytosis and recruit cargo on the plasma membrane, then the membrane is deformed to create an invagination, and lastly, a vesicle is released into the cytoplasm. Much of the endocytic protein machinery is conserved across eukaryotes. However, there are a significant number of proteins that vary. Furthermore, the physical parameters of invagination and vesicle vary across species. Little is understood about how the endocytic processes diverged, and the large evolutionary gap between yeast and animals makes this divergence challenging to study. We aim to understand interspecies differences to identify the conserved and variable molecular mechanisms of endocytosis and ultimately reveal the evolutionary pathways that have led to variation of clathrin-mediated endocytosis.

We chose three distantly related fungal yeast species as model organisms: *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*, and *Ustilago maydis*. These species diverged around 600MYA. They are amenable to genetic manipulations and live-cell imaging and thus provide a powerful model clade to begin to understand the evolutionary cell biology of endocytosis.

We used quantitative live-cell imaging to compare the assembly and disassembly dynamics, and movements of seven groups of orthologous endocytic proteins tagged with fluorophores. Our comparative data across the three species revealed an unexpected diversity in protein dynamics. This variability was most prominent during the early phase and the last steps of endocytosis. Between these variable periods, we found that the growth rate of the membrane invagination was strikingly identical for the first 100 nm. Afterwards, the invaginations grew at variable rates and reached different total lengths in the different species. This reveals a previously unknown evolutionary constraint on membrane shaping.

This study quantitatively establishes that different modules of endocytosis evolved independently as a mosaic. Defining the variabilities, in addition to the conservation across species, is necessary for understanding the mechanisms that underly membrane shaping in a variety of cellular contexts. Furthermore, our comparative data lay the foundation to estimate ancestral states of endocytosis.

B335/P2723

Flat Clathrin Lattices Nucleate Reticular Adhesions

L. Hakanpää[1], A. Abouelezz[1], A. Lenaerts[1], M. Algie[1], J. Bärlund[1], P. katajisto[1], H. McMahon[2], **L. Almeida-Souza**[1]; [1]HiLIFE, University of Helsinki, Helsinki, FINLAND, [2]MRC Laboratory of Molecular Biology, Cambridge, UNITED KINGDOM.

The molecular machinery involved in clathrin mediated endocytosis (CME) forms two distinct structures at the plasma membrane: clathrin coated pits (CCPs) and flat clathrin lattices (FCLs). CCPs are the canonical endocytic carriers for CME and have been extensively studied. In contrast, the cellular role of FCLs, characterised by their stability and localisation to reticular adhesions, are not well understood. Reticular adhesions are a recently described type of cellular adhesion composed of integrin αvβ5 and devoid of typical focal adhesion markers.
Here we show that FCLs mediate the formation of reticular adhesions and that this process is controlled by the composition of the extracellular matrix.
We observed that cells plated on fibronectin displayed few FCLs and reticular adhesions. Notably, this effect occurred locally in cells, in an extracellular matrix-contact dependent manner. Pointing to a close relationship between these structures, inhibition of the CME machinery, using knockdowns or dominant negatives, led to complete disappearance of reticular adhesions. In agreement, using live-cell imaging we could visualise that FCL assembly is required for the establishment of reticular adhesions.
Manipulation of the fibronectin receptor integrin β1 revealed that the formation of FCLs - and consequently reticular adhesions - are controlled by the activity of this receptor.
CME and other endocytic routes have conventionally been linked to the disassembly of cellular adhesions by mediating the internalisation of their components. Our results present a novel paradigm in the relationship between these two processes by showing that endocytic proteins can also play a role in the assembly of cellular adhesions.

B336/P2724

Superresolution microscopy reveals partial preassembly and subsequent bending of the clathrin coat during endocytosis

A. Tschanz[1], M. Mund[2,1], Y. Wu[1], F. Frey[3], J. L. Mehl[1,4], M. Kaksonen[2], O. Avinoam[1,5], U. S. Schwarz[6,7], J. Ries[1]; [1]EMBL, Heidelberg, GERMANY, [2]University of Geneva, Geneva, SWITZERLAND, [3]Delft University of Technology, Delft, NETHERLANDS, [4]ETH, Zürich, SWITZERLAND, [5]Weizmann Institute of Science, Rehovot, ISRAEL, [6]Institute for Theoretical Physics and Bioquant, Heidelberg, GERMANY, [7]Bioquant, Heidelberg, GERMANY.

Eukaryotic cells use clathrin-mediated endocytosis to take up a large range of extracellular cargos. During endocytosis, a clathrin coat forms on the plasma membrane, but it remains controversial when and how it is remodeled into a spherical vesicle. Here, we use 3D superresolution microscopy to determine the precise geometry of the clathrin coat at large numbers of endocytic sites. Through pseudo-temporal sorting, we determine the average trajectory of clathrin remodeling during endocytosis. We find that clathrin coats assemble first on flat membranes to 50% of the coat area, before they become rapidly and continuously bent, and confirm this mechanism in three cell lines. We introduce the *cooperative curvature model*, which is based on positive feedback for curvature generation. It accurately describes the measured shapes and dynamics of the clathrin coat and could represent a general mechanism for clathrin coat remodeling on the plasma membrane.

B337/P2725

clathrin dynamics in endothelial cells are impacted by shear stress

T. Nawara, E. Sztul, A. Mattheyses; UNIVERSITY OF ALABAMA AT BIRMINGHAM, Birmingham, AL.

The environmental conditions present in the vasculature, including osmotic changes and cell squeezing, inhibit clathrin-mediated endocytosis (CME) in non-endothelial cells, such as fibroblast-like Cos-7 cells. How endothelial cells overcome physiological stresses such as cyclic stretch and shear stress, and preserve CME is not understood. To provide insight into this critically important physiological enigma, we expressed the clathrin light chain a dual-tagged with iRFP713 and EGFP (CLCa-STAR) in vascular model human umbilical vein endothelial cells (HUVECs) and probed clathrin dynamics using simultaneous two-wavelength axial ratiometry (STAR) microscopy. We show that clathrin dynamics, specifically the timing of clathrin accumulation and initiation of curvature in vesicle formation and the ratio of curved to flat clathrin structures in HUVECs grown under static conditions are similar to those in Cos-7 cells. We next examined if clathrin dynamics in HUVECs are altered by sheer stress. When HUVECs were cultured under static or flow conditions, sheer stress led to a characteristic cell alignment and actin organization. We found sheer stress also led to an increase in clathrin dynamics. Surprisingly, we found this was due to an increase of flat clathrin accumulations in flow-stimulated cells, while the number of curved events remained consistent between groups. The curvature positive events had significantly delayed curvature initiation in flow-stimulated cells, highlighting a shift toward flat-to-curved clathrin transitions in vesicle formation. We plan to investigate whether sheer stress changes the response of HUVECs to changes in osmotic pressure. Overall, our findings indicate that clathrin dynamics and endosomal vesicle formation can be modulated by local environment and represents an important regulatory mechanism.

B338/P2726

Clathrin-mediated trafficking of phospholipid flippases is required for local plasma membrane/cell wall damage repair in budding yeast

Y. Yamazaki, K. Kono; Okinawa Institute of Science and Technology, Okinawa, JAPAN.

Plasma membrane damage and repair frequently happen in cells. A critical process underlying plasma membrane repair is to redirect repair factors, such as protein kinase C and the exocyst complex, from the polarized site to the damage site. However, the mechanism underlying the repair factor delivery to the damage site remains unknown. Here, we demonstrate that clathrin-mediated trafficking of repair factors is involved in plasma membrane/cell wall repair in budding yeast. Using laser-induced plasma membrane/cell wall damage assay, we identified phospholipid flippases, Lem3-Dnf1/Dnf2 and Cdc50-Drs2, as essential clathrin cargos for plasma membrane/cell wall repair. We found that flippase impairment significantly compromised the recruitment of exocyst Exo70 to the damage site. In contrast, the recruitment of protein kinase C (Pkc1) was only mildly compromised. Taken together, clathrin-mediated trafficking of the phospholipid flippases is critical for the recruitment of exocyst to the damage site. Mechanisms to redirect exocyst via the clathrin and flippase-mediated pathways may be a general feature of effective plasma membrane repair in polarized cells.

B339/P2727

Measuring conformational changes in clathrin light chain at single sites of endocytosis with FRET-CLEM

K. Obashi, K. A. Sochacki, M. Strub, J. W. Taraska; National Heart, Lung, and Blood Institute, NIH, Bethesda, MD.

Clathrin mediated endocytosis is the primary internalization mechanism of mammalian cells. Over 50 proteins have been shown to be involved in this process. The nanoscale localizations, interactions, and conformations of endocytic proteins are key regulators of clathrin-mediated endocytosis. Although super-resolution microscopy has revealed the detailed organization of endocytic proteins, the resolution of super-resolution imaging cannot assess molecular interaction and conformational changes. Fluorescence resonance energy transfer (FRET) occurs when dyes are separated by less than 10 nm for most fluorescent proteins pairs. Thus, it can be used to map close-range molecular complexes and dynamics. Yet, to understand how endocytosis works, measurements from FRET must be correlated to the distinct stages of endocytosis. To accomplish this, we developed a new correlative lifetime-based FRET (FLIM-FRET) and platinum replica transmission electron microscopy (PREM) method, named FRET-CLEM. Here, FRET-based atomic distances can be mapped directly to individual cellular structures visualized in EM at the plasma membrane. We used this method to measure the conformational changes in clathrin light chain (CLC), a component of the clathrin triskelion and assembled clathrin lattice. CLC conformational changes have been proposed to regulate the assembly of clathrin in solution. However, CLC conformational changes and their effects on clathrin lattice growth, curvature, and endocytosis at the membrane of living cells are unknown. Using FRET-CLEM, we discovered that CLC undergoes a conformational switch as clathrin lattices curve. Preventing this conformational switch with acute chemical tools increased clathrin lattice sizes and inhibited endocytosis. Therefore, a specific conformational switch in CLC regulates lattice curvature and endocytosis in mammalian cells. These new correlative light and EM data will help develop a complete mechanistic model of endocytosis. More generally, FRET-CLEM can map molecular interactions and conformational changes at targeted membrane-associated proteins at identified cellular compartments including exocytic sites and neuronal synapses.

B340/P2728

Clathrin light chain regulates neural development and function in *Drosophila melanogaster*

J. Das[1,2], A. Majumdar[1], D. Subramanyam[1]; [1]National Center for Cell Science, Pune, INDIA, [2]Savitribai Phule Pune University, Pune, INDIA.

Clathrin is a cytosolic protein involved in the intracellular trafficking of a wide range of cargo. It is composed of three molecules of the clathrin heavy chains and three molecules of the clathrin light chains that together form a triskelion, the subunit that polymerizes to form a clathrin coated vesicle. Although the role of the heavy chains in regulating important physiological processes has been well documented, we still lack a complete understanding of how the clathrin light chains regulate membrane traffic and cell signaling. In this study, we use *Drosophila melanogaster* as a model system to understand the role of clathrin light chains (CLC) in neural development and function. Using CRISPR -Cas9, we show that adult flies exhibit a severe locomotion defect upon ubiquitous depletion of the light chain. This phenotype is also seen upon neuron-specific loss of the protein indicating that a neuron specific function of the light chain, presumably it's role in synaptic vesicle recycling, is essential for locomotion in

adult flies. Interestingly, this behavioural defect is not seen at the larval stage. We also observe additional behavioural changes in flies lacking the clathrin light chain. These are accompanied by altered mushroom body structures, leading us to believe that the light chain may play an important role in brain development and function.

B341/P2729

Exploitation of components of the mammalian ESCRT-III machinery by the parasite *Toxoplasma*for the sequestration of host organelles into the parasitophorous vacuole

J. D. Romano[1], J. Mayoral[2], R. B. Guevara[2], Y. Rivera-Cuevas[3], V. B. Carruthers[3], L. M. Weiss[2], I. Coppens[1]; [1]Johns Hopkins University School of Public Health, Baltimore, MD, [2]Albert Einstein College of Medicine, Bronx, NY, [3]University of Michigan Medical School, Ann Arbor, MI.

The intracellular parasite *Toxoplasma gondii* multiplies in mammalian cells within a self-made niche - the parasitophorous vacuole (PV). Parasite proteins are incorporated into the PV membrane (PVM) creating a specialized compartment that avoids fusion with host cellular organelles. However, *Toxoplasma* proficiently salvages lipids from host organelles by diverting endosomal recycling pathways to the PV. The parasite sequesters host endo-lysosomes and Rab vesicles into the PV using an IntraVacuolar Network (IVN) of parasite-derived membranous tubules that can fuse to the PVM, creating open gates; in a mutant lacking an IVN, a significant decrease of host organelle internalization is observed. Host organelles accumulate in the PV center, suggesting dissociation from the PVM. We hypothesize that the parasite recruits host ESCRT components to mediate this scission. In HeLa cells, stably expressed GFP-CHMP4B localizes to the host cytosol/nucleus, and upon infection, associates with the PV and IVN as puncta, suggesting recruitment to the PV. To analyze host CHMP4B-PV association, we overexpressed host CHMP4B tagged C-terminally with mEmerald to induce dominant negative (DN) effects. CHMP4B-mEmerald largely distributes on the PVM; its more uniform distribution and absence on the IVN suggests the C-terminal tag may interfere with later scission steps. EM observations illustrate PVM invaginations forming long tubules containing CHMP4B polymers organized in spirals within the tubules, leading to tubule constriction to a diameter of 105 nm. These invaginations are significantly shorter in the IVN-deficient mutant, suggesting IVN tubule contribution to the elongation of PVM invaginations triggered by DN CHMP4B. In infected cells overexpressing $VPS4^{EQ}$, we observe abnormally enlarged intra-PV structures containing host endo-lysosomes, reflecting defects in PVM tubule scission. Knock-out mutants of two parasite proteins (TgGRA14, TgGRA64), that interact with ESCRT motifs, exhibit defects in CHMP4B-mEmerald-induced invagination formation and host organelle internalization, with more pronounced defects observed in the PV of *Δgra14Δgra64*, suggesting a synergistic role at the PVM/IVN via interactions with host ESCRT components.

Quantitative fluorescence analysis of the endocytosis of GPCR Ste3

K. G. Oppenheimer[1], N. A. Hager[1], C. K. McAtee[1], M. P. Bruchez[2], A. F. O'Donnell[1]; [1]Biological Sciences, University of Pittsburgh, Pittsburgh, PA, [2]Biological Sciences and Chemistry, Carnegie Mellon University, Pittsburgh, PA.

The ability to sense and respond to extracellular signals is essential for cellular function and an organism's health. G-protein coupled receptors (GPCRs) enable specific and rapid response to extracellular signals through their ligand-induced activation of associated heterotrimeric G-proteins. Our

previous work demonstrated that the constitutive endocytosis of the yeast mating pathway GPCR, Ste3, is regulated by α-arrestins Ldb19, Aly1 and Aly2, but the contribution of these α-arrestins' to ligand-induced Ste3 endocytosis has yet to be explored. We have developed a new quantitative microscopy approach aimed at defining Ste3 endocytic trafficking dynamics in response to ligand. We developed the fluorogen activated protein (FAP) imaging technology for use in quantitative trafficking studies in yeast. We have calibrated the FAP-tag for yeast cell biology studies by codon optimization and have refined imaging conditions to optimize FAP's utility in this organism. Using this system, we determined that the α-arrestins Aly1, Aly2, and Ldb19 mediate the ligand-dependent endocytosis of Ste3, with a significant retention of the receptor at the plasma membrane in the absence of these three α-arrestins. We further re-assess regions of the Ste3 C-terminal tail that were identified as important for constitutive or ligand-induced internalization of Ste3. We found that the PEST-like domain, previously thought to be important for only constitutive internalization, also impacts ligand-dependent Ste3 endocytosis. Additionally, we find that a single lysine mutation in the C-tail of Ste3 impedes its endocytosis and posit that this may be an important site of receptor ubiquitination. We perform compared analyses between the FAP imaging technology to the pH sensitive fluorescent marker pHluorin, confirming that both FAP and pHluorin tagged Ste3 show similar internalization dynamics. This comparison also illustrates the advantage of FAP application in endocytic assays, as we can spatially and temporally visualize select Ste3 populations with FAP. Together, this work expands the role of α-arrestins in GPCR trafficking and demonstrates the utility of the FAP technology in yeast cell biology studies.

Upregulated-flotillins derail endocytosis and vesicular traffic to induce cellular invasion

C. Gauthier-Rouviere, S. Bodin; CNRS-CRBM, Montpellier, FRANCE.

Altered endocytosis and vesicular trafficking are major players during tumorigenesis.Flotillins 1 and 2 are two ubiquitous, highly conserved homologous proteins that assemble to form heterotetramers at the cytoplasmic face of the plasma membrane (PM) in microdomains enriched in cholesterol and sphingolipids. They scaffold membrane microdomains - where different proteins concentrate - thanks to their oligomerization property. Flotillin 1 and 2 are upregulated in a large number of cancers, which is associated with a poor prognosis. Flotillin upregulation is necessary and sufficient for the acquisition of invasive cell properties. The upregulation of flotillins favors their oligomerization and induces the Upregulated Flotillin-Induced Trafficking (UFIT) pathway, an endocytosis pathway that targets cargo proteins in late endosomes positive for CD63 and LAMP-1, where flotillins accumulate. These flotillin-enriched late endosomes are not degradative and contain numerous intraluminal vesicles, their fusion with the PM allows the recycling of the proteins present in their outer membrane and the release of the exosomes/extracellular vesicles (EVs) they contain in the extracellular medium.We found that, in non-tumoral mammary epithelial cells, induction of the UFIT pathway promotes epithelial-to-mesenchymal transition (EMT) and accelerates the endocytosis of several transmembrane receptors towards flotillin-positive non-degradative late endosomes. The receptor tyrosine kinase AXL, the overexpression of which, frequently observed in cancer cells, is linked to EMT and metastasis formation, is stabilized and consequently overexpressed by the UFIT pathway. We also showed that flotillin upregulation in epithelial mammary (MCF10A) and mesenchymal myoblastic (C2C12) cells increases the number of secreted EVs. To identify the mechanisms, we are performing a siRNA-based screen with the Nluc-CD63 reporter in flotillin-overexpressing non-tumoral MCF10A cell line. The UFIT-pathway requires sphingosine-kinase 2 which is recruited in flotillin-rich membrane-domains at endocytic sites and in late

endosomes. This lipid kinase phosphorylates sphingosine to generate sphingosine-1 phosphate, a lipid frequently overproduced in cancer cells. We propose that in cancer cells, flotillin-upregulation promotes the formation of sphingosine-rich membrane microdomains where sphingosine kinase-2 locally generates sphingosine-1-phosphate to induce membrane remodeling events involved in the UFIT-pathway.Thus, flotillins along with sphingosine-kinase 2 emerge as a new machinery involved in the deregulation of endocytosis and vesicular trafficking that impacts on the level and activity of cargos involved in tumoral invasive progression.

Loss of DLG1 Leads to Profound Changes in the Ciliary Proteome of Kidney Epithelial Cell Lines

C. K. Rezi[1], Z. Anvarian[1], M. Aslanyan[2], G. Diwan[3], K. Junger[4], K. B. Pauly[1], Y. Afshar-Bahadori[1], M. Georgieva[5], P. M. H. Olesen[1], S. T. Christensen[1], R. Russell[3], K. Boldt[4], R. Roepman[2], L. B. Pedersen[1]; [1]Department of Biology, University of Copenhagen, Copenhagen Ø, DENMARK, [2]Department of Human Genetics, Radboud Institute for Molecular Life Sciences, Radboud University Medical Center, Nijmegen, NETHERLANDS, [3]Bioquant and Biochemistry Center (BZH), Heidelberg University, Heidelberg, GERMANY, [4]Institute for Ophthalmic Research, Eberhard Karl University of Tübingen, Tübingen, GERMANY, [5]Bioquant, Heidelberg University, Heidelberg, GERMANY.

Background and objective: Polarized protein trafficking is essential for many cellular functions, such as the transport of polycystins and other transmembrane proteins to the primary cilium. However, for many ciliary proteins, the specific intracellular pathways that mediate their targeting to the cilium remain unknown. Disks Large MAGUK Scaffold Protein 1 (DLG1) is a core component of the Scribble complex implicated in regulating epithelial cell polarity. In addition to this well-described function of DLG1, several proteomics studies indicated that a pool of DLG1 may be present at the primary cilium. Here we used an unbiased, proteomics-based approach to address possible ciliary functions for DLG1 in kidney epithelial cells.

Methods and results: Using quantitative cilia-targeted BioID2-based proximity-labeling proteomics in wild-type and *Dlg1* knockout IMCD3 cells, we found that loss of DLG1 leads to significant and profound changes in the ciliary proteome. Specifically, ciliary levels of several proteins known to function in vesicle-mediated trafficking, cytoskeleton organization, or signaling were reduced in the *Dlg1* knockout cells. These included the retromer component Serologically Defined Colon Cancer Antigen-3 (SDCCAG3) and Intraflagellar Transport 20 (IFT20), previously shown to facilitate ciliary transport of Polycystin-2 (PC2), as well as Transforming Growth Factor β (TGF-β)-Activated Kinase 1 (TAK1; aka MAP3K7), which plays a crucial role in many cellular processes. Immunofluorescence microscopy analysis confirmed that loss of DLG1 impairs ciliary targeting of these proteins, and also revealed reduced ciliary levels of PC2 in DLG1-depleted cells. Results from live cell imaging experiments of cells expressing fluorescently tagged versions of DLG1 suggest that DLG1 primarily localizes to cell junctions, and localizes to the cilium only transiently or when overexpressed.

Conclusion: We propose that DLG1 regulates the transport of several ciliary membrane and signaling proteins by mediating their internalization from cell junctions prior to further transport via recycling endosomes to the cilium.

Funding: Supported by grant No. NNF18SA0032928 from the Novo Nordisk Foundation and the European Union's Horizon 2020 research and innovation program Marie Sklodowska-CurieInnovative Training Networks (ITN) under grant No. 861329.

Phosphatidylinositide-3-Kinase Regulated Trafficking of C-C Chemokine Receptor 7 to Endosomal Compartments in Human T-cells

M. A. Brissette, C. A. Bill, C. I. Cardona, C. M. Vines; The University of Texas of El Paso, EL PASO, TX

The G-protein coupled receptor, C-C Chemokine Receptor 7 (CCR7), is important for chemotactic migration of immune cells to lymphoid organs and subsequent immune responses. We have shown in human and mouse T-cells that signaling via CCR7/C-C Chemokine Ligand 19 (CCL19) promotes rapid receptor internalization mediated by arrestin-3. In the human T cell line HuT78, we showed that ~20% of CCR7 re-expresses or recycles to the cell membrane. We hypothesized that internalized CCR7/CCL19 is recycled and/or degraded. Therefore, to better understand the pathway of CCR7 intracellular trafficking, we transduced human CEM T-cell acute lymphoblastic leukemia cells, which endogenously expresses CCR7, with Rab4-mCherry, Rab5-mCherry, Rab7-mCherry, and Rab11-mCherry to track CCR7 from the cell membrane through endosomal compartments. Following stimulation with 200nM CCL19 we examined colocalization at 0 min, 30 s, 1 min, 10 min, 30 min, 1 hr and 2 hr timepoints using confocal microscopy. Interestingly, even at 0 minutes, ~40% of CCR7 localized to the Rab11 compartment, suggesting that CCR7 may be stored in this compartment prior to expression on the cell membrane. Within 30s of stimulation, colocalization of CCR7 was observed with Rab4/5 proteins, indicating the presence of CCR7 in early endosomes. At 30 minutes ~78% of CCR7 was localized to late endosomes (Rab11). Upon continued incubation for 2 hrs, ~43% of CCR7 colocalized within the Rab7 compartment (lysosomes) indicating that CCR7 is also trafficked for destruction. Phosphatidylinositol-3-kinase (PI3K) family members regulate membrane composition within specific endosomes to control vesicle trafficking. To determine the role of PI3K in the recycling/degradation of CCR7 via Rab11 or Rab7, we used 5μM wortmannin to block class I and class II PI3K's and 0.5μM to block class I PI3K during CCR7 recycling using flow cytometry. We found that under both conditions, receptor recycling was reduced by 20% suggesting a role for class I or class II PI3K family members in recycling of CCR7 to the cell membrane via Rab11. In addition, following CCR7-eGFP internalization with CCL19 and 2 hrs of recycling, CCR7 remained within the trans-Golgi network in the presence of 0.5μM wortmannin, in contrast CCR7-eGFP, recycled to the cell membrane in the absence of wortmannin further demonstrating a potential role for class II PI3K in CCR7 recycling. We are currently confirming a role for class II PI3K in CCR7/CCL19 recycling using PI3K Class II shRNA (PI3KC2A), since PI3KC2A is a Rab11 effector protein and has been shown to regulate recycling of various GPCRs.

Uncovering the role of actin assembly in fast-endophilin mediated endocytosis

S. L. Smith; University of California, Berkeley, Berkeley, CA

Force transmission through the actin cytoskeleton is fundamental for cells to sense the geometric and mechanical constraints of their environments, move through tissues, remodel the extracellular matrix, and regulate signaling receptors at the plasma membrane (PM) to determine cell fate. In cell systems, such as the leading edge of migrating cells or the endocytic machinery, polymerizing actin generates forces on the membrane. The dynamics, structure, and force generation of actin filaments are regulated by actin binding proteins (ABPs). In mammalian cells, actin assembly is not required at every endocytic site, but the dependency on actin assembly forces increases as membrane tension increases. The mechanisms responsible for actin assembly and load adaptation have been investigated for clathrin-

mediated endocytosis, but less so for other endocytic pathways such as fast-endophilin mediated endocytosis (FEME). While pathogen-hijacked FEME shows a requirement for actin assembly to facilitate proper internalization, how actin adaptation is triggered and the proteins responsible for this signaling cascade both have yet to be identified. I propose that, under high membrane tension, FEME sites require a more robust actin meshwork to aid in membrane deformation and promote successful cargo internalization. I hypothesize that actin binding proteins, which bind to both the plasma membrane and actin filaments, facilitate this adaptation. One particularly attractive candidate to provide this function is Myosin1E because it can transduce force and link the cytoskeleton to the membrane. High-resolution fluorescence microscopy of genome-edited human induced pluripotent stem cells (hiPSCs) expressing fluorescent protein fusions of Myosin1E demonstrated localization of Myosin1E at sites of FEME. Additionally, under increased membrane tension in response to osmotic shock, there is increased co-localization between Myosin1E and Dynamin2, a marker of endocytic scission. This endocytic pathway also appears to be conserved in hiPSC differentiated fibroblasts. From this work, I hope to build an understanding of how the actin network adapts to increased load to ensure successful vesicle internalization.

Endosome recycling of guidance receptor regulates dendrite morphogenesis in *C. elegans.*

C. E. Richardson[1], C. Yee[2], K. Shen[2]; [1]University of Wisconsin Madison, Madison, WI, [2]Stanford University, Stanford, CA

In dendrite morphogenesis, guidance receptors on the neuron's plasma membrane instruct local actin dynamics to mediate attraction, stabilization, and repulsion. How these movements are coordinated temporally and spatially at the molecular level is incompletely understood. The *C. elegans* PVD neuron grows an elaborate dendritic arbor over the course of larval development that can be easily interrogated with genetic approaches. Such studies have identified PVD dendrite guidance receptors and downstream actin regulators that are required for morphogenesis, including DMA-1 and TIAM-1 (Tumor Invasion And Metastasis), respectively. Here, we used the *C. elegans* alternate physiological state, dauer, as an orthogonal tool to interrogate dendrite morphogenesis. Whereas the PVD dendrite gets progressively larger and more complex throughout normal larval development, dendrite morphogenesis is reversibly arrested in the dauer state. We found that this arrested morphogenesis is accompanied by an enrichment of the PVD dendrite guidance receptor DMA-1 on the plasma membrane. By developing a novel tool to distinguish between recycled endosomes and biosynthetic vesicles *in vivo,* we determined that this plasma membrane DMA-1 enrichment is accompanied by a corresponding depletion of DMA-1 from recycling endosomes. Using a combination of live imaging of dendrite growth dynamics and mis-targeting the TIAM-1 to different subcellular compartments in the dendrite, our data support the model that recycling of DMA-1-containing endosomes regulates the balance between dendrite stabilization and growth. We aimed to identify the mechanism whereby the dauer state inhibits DMA-1 endosomal recycling. Surprisingly, we found that constitutive endocytosis is broadly suppressed in dauer across multiple tissues. We envision that this would simultaneously arrest the many cell growth and development pathways that involve endosome recycling to suspend development in the dauer state.

B348/P2736

Roles and regulation of endocytic recycling at the postsynapse

T. Uygun[1,2], P. Rivero Rios[1,2], T. Tsukahara[1], G. Chavis[1], L. S. Weisman[1], M. A. Sutton[1]; [1]University of Michigan, Ann Arbor, MI, [2]Life Sciences Institute, Ann Arbor, MI

The levels of many cell surface proteins are regulated by trafficking from endosomes to the plasma membrane. In HeLa cells, the majority of cell surface proteins traffic via either the SNX27-Retromer-WASH pathway, or the SNX17-Retriever-CCC-WASH pathway. Endocytic recycling also plays important roles in synaptic function. Indeed, the SNX27-Retromer pathway regulates the recycling of several key neuronal receptors, including GLUT1, AMPA receptors, and Kir3. In addition, our recent data using rat hippocampal neurons shows that the SNX17-Retriever pathway is critical for the regulation of postsynaptic function and plasticity, and acts in part by regulating the recycling of β1-integrin, a well characterized SNX17 cargo in HeLa cells. Both Retromer and Retriever have been shown to localize to the same microdomain on endosomes in HeLa cells. This raises the question of whether these distinct pathways emerge from the same endosomes at postsynaptic sites. Here, I present the development of tools that will enable me to test whether the SNX17-Retriever, and SNX27-Retromer pathways colocalize at post-synaptic sites. I identified commercially available antibodies suitable for immunofluorescence that specifically recognize SNX17 and SNX27. I tested their specificity using shRNA mediated knockdown. In addition, wild-type SNX17, SNX27, VPS26B, and VPS26C proteins (which are subunits of the Retromer and Retriever complexes, respectively) have been fused with mScarlet and mNeonGreen fluorescent proteins. Using these tools I will test the subcellular localization of each complex via immunofluorescence and live cell imaging, both under basal conditions and upon long-term potentiation. Additionally, shRNAs which specifically target SNX17, SNX27, VPS26B, and VPS26C have been generated to investigate the effects of depletion of these complexes on synaptic function, synaptic plasticity and the architecture of dendritic spines. Elucidating the mechanisms regulating Retromer- and Retriever- dependent recycling in neurons will likely provide new insights into the regulation of surface-exposed proteins at postsynaptic sites, as well as their contribution to altered receptor recycling in diseases of the nervous system.

Pathogenetic mechanism of a novel neurodevelopmental disorder caused by mutations in EIPR1

S. Ghosh[1], A. Sawafta[2], N. Damseh[3], S. Edvardson[4], O. Elpeleg[5], J. Bonifacino[1]; [1]National Institutes of Health, Bethesda, MD, [2]Faculty of science, An Najah National University Nablus Palestine, Nablus, Palestinian Territory, [3]Faculty of Medicine, Al-Quds University, Abu Deis, Palestinian Territory, [4]Department of pediatrics, neuropediatric unit, Hadassah-Hebrew University Medical Center, Jerusalem, Israel, [5]Monique and Jacques Roboh Department of Genetic Research, Hadassah-Hebrew University Medical Center, Jerusalem, Israel

Endosomes are a major hub of protein sorting that receive proteins from the plasma membrane (i.e., endocytosis) and the *trans*-Golgi network (TGN) (i.e., biosynthetic transport), and recycle them back to the plasma membrane (i.e., endocytic recycling) and TGN (i.e., retrograde transport). Proteins that are not retrieved by these pathways remain in endosomes for subsequent delivery to lysosomes. Two related multisubunit tethering complexes named endosome-associated recycling protein (EARP) and Golgi-associated retrograde protein (GARP) complex participate in endocytic recycling and retrograde transport, respectively. EARP associates with endosomes and supports recycling of proteins such as

transferrin receptor to the plasma membrane. GARP associates with the TGN to enable retrograde trafficking of proteins like the cation-independent mannose 6-phosphate receptor which recycles after delivering acid hydrolase precursors to lysosomes. Dysfunction of GARP leads to missorting of lysosomal acid hydrolases, as well as impaired trafficking of lipids and sterols, and compromise retrograde trafficking of bacterial toxins. In previous work, our lab identified a WD40-domain protein named EIPR1 that cooperates with EARP and GARP in these processes. However, the role of EIPR1 in human physiology remained unclear. Recently, we have identified the patients with biallelic mutations in the *EIPR1* gene. The three patients were children with severe global developmental delay, microcephaly, and spasticity. Throughout childhood there was hardly any acquisition of developmental milestones. To examine the effect of the mutations on EIPR1 properties, I expressed the mutant proteins in heterologous cell lines and found that the mutant proteins have lower expression levels and are less stable compared to wild-type form. The mutations also affected the interaction and co-localization of EIPR1 with the EARP and GARP complexes. Furthermore, analysis of patient fibroblasts showed a strong defect in retrograde transport from endosomes to the TGN and swollen lysosomes. Electron microscopy with immunofluorescence study revealed accumulation of autophagic vesicles and increased level of lipid droplets inside cells. Therefore, mutations in EIPR1 lead to defective retrograde trafficking, dysfunctional lysosomes, and altered autophagy. Taken together, these findings demonstrate a critical role for EIPR1 in human physiology and shed light on the molecular and cellular basis of a novel neurodevelopmental disorder.

B350/P2738

Rab Coupling Protein (RCP) function upon EGFR trafficking from perinuclear recycling endosomes is regulated by PKA

J. Venegas[1], J. Barra[1,2], C. López[1], C. Retamal[1], A. González[1,2,3]; [1]Universidad San Sebastian, Santiago, Chile, [2]Centro Científico y Tecnológico de Excelencia Ciencia & Vida, Santiago, Chile, [3]Centro de Envejecimiento y Regeneración (CARE-UC), Santiago, Chile

Introduction: RCP (Rab11-FIP1C) is an effector of Rab11 involved in the endocytic recycling pathway at the level of the Endocytic Recycling Compartment (ERC), a series of perinuclear tubular and vesicular membrane mediating the slow recycling pathway. Endocytic recycling of nutritional and signaling cell surface receptors is crucial in a variety of physiological and pathological conditions including cancer. However, its regulation by cell surface receptor signaling pathways remain unknown. We recently described that protein kinase A (PKA) basal activity is required for the recycling of epidermal growth factor receptor (EGFR), transferrin receptor (TfnR) and low-density lipoprotein receptor (LDLR) from ERC. Based on bioinformatic data, here we explored whether RCP has a role in endocytic recycling as a potential PKA substrate. **Material and Methods:** We evaluated PKA-mediated phosphorylation of RCP by immunoblot and compared the effects of PKA inhibitors (Myr-PKI) and TGF-α stimulation that decrease or promote EGFR recycling, respectively. We also compared trafficking effects of RCP phospho-inert and phospho-mimetic mutants. Analysis included confocal microscopy images of fluorescently tagged markers in live cells, cell surface EGF binding and biotinylation, coimmunoprecipitation (co-IP) assays and PKA activity assessed by a fluorescent sensor and immunoblot against PKA substrates. **Results:** TGF-α treatment known to promote EGFR recycling increased the PKA activity, resulting in higher RCP phosphorylation, whereas PKI arrested EGFR recycling and decreased the phosphorylation of RCP, leading to EGFR concentration at ERC in a complex with RCP and Rab11. Both TGF-α and PKI increased the co-IP of RCP with EGFR and Rab11. Phospho-inert RCP^{S435A} inhibited EGFR exiting from ERC,

colocalizing there with TfnR and Rab11, while the phospho-mimetic RCP^{S435D} showed opposite effects. **Conclusions:** RCP is a PKA substrate sensitive to EGFR recycling stimulators such as TGF-α and its PKA phosphorylation status impacts upon its interactions with EGFR and Rab11, as well as upon its role in EGFR recycling from ERC. **Acknowledgements:** National Agency for Research and Development (ANID)/Scholarship Program/DOCTORADO BECAS CHILE/2021-21110001, Basal Project ACE210009, and Centro Ciencia & Vida, Basal FB 210008. Jim Norman (Beatson Institute, Glasgow, UK) kindly provided anti-Phospho-RCP-Ser435 antibodies and the phosphoinert RCP^{S435A}-mCherry plasmid.

Caveolin-1 Endocytosis upon Hypotonic Shock

T. H. Wong, L. Li, P. Torigny, B. Joshi, I. R. Nabi; University of British Columbia, Vancouver, BC, CANADA.

Caveolin-1 (Cav1) oligomerizes to form stable caveolar coats at the plasma membrane. Under hypotonic shock, caveolae disassemble in response to the mechanical stress providing a membrane buffer and protecting the membrane from mechanical stress. Using STED super resolution microscopy, we observe that large Cav1 positive spherical structures form at 15 minutes of hypotonic shock and accumulate over time in MDA-MB-231 cells. After hypotonic shock, Cav1 spherical structures are endocytic structures as they are labeled by uptake of antibodies to β1-integrin and CD44 after acid wash of the cell surface and their formation is prevented by dynasore inhibition of dynamin-dependent endocytosis. Cav1-positive spherical structures do not colocalize with endosomal markers Rab5 and Rab7 and show only partial colocalization with the lysosomal marker Lamp1. In PC3 prostate cells, that express Cav1 but not the coat protein Cavin1 required for caveolae formation, Cav1 spheres also form under hypotonic shock but do not accumulate over time as observed to the MDA-MB-231 cells. These findings suggest that Cav1 is internalized via a caveolae-independent, dynamin-dependent endocytic pathway in response to hypotonic shock.

B352/P2740

Endocytic dynamics are tissue dependent in developing embryos

C. Shirazinejad, I. Swinburne, D. Drubin; University of California, Berkeley, Berkeley, CA

Clathrin-mediated endocytosis (CME) is a receptor internalization pathway used in diverse cell types. While much of its parts list is known, how these parts are recycled for specialization in differentiated cells is less characterized. Here, we establish a vertebrate system that expresses fluorescent proteins fused to endogenous enzymes important for detecting CME. Following circulating blood during development, we have begun characterizing when and where blood cells internalize iron-bound receptors. Additionally, we are interested in how cells adapt to their local environments during CME with the assembly of branched actin, a force-generating cytoskeletal arrangement of dendritic actin created with the ARP2/3 complex. Our preliminary results indicate epithelial cells as well as non-epithelial cells may use ARP2/3 during CME.

B353/P2741

Identifying Curvature-Sensitive Features in the Early Stages of Clathrin-Mediated Endocytosis

P. Marchando, R. Cail, D. Drubin; University of California, Berkeley, Berkeley, CA

The plasma membrane (PM) is a highly dynamic structure that can be deformed, such as during cell locomotion and trafficking. In clathrin-mediated endocytosis (CME), the primary pathway through which extracellular cargo and transmembrane receptors are internalized, dozens of proteins work in concert to deform the PM into a deep pit that can undergo scission into the cytosol. Many of these components have been shown to be strongly sensitive to changes in membrane geometry. Recent advances in nanofabrication have enabled the creation of "nanoshapes," nanometer-scale structures that can reproducibly deform the PM of cells cultured on them, facilitating research into the relationship between membrane shape and protein recruitment. At small radii of positive curvature, the entire CME machinery has been shown to strongly relocate to nanoshape-induced PM bending. This nanoshape-induced curvature has even been shown to bypass the curvature-generating role of clathrin in clathrin knockdown cells. Many questions remain about the relationship between membrane curvature and CME. Since localization to induced curvature appears to start very early in CME, I have employed a screening strategy of knocking down several early CME components to identify proteins necessary for robust curvature-localized CME. Using homemade nanoshapes in concert with genome-edited human cells to study endocytic dynamics and pulse-chase assays to assess bulk endocytic defects, I have identified a condition that impairs CME differentially upon inducing curvature. Cells with early-arriving adaptor proteins EPS15 and EPS15R knocked down in concert with clathrin lose their ability to cluster the endocytic cargo transferrin, but upon inducing curvature, transferrin clusters once again along nanostructures in a way that depends on adaptor protein AP2's strong enrichment at sites of curvature. These results suggest a central role for AP2 in curvature-sensitive CME localization, as its localization to curvature is largely unperturbed by removal of its interacting partners and clathrin. Further studies are necessary to fully understand how early CME proteins and membrane curvature work in concert to initiate the process.

B354/P2742

Investigating the Role of Clathrin-Mediated Endocytosis in T-cell Activation

Y. Iwamoto, A. Ye, C. Shirazinejad, J. Hurley, D. Drubin; UC Berkeley, Berkeley, CA

Decades of research has established clathrin-mediated endocytosis (CME) as a major pathway through which mammalian cells internalize surface proteins. Recent studies have began to show that the function of the CME pathway goes well beyond its canonical role of internalization. For example, the pathway has been linked to functions such as scaffolding the cytoskeleton, wrapping around the extra-cellular matrix, and serving as hubs for organizing signaling factors. Furthermore, distinct CME structures and dynamics have been observed in different cell types, suggesting further exploration of CME in different cellular contexts will lead to novel insights. To further our understanding of the CME pathway, we chose to investigate its role in the context of T-cells. This is because, although defects in the CME pathway has linked to impaired stimulation of T-cells during an immune response, the exact role of the pathway is not understood. In this study, we utilize genome-edited Jurkat cells fluorescently expressing CME markers AP2 and DNM2 to visualize live dynamics of CME in a T-cell like system for the first time. We show that CME is a constitutively active pathway in unstimulated Jurkat cells but that the dynamics of the pathway change when the cells are activated. Activation with both PMA/Ionomycin and

CD3/CD28 bound dynabeads induce a transient stalling of CME, indicated by long lived AP2 puncta at the plasma membrane. Interestingly, this transient stalling is observed in the middle focal plane of the Jurkat cells, distinguishing them from previously observed stable CME structures such as plaques that form at the basal surface of the cell. Currently we are investigating the functional significance of this transient CME stalling upon Jurkat cell stimulation. We hypothesize that the stalling could be important for prioritizing other clathrin-independent endocytic pathways or that these sites are serving as hubs for organizing signaling factors involved in T-cell activation. In conclusion, we have observed that the CME pathway is constitutively active in unstimulated Jurkat cells but stalls in response to stimulation. Investigating the significance of this phenomenon will elucidate the molecular details of CME pathway's important connection to T-cell activation.

Dynamin is primed at endocytic sites for ultrafast endocytosis

Y. Imoto[1], S. Raychaudhuri[1], Y. Ma[1], P. Fenske[2], E. Sandoval[1], K. Itoh[1], E. Blumrich[3], H. T. Matsubayashi[1], L. Mamer[2], F. Zarebidaki[2], B. Söhl-Kielczynski[2], T. Trimbuch[2], S. Nayak[4], J. H. Iwasa[4], J. Liu[1], B. Wu[1], T. Ha[1], T. Inoue[1], E. M. Jorgensen[4], M. A. Cousin[3], C. Rosenmund[2], S. Watanabe[1]; [1]Johns Hopkins University, Baltimore, MD, [2]Charité Universitätsmedizin Berlin, Berlin, GERMANY, [3]University of Edinburgh, Edinburgh, UNITED KINGDOM, [4]University of Utah, Salt Lake City, UT.

Dynamin mediates fission of vesicles during endocytosis. During clathrin-mediated endocytosis, recruitment of dynamin from the cytosol to endocytic pits takes tens of seconds. For synaptic vesicle endocytosis, dynamin must be recruited to the site of endocytosis on the order of milliseconds to mediate ultrafast endocytosis. However, the mechanism underlying such rapid recruitment is unknown. Here, we demonstrate that Dynamin 1 is enriched at endocytic sites prior to the initiation of ultrafast endocytosis. Specifically, Dynamin 1xA, a splice variant of Dynamin 1, interacts with Syndapin 1 to form molecular condensates on the plasma membrane. Single-particle tracking of Dynamin 1xA molecules confirms the liquid-like property of condensates with a small immobile fraction of molecules. Time-resolved electron microscopy by flash-and-freeze suggests that loss of Dynamin 1 causes an accumulation of endocytic pits on the plasma membrane; the base of these pits is wide-open, suggesting that Dynamin 1 is potentially involved from the early stage of ultrafast endocytosis. Over expression of Dynamin 1xA, but not another splice variant xB, rescues this defect. When binding of Dynamin 1xA to Syndapin 1 is dirupted, Dynamin 1xA cannot form condensates. Likewise, when Syndapin 1 binding to Dynamin 1 is disrupted, Dynamin 1xA becomes diffuse. Interestingly, disrupting Syndapin 1 interaction with the plasma membrane also leads to diffuse localization of Dynamin 1xA, suggesting that Syndapin 1 likely acts as a hub. When Dynamin 1xA is diffusely localized, ultrafast endocytosis is slowed. Thus, Dynamin 1xA condensates concentrate Dynamin 1xA at the sites of endocytosis to bypass the recruitment phase and accelerate.

A Mechanism for Sculping Endosomal Tubular Carriers

C. Lopez-Robles[1], S. Scaramuzza[2], **E. N. Astorga-Simon**[1], M. Ishida[3], C. D. Williamson[3], S. Baños-Mateos[1], D. Gil-Carton[4], M. Romero[5], A. Vidaurrazaga[1], J. Fernandez-Recio[6], A. L. Rojas[1], J. S. Bonifacino[3], D. Castaño-Díez[4], A. Hierro[1]; [1]CICbioGUNE, Derio, SPAIN, [2]Biozentrum, Universtity of Basel, Basel, SWITZERLAND, [3]National Institutes of Health, Bethesda, MD, [4]Instituto Biofisika (UPV/EHU, CSIC), University of Basque Country, Leioa, SPAIN, [5]Barcelona Supercomputing Center (BSC), Barcelona, SPAIN, [6]Instituto de Ciencias de la Vid y del Vino (ICVV), CSIC, Logroño, SPAIN.

Just as cargoes enter the endosomal network, various protein machineries contribute to their recycling by either bulk flow or selective processes. The SNX-BAR subfamily of sorting nexins, which contain a phox-homology (PX) domain and a Bin/Amphiphysin/Rvs (BAR) domain, play a central role as coat proteins in multiple endocitic retrograde/recycling pathways. Generation of tubular carriers by SNX-BAR proteins combines membrane association, cargo capture, coat assembly and lipid bilayer deformation mechanisms that remain unresolved. Using X-ray crystallography, cryo-electron tomography and cell-based analysis we reveal an unprecedented coat architecture for tubular-based cargo sorting.

Dynamically tuning the membrane lipid composition can control macromolecular assembly

J. A. Fischer[1], M. E. Johnson[2]; [1]Department of Biology, Johns Hopkins University, Baltimore, MD, [2]Department of Biophysics, Johns Hopkins University, Baltimore, MD.

Clathrin-mediated endocytosis (CME) is an essential process for transport into the cell that requires cytoplasmic proteins like clathrin to assemble into large macromolecular assemblies on the cell membrane. The protein components specifically bind to the lipid phosphotidylinositol-4,5-bisphosphate (PI(4,5)P2), and thus assemblies form at areas of the membrane enriched with PI(4,5)P2. The kinase PI(5)K and phosphatase synaptojanin can dynamically tune the local abundance of lipid PI(4,5)P2 in opposing ways**,** and both enzymes localize to sites of CME via interactions with adaptor proteins. The complexity and relatively fast time scales of CME make it difficult to resolve the specific roles of individual proteins *in vivo,* and thus it is not known whether these lipid enzymes impact the nucleation or success of clathrin-coated vesicle formation. Here, we use computational modeling to quantify and classify how macromolecular self-assembly depends on the composition of the plasma membrane as it is dynamically remodeled by lipid-modifying enzymes. Our models solve differential equations implemented in the structure-resolved reaction-diffusion software NERDSS, as well as non-spatial ordinary differential equations that are amenable to efficient parameter optimization and sensitivity analysis. We found a novel mechanism for biochemical feedback loops that allowed for a synchronous and rapid transition to and from a membrane with high PI(4,5)P2 density; because both PI(5)K and synaptojanin localize to the membrane surface via adaptor protein binding, they can exploit dimensional reduction to amplify their activity rate as their effective concentration is higher on a 2D membrane. This effect allows for switch-like lipid remodeling, which we found could be achieved within the time-scales of CME nucleation and using physiological concentrations. Our model can be pushed into an oscillatory regime, demonstrating how positive and negative feedback can couple to trigger protein recruitment or dissociation from the membrane, with a significant dependence on the ratio of cytosol volume to membrane area**.** We discuss how the principles established here for controlling recruitment,

dissociation, and oscillations of protein copy numbers on and off the membrane via enzymatic activity are informative for a broader range of membrane remodeling processes across cell biology.

Impact of zip8 and fabp5 in liver diseases an iron trafficking related genes signature in metabolic dysfunction associated fatty liver disease

S. PRAKASH[1], P. Priyatma[1], S. Shalimar[2], N. K. Vikram[3], A. Priya[1], M. Saroj[1], R. Aasarey[1]; [1]Laboratory Medicine, ALL INDIA INSTITUTE OF MEDICAL SCIENCES, ANSARI NAGAR, NEW DELHI, INDIA-110029, New Delhi, INDIA, [2]Gastroenterology and Human Nutrition, ALL INDIA INSTITUTE OF MEDICAL SCIENCES, ANSARI NAGAR, NEW DELHI, INDIA-110029, New Delhi, INDIA, [3]Medicine, ALL INDIA INSTITUTE OF MEDICAL SCIENCES, ANSARI NAGAR, NEW DELHI, INDIA-110029, New Delhi, INDIA.

Nonalcoholic fatty liver diseases (NAFLD) is the most common chronic liver disease worldwide and related to comorbid with metabolic syndrome, obesity, type 2 diabetes, and insulin resistance. Instability in mitochondrial architecture and mitochondrial fusion-related genes are involved in situations of type 2 diabetes, metabolic dysfunction of fatty liver, hypertension and obesity, leading to enormously fissioned mitochondrial network. As zinc deficiency is common worldwide and triggering a variety of transcription factors i.e. variants in metal ion transporters via ZIP8 which suppress mitofusin proteins with the association of fatty acid binding protein 5 (FABP5) and triggering to IL-6 and IL-10 mRNA in metabolic syndrome. Despite extensive research efforts, there are no treatments of metabolic fatty liver disorders. Iron trafficking proteins (ZIP8/ZIP14), FABP-5, mitofusin/s and dysregulation of Nrf-2 genes may have potential role in MAFLD, we explored whether FABP-5, iron proteins and mitofusin/s (MFN1and MFN2) are involved in NAFLD, NASH, cirrhosis or hepatocellular carcinoma (HCC). Liver tissues and blood samples were collected from Gastroenterology, AIIMS, Delhi. Liver biopsy was done only in NAFLD patients. Fibroscan was done in NAFLD (n=25), diabetes mellitus (DM without Mets) (n=35), Metabolic syndrome (Mets without DM) (n=30), and Healthy subjects (n=25). ZIP8, Zip14, FABP5, Nrf2, MFN1and MFN2 expressions were determined in all groups. FABP5 enhances ZIP8 activity by promoting the ZIP14 synthesis while disrupting the MFN2 integration in NAFLD. Though, increased expression of FABP5 mRNA was associated with the poor prognosis with NASH and cirrhosis. On contrary FABP5 and ZIP14 association was decreased in diabetic patients. ZIP-8 and MFN-2 expressions were highly associated with metabolic syndrome without diabetes and MFN-1 was suboptimal. Mitofusin2 levels may have pleotropic relations in respect to waist hip ratio, BMI and HOMA IR. Nrf-2 was 5folds downregulated in NASH, cirrhosis and HCC. Zip8 and FABP5 mRNA expressions were upregulated in NASH and HCC patients. MFN-2 levels and FABP-5 are positively correlated with the stages of liver fibrosis (>F2 to F4). No correlations to Zip14 expressions with MFN-1 and IL-10 were found. Our study potentially identifies ZIP-8, a new class of route may be interlinked with fatty acid induced FABP-5 upregulation that drives NASH, cirrhosis and HCC progression through mitochondrial fusion proteins especially MFN-2 in circulation. Dysregulation of iron trafficking proteins and FABP-5 expressions could be novel emerging blood biomarkers of hepatocytes injury. Zip8 may possible therapeutic option to prevent liver diseases in at risk individuals and open the door to understand the pathogenesis of MAFLD..

B359/P2747

Dynamin regulates synaptic actin organization and dynamics at endocytic sites

A. M. Silveira, S. J. Del Signore, A. A. Rodal; Brandeis University, Waltham, MA.

Endocytosis relies on F-actin and dynamin GTPases to deform membranes and release vesicles. Recently, dynamin was shown to bind and bundle actin filaments in a manner that is dependent on its GTPase activity and proline-rich domain (PRD), but independent of membrane-binding. These dynamin-actin interactions likely contribute to the function of diverse actin-rich structures. Yet, their role in endocytosis at neuronal synapses, where efficient membrane trafficking is particularly important, is unknown. To begin to answer this question, we investigated how Drosophila dynamin mutants affect the organization and dynamics of synaptic actin patches, which are functionally correlated to endocytosis. Temperature sensitive GTPase mutants showed an overall increase in the number of actin patches and a reduction in the frequency of actin patch initiation at the neuromuscular junction (NMJ), which suggests that dynamin's GTPase activity is important for actin structure initiation and turnover. Interestingly, distinct neuronally-expressed isoforms of dynamin are predicted to differentially affect an actin-binding site in the PRD, which raises the hypothesis that the isoforms may have unique actin-related functions. These isoforms can also be distinguished by their localization patterns at the NMJ, where the long isoform is more punctate and the short isoform exhibits a reticulum-like pattern. Thus, the dynamin isoforms and their interaction with F-actin may add an unexpected layer of regulation to actin dynamics, protein organization, and endocytic efficiency at synapses.

B360/P2748

Reconstitution of membrane scission by ESCRT-III (Endosomal sorting complexes required for transport)

P. Aditya[1], N. Miguet[2], W. Weissenhorn[2], P. Bassereau[1]; [1]Institut Curie, Paris, FRANCE, [2]Institut de Biologie Structurale, Grenoble, FRANCE.

Endosomal sorting complexes required for transport (ESCRT) proteins are involved in severing of narrow membrane necks in several processes like HIV virus release, exosomal and intra-endosomal budding (Multi-vesicular bodies formation) from membranes and cytokinesis (cell division), among others. It is an evolutionarily conserved protein machinery composed of ESCRT-0, ESCRT-I, ESCRT-II and ESCRT-III. ESCRT-III complexes and VPS4, an accessory protein, have been proposed to constitute the membrane fission machinery in these processes. The proteins of these complexes tend to assemble into polymer filaments. Recent findings point towards an affinity of ESCRT-III to positively curved membranes or with a **negative Gaussian curvature**, like necks or horse saddle. The geometry for this process is complimentary to the process of endocytosis using Dynamin and is referred to as inverse geometry. The underlying mechanisms involving scission by ESCRT-III are still unclear. Different physical models have been proposed to account for membrane constriction and cleavage but no hard-experimental proof of any of the models has yet been confirmed. The objective of my work is to understand the mechanism of **human ESCRT-III** and VPS4-catalyzed membrane remodeling processes leading to membrane fission. Since ESCRTs are involved in plethora of processes, them along with some accessory proteins are associated with deformation of the membrane, formation of neck, constriction, scission and finally dispersal of the machinery. Our focus is more on the scission process and to that end, we do experiments using an **in-vitro system** of **Giant Unilamellar Vesicles** (GUVs) and polystyrene beads to reproducibly make the neck like shape. The scission event has been shown in yeasts with a large set of

proteins. In other set of experiments with human ESCRTs, the scission event took minutes. Some viruses like HIV-1 uses only a subset of these proteins to perform scission in seconds, and we are trying to reproduce this event. The attempt is to find the **minimum set of proteins** needed for the scission step and identify the affinity of the respective proteins on the **geometry and the effect of shape**, in general, on the process.

An activating *de novo* variant in ARF1 causing a neurodevelopmental disorder

M. Ishida[1], M. G. Otero[2], C. Freeman[2], P. A. Sánchez-Lara[2], C. M. Guardia[1], T. M. Pierson[2], J. S. Bonifacino[1]; [1]NIH, Bethesda, MD, [2]Cedars-Sinai Medical Center, Los Angeles, CA

ARF1 is a small GTPase that regulates protein sorting from the Golgi apparatus to the ER, endosomes and plasma membrane by recruiting effectors. Although ARF1 is one of the most studied small GTPases, the functional importance of ARF1 in human physiology is still poorly understood. In this presentation, we report a child with a monoallelic *de novo* missense mutation (c.296 G>A; p.R99H) in the *ARF1* gene, associated with developmental delay, hypotonia, intellectual disability, and motor stereotypies. Neuroimaging revealed a hypoplastic corpus callosum and subcortical white-matter abnormalities. Functional studies of the ARF1-R99H variant protein revealed that it was expressed at normal levels and properly localized to the Golgi apparatus; however, expression of this variant caused swelling of the Golgi apparatus, increased the recruitment of coat proteins such as COPI, AP-1, and GGA3, and altered the morphology of recycling endosomes. In addition, we observed that expression of ARF1-R99H prevented dispersal of the Golgi apparatus caused by the ARF1-inhibitor brefeldin A (BFA). Finally, protein-interaction analyses showed that ARF1-R99H bound more tightly to the ARF1-effector GGA3 relative to wild-type ARF1. These properties resemble those of the well-characterized constitutively-active ARF1-Q71L mutant, indicating that the pathogenetic mechanism of the ARF1-R99H variant involves constitutive activation with resultant Golgi and endosomal alterations. These findings suggest that the neurodevelopmental disorder in the patient is caused by a gain-of-function mutation in ARF1, opening up the possibility of treatment using ARF1 inhibitors.

High-resolution interaction map between Rab1 and secretory cargo using Photo-switching FRET reveals Cis-Golgi domainsassociated with carrier fusion.

Y. Malis[1], G. M. Hirschberg[1], E. H. Sklan[1], G. H. Patterson[2], **K. Hirschberg**[1]; [1]Tel Aviv University, Tel Aviv, Israel, [2]NIH, National Institute of Biomedical Imaging and Bioengineering, Bethesda, MD

FRET is a powerful tool for biologists asking to simultaneously establish and localize interactions between fluorescently tagged proteins with high spatial resolution. Photo-switching FRET (psFRET) using the Dronpa Photo-switching fluorescent protein was recently introduced by Rainey K.H. and Patterson G. H.(Rainey and Patterson, PNAS, 2019). Here we formulated a comprehensive experimental approach and provide a powerful software tool to perform the extensive data analysis involved. This allows a straightforward assimilation of psFRET to diverse experimental systems. Image stacks, recording the decay of the Dronpa donor serve as input to the software utility that calculates exponential decay coefficients at the single pixel level allowing to create a highly detailed interaction map. Moreover, image preprocessing options increase the adaptability and versatility of the psFRET method. psFRET analysis demonstrated that the interaction between the GTPase Rab1 and the VSVG cargo protein or the

tethering protein GRASP65 was detected during ER to Golgi transport yet did not proceed within the Golgi apparatus. Additionally, Micro domains associated with transport carrier fusion decorating the cis side of the Golgi exhibited high FRET efficiency between above interactors. Lastly, we employ the psFRET method in live cell imaging to document interactions at different time points throughout ER to Golgi transport.

Post-Golgi Trafficking

Liquid-liquid phase separation in the TGN mediates delivery of proinsulin to secretory storage granules

A. PARCHURE[1], M. Tian[1], D. Stalder[2], S. K. Mahata[3], S. B. Stephens[4], D. Gershlick[2], J. V. Blume[1]; [1]Cell Biology, Yale University, New Haven, CT, [2]University of Cambridge, Cambridge, UNITED KINGDOM, [3]University of California San Diego, La Jolla, CA, [4]University of Iowa, Iowa City, IA.

Insulin secretion helps regulate blood glucose levels and is thus a critical metabolic regulator in mammals. Insulin is made by pancreatic β-cells and stored in their secretory granules (SGs). Responding to nutrient stimuli, mature SGs are mobilized to fuse with the plasma membrane and deliver insulin to the bloodstream. The mechanism of how proinsulin and its processing enzymes are sorted and targeted from the *trans*-Golgi network (TGN) to SGs remains largely mysterious. Remarkably, no cargo receptor for proinsulin has been identified in the last three decades. Chromogranin proteins (CGs) are central regulators of granule biogenesis in many cell types. Here, we show that CGs organize in condensate-like structures in the lumen of the TGN of rat insulinoma INS-1 cells. Furthermore, purified CGs undergo liquid-liquid phase separation (LLPS) at a mildly acidic pH independently of divalent cations, such as calcium and recruit clients like proinsulin to the condensates. Similarly, in INS-1 cells, the elevation of the TGN pH or downregulation of CG proteins leads to a redistribution of CG clients from a punctate to a diffuse pattern. Intriguingly, material properties of CG assemblies govern client recruitment as liquid-like CG condensates, but not aggregates, recruit and sort granule-destined cargo molecules. Strikingly, our work shows that cargo selectivity of CGs is independent of conserved sequence but is based on the relative abundance of the client molecules at the TGN. In conclusion, we propose that the TGN provides the milieu in which soluble CGs convert into a “cargo sponge,” gathering soluble client proteins into the condensate. Client molecules can partition into the condensate driven by weak intermolecular interactions, a feature of IDR-containing proteins, thus, facilitating receptor-independent sorting. These findings challenge the canonical TGN sorting models in insulin-secreting β-cells and potentially many other cell types. They are therefore of central relevance for cell biology and diabetes research.

The insulin inhibitory receptor regulates insulin turnover in pancreatic beta cells

J. Siehler[1], **P. Chapouton**[1], S. Bilekova[1], F. Ribaudo[1], S. bhattacharya[1], P. Xu[1], C. Malhotra[1], H. Lickert[1,2,3]; [1]Institute of Diabetes and Regeneration Research, Helmholtz Zentrum Muenchen, Neuherberg, GERMANY, [2]German Center for Diabetes Research (DZD), Neuherberg, GERMANY, [3]Technical University Munich, School of Medicine, Munich, GERMANY.

We are aiming at understanding the dynamics of proinsulin processing and turnover in beta cells of the pancreas, an important process that controls the biosynthesis of the insulin hormone. Among the

players involved, the insulin inhibitory receptor (inceptor) is a newly characterized single pass transmembrane protein described recently in our lab for its role in the internalization of the insulin receptor via clathrin-coated endocytosis at the plasmamembrane of beta cells (Ansarullah et al., 2021). Our new results reveal the biochemical binding of inceptor to insulin and proinsulin and the subcellular localization of inceptor to the trans-Golgi network as well as a to nascent secretory granules, where it co-localizes with proinsulin. The confined localization in the trans-Golgi network is increased under starvation. In human stem cell-derived beta cells, an absence of inceptor leads to a massive increase in insulin content. We are currently testing two hypotheses to understand the mode of action of inceptor in proinsulin turnover: inceptor might route (pro)-insulin or nascent granules directly to the lysosome for degradation, or it might as well maintain proinsulin for longer times in the trans-Golgi network and nascent granules. To test these hypotheses, we use biochemical and imaging approaches on inceptor knock-outs insulinoma cell lines as well as antisense oligonucleotides in primary islets. We are further analysing in human donor samples how the colocalization of inceptor to proinsulin is altered under diabetic conditions. Together, inceptor plays a key function in regulating insulin turnover in beta cells.

B365/P2753

Uncovering the Role of VPS33B/16B in Megakaryocyte A Granule Formation

H. H. Y. Yao; University of Toronto-47731885, Toronto, ON, CANADA.

Platelets are small and numerous anucleate blood cells that play a primary role in recognizing vascular wound sites, where they adhere, aggregate, and activate to facilitate fibrin generation during hemostasis to limit blood loss. Platelets also play roles in wound healing and bone regeneration, and they have been implicated in atherogenesis and cancer progression. Many platelet functions are linked to vesicles known as alpha granules, which contain an assortment of proteins that can be secreted upon platelet activation. The development of platelet secretory vesicles is poorly understood. Our lab has established that the vacuolar protein sorting-associated proteins VPS33B and VPS16B form a complex, VPS33B/16B, that is essential for alpha granule biogenesis. This role was initially detected in studies of patients afflicted by the rare autosomal recessive neonatal lethal multisystem disorder Arthrogryposis, renal dysfunction, and cholestasis (ARC) syndrome, which is associated with gene variants that cause loss of VPS33B or VPS16B expression/function. The goal of this project is to define the specific role of VPS33B/16B for alpha granule formation using a VPS33B KO mouse model. Mouse models can provide megakaryocytes in their bone marrow niche to evaluate morphology and maturation. I have indicated the potential of using a tamoxifen-inducible hematopoietic lineage-specific Vps33b knockout mouse by validating the deletion of VPS33B, absent VPS16B and showing reduced or absent cargo protein levels, and absent platelet alpha granules, abnormal endosomal morphology, and abnormal trafficking of cargo proteins. Using immunofluorescence microscopy, I showed altered localization of alpha granule cargo proteins using antibodies, thus providing further evidence for their roles in alpha granule formation. These data suggest that VPS33B/16B is involved in the trafficking of synthesized cargo proteins from the Golgi and along the endosomal vesicular transport pathway - specifically, to the late endosomes/multi-vesicular bodies. This project will identify functions of VPS33B/16B during megakaryocyte maturation and alpha granule formation, thus advancing our understanding of platelet development and processes affecting other cells and physiological systems. This could potentially facilitate efforts to develop new therapies for a range of health problems, such as bleeding and thrombotic disorders.

B366/P2754

Quaternary Structure Dynamics Regulate Lipoprotein Lipase Activity During Trafficking

K. H. Gunn[1], B. S. Roberts[1], F. Wang[2], J. D. Strauss[3], M. J. Borgnia[3], E. H. Egelman[2], S. B. Neher[1]; [1]Biochemistry and Biophysics, UNC, Chapel Hill, NC, [2]Biochemistry and Molecular Genetics, University of Virginia School of Medicine, Charlottesville, VA, [3]Genome Integrity and Structural Biology Laboratory, National Institute of Environmental Health Sciences, Durham, NC.

Lipoprotein lipase (LPL) is the enzyme responsible for hydrolyzing triglycerides from chylomicrons and very low-density lipoproteins (VLDL) in the capillaries to release free fatty acids. LPL adopts at least three different oligomeric states and these changes to LPL's oligomeric state ensure precise spatiotemporal regulation of its activity during trafficking. We uncovered an inactive helical LPL oligomer and used cryogenic electron microscopy (cryoEM) to solve the structure of this LPL filament. We showed that LPL stored inside of adipocyte vesicles forms a filament-like structure in association with heparan sulfate proteoglycan (HSPG) syndecan-1 (SDC1). We have purified LPL containing vesicles and are using cryo-electron tomography to visualize the LPL filament *in situ.* To further explore the role of oligomeric state in regulating LPLs activity, we used cryoEM to determine the structure of an active LPL dimer at 3.9 Å resolution. The structure of dimeric LPL reveals an unexpected dimerization interface that bears significant overlap with the interface for LPL binding to glycosylphosphatidylinositol anchored high density binding protein 1 (GPIHBP1). GPIHBP1 is a vascular endothelium membrane protein that forms a heterodimer with monomeric LPL and facilitates its transfer to the capillary. LPL is active while bound to GPIHBP1 and following dissociation from GPIHBP1, LPL associates with free-floating lipoproteins in the capillary. This is likely where LPL adopts an active dimeric state. Thus, LPL engages in quaternary structure dynamics as it transitions from storage in adipocytes as a helical oligomer, to secretion out of cells and into the capillary as a hetero- and homodimer. These changes constitute an intricate dance in which changes to LPL's oligomeric state regulate its activity.

B367/P2755

Arf-GAP Gcs1 phosphorylation modulates SNARE Snc1 recycling transport in response to ER stress

P. Cai[1], Y. Wu[1], W. Chiu[1], C. Yu[2], F. Lee[1,3]; [1]Institute of Molecular Medicine, College of Medicine, National Taiwan University, Taipei, TAIWAN, [2]Department of Cell and Molecular Biology, Chang Gung University, Tao-Yuan, TAIWAN, [3]Department of Medical Research, National Taiwan University Hospital, Taipei, TAIWAN.

ADP-ribosylation factor (Arf) and Arf-like (Arl) small GTPases are known to play important roles in membrane trafficking. In *Saccharomyces cerevisiae*, the activity of Arl1 is regulated by guanine nucleotide exchange factor (GEF) Syt1 and GTPase activating protein (GAP) Gcs1. Previously, we demonstrated that unfolded protein response (UPR) induces phosphorylation of Syt1 GEF, which is critical for Arl1 activation and the recruitment of golgin protein Imh1 to the late-Golgi (1). We recently reported that Slt2/Erk2-dependent phosphorylation of Imh1 is critical for SNARE recycling under ER stress (2). However, the mechanisms of how Gcs1 is involved in tuning late-Golgi protein transports in response to UPR remain unclear. Gcs1 possesses several phosphor-residues according to prior large-scale screening analysis. Here, we showed that Gcs1 phosphorylation was induced after the treatment of UPR inducer tunicamycin (TM). We identified Slt2/Erk2 as the responsible kinase to dictate this phosphorylation. Deletion of Gcs1 leads to the defects in the recycling transports of SNARE Snc1 to the plasma membrane (PM). The phosphor-deficient Gcs1, but not phosphor-mimetic Gcs1, restore the Snc1

PM distribution in the TM-treated *gcs1*-deletion cells. However, Arl1 and Imh1 remain proper Golgi localization in cells expressing phosphor-deficient or phosphor-mimetic Gcs1 upon ER stress. Together, we reveal a novel role of Gcs1 phosphorylation in regulating proper Snc1 recycling transport under ER stress, which is independent of Arl1-Imh1pathway.

Golgin Imh1 and GARP complex cooperate to restore the impaired SNARE recycling transport induced by ER stress

Y.-H. Wang[1], W.-Y. Chiu[1], Y.-T. Chen[1], P.-J. Cai[1], Y.-C. Wu[1], J.-L. Wu[1], B.-H. Chen[1], Y.-W. Liu[1,2], C.-J. Yu[3,4], F.-J. Lee[1,2,5]; [1]Institute of Molecular Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan, [2]Center of Precision Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan, [3]Department of Cell and Molecular Biology, College of Medicine, Chang Gung University, Taoyuan, Taiwan, [4]Chang Gung Memorial Hospital, Taoyuan, Taiwan, [5]Department of Medical Research, National Taiwan University Hospital, Taipei, Taiwan

The accumulation of misfolded proteins in the endoplasmic reticulum (ER) induces the unfolded protein response (UPR), which acts through various mechanisms to reduce ER stress. Whereas the UPR has been well studied for its effects on the ER, less understood has been its effects on the Golgi. The Golgi complex receives transport vesicles from the endosome through two types of tethering factors: long coiled-coil golgin and the multisubunit Golgi-associated retrograde protein (GARP) complex. Whether these two types of tethers cooperate in endosome-to-Golgi recycling remains unclear. Here, we report that ER stress increases the phosphorylation of golgin Imh1 to maintain the GARP-mediated recycling of the t-SNARE Tlg1 to the Golgi and the exocytic transport of the v-SNARE Snc1 from the Golgi to the plasma membrane. We also identify a specific function of the Golgi affected by ER stress and elucidate a homeostatic response to restore this function, which involves both an Ire1-dependent and a MAP kinase Slt2/ERK2-dependent mechanism. Furthermore, our findings advance a general understanding of how two different types of tethers act cooperatively to mediate a transport pathway.

A new function of caveolin in sphingolipid trafficking

J. Podkalicka, C. Viaris De Lesegno, J. Manzi, C. Lamaze, P. Bassereau; Institut Curie, Paris, France

Various lipid and protein composition gives identity to membrane compartments and is essential to their unique biophysical and biological properties hence organelle functioning. In that context efficient lipid and protein sorting cannot be underestimated. Mechanisms of protein sorting are well established, yet

still little is known about the sorting mechanisms of lipids thus, in **this study we aim to understand one mechanism of sphingolipids trafficking within the cells.** Sphingolipids (SLs) are a particular class of lipids, that are synthesized only at trans-Golgi network (TGN) and transported to the plasma membrane (PM) where they are highly enriched. Moreover, to date there is no PM-Golgi contact site reported suggesting that SLs are transported by a classical vesicular secretory pathway. However, SLs enrichment in curved, vesicular carriers cannot occur spontaneously due to increased SLs bending energy and propensity to form stiff membranes, comparing to bulk phospholipids, and to the very weak effect related to intrinsic curvature for lipids. Therefore, for SLs a mechanism of protein-assisted lipid sorting has been proposed that, takes advantage of protein's affinity for curved membranes and specific lipids. One of the proteins enriched in the same secretory pathway as SLs is caveolin (Cav1), which shuttles from the Golgi to the PM where it forms cup-shape, SLs-cholesterol-enriched domains called caveolae. Although the abundance of SLs within caveolae is well documented, it is not known whether SLs are enriched and co-transported with Cav1 after assembling at the TGN or sequestered only at the PM level. Our study demonstrates, by live and fixed cells imaging, that cells lacking Cav1 show a major distributional change in SLs with significantly reduced PM level and SLs sorting redirected towards lysosomes, indicating that Cav1 plays a role in SLs trafficking. Using RUSH technology, which enables synchronized release and trafficking of desired molecules, we demonstrate that SLs-Golgi-exit is significantly slowed down in the absence of Cav1. Moreover, feeding Cav1-deficient cells with fluorescent glyco-SLs results in SLs accumulation in lysosomes by failing incorporation into recycling tubule at the level of recycling endosome. All together suggesting that interaction with Cav1 is the limiting factor for proper SLs sorting and distribution within the cell.

Live Cell Imaging of PI4P During Osh-Dependent Polarized Secretion

L. A. Heckle, K. G. Kozminski; University of Virginia, Charlottesville, VA

To support polarized cell growth in *S. cerevisiae*, secretory vesicles traffic to the presumptive bud site, bud tip, and bud-neck. While trafficking, vesicles undergo a process known as maturation during which specific proteins associate and dissociate with the vesicle surface. Several models (Mizuno-Yamasaki *et al.*, 2010; Ling *et al.*, 2014; Smindak *et al.*, 2017) posit that vesicle maturation also requires an Osh protein-dependent loss of vesicle-associated PI4P, creating a PI4P gradient between the Golgi and plasma membrane. However, there is a lack of direct data supporting the existence of this gradient. To test these models, we used live cell imaging with fluorescent proteins to track secretory vesicles and quantify vesicle-associated PI4P. We validated the specificity of the PI4P-probe P4M in *S. cerevisiae* by demonstrating P4M localizes to membranes enriched in PI4P and P4M distribution reflects known changes in PI4P localization. These data demonstrated P4M is specific to PI4P in *S. cerevisiae,* and can be used to detect changes in PI4P levels. To quantify vesicle-associated PI4P, we co-expressed mCherry-P4M and GFP-Ypt32p, a Rab GTPase reported to dissociate from secretory vesicles as the PI4P gradient is established. Using live cell imaging, we quantified the percent change in the intensity of mCherry-P4M and GFP-Ypt32p as vesicles trafficked to sites of polarized growth. Consistent with current models, we found mCherry-P4M and GFP-Ypt32p co-localize on secretory vesicles and at sites of polarized exocytosis. However, the intensity of vesicle-associated mCherry-P4M did not consistently decrease over time and distance as expected. Rather, mCherry-P4M and GFP-Ypt32p intensity fluctuated as vesicles trafficked, with no correlation between mCherry-P4M and GFP-Ypt32p. These data suggest the PI4P gradient may not be steep or may manifest only when vesicles are in very close proximity to the

plasma membrane. To determine whether the Osh protein family effects PI4P distribution, we expressed Clover-P4M in strains lacking one of the seven members of the Osh protein family. Loss of any member of the Osh protein family resulted in altered PI4P distribution relative to wildtype cells. Although the Osh protein family shares a yet unknown common function, these data indicate individual Osh proteins serve unique roles in maintaining PI4P distribution.

Golgi localized Arl15 regulates cargo transport, cell adhesion and motility

P. Sharma[1], P. Hoovina Venkatesh[1], N. Paddillaya[1], N. Shah[2], R. BR[2], A. Dakua[1], A. Penmatsa[1], N. Balasubramanian[2], N. Gundiah[1], S. Gangi Setty[1]; [1]IISc, bangalore, India, [2]IISER, Pune, India

Small G-proteins of Arf-like (Arl) GTPase subfamily are shown to regulate several cellular processes including intracellular trafficking, cytoskeletal organization, organelle biogenesis, cell adhesion and migration. Around 21 genes belong to this family have been identified in human. However the role of Arl15 in cargo transport was unclear. In our study we observed that Arl15-GFP localizes to Golgi, plasma membrane (PM) including filopodia, and a cohort to recycling endosomes. The dual localization of Arl15 to Golgi and PM is independent of the actin cytoskeleton, but it is dependent on Golgi integrity. The dissociation of Golgi using small molecular inhibitors or the expression of Arf1 dominant-negative mutant completely mislocalizes Arl15 to the cytosol. We identified a novel V80A mutation in the GTP-binding domain that turns the Arl15 into a dominant-negative form and results in a reduced number of filopodia. Depletion of Arl15 in HeLa cells causes mislocalization of cargo such as caveolin-2, STX6 from Golgi and accumulation of lipid droplets. Further, Arl15 knockdown cells display reduced filopodial number, altered focal adhesion kinase organization, and enhanced soluble and receptor-mediated cargo uptake without affecting the recycling kinetics. In addition, Arl15 knockdown decreases cell migration and increases cell adhesion, and displays enhanced cell spreading. Traction force microscopy studies revealed that Arl15 depleted cells exert higher traction force and generate multiple focal adhesion points. These studies demonstrated a function to Arl15 in Golgi, which regulates cargo transport to organize membrane domains at the cell surface to control cell migration, spreading and adhesion, including filopodial biogenesis.

Establishment and Maintenance of Polarity

B373/P2760

Cytokinesis Drives Apical Migration of Centrosomes to Promote Polarized Vesicle Trafficking and Epithelial Polarization

P. Wang[1], K. Lin[2], T. Tang[3]; [1]Program in Molecular Medicine, National Yang Ming Chiao Tung University and Academia Sinica, Taipei, TAIWAN, [2]Institute of Physics, Academia Sinica, Taipei, TAIWAN, [3]Institute of Biomedical Sciences, Academia Sinica, Taipei, TAIWAN.

The centrosome has been observed to be always located near apical surface in polarized epithelial cells. However, the detail mechanisms of how centrosomes migrate to the precise position and how the centrosome position affects the cell polarity remain elusive. Using 3D cultures of renal MDCK cysts, we show that the apical membrane components clustering at the pericentrosomal region follow the path of centrosome migration during cytokinesis and transport to apical membrane initiation site (AMIS) for *de novo* epithelial polarization. Unexpectedly, we found that the centrosome is not essential for apical

lumen formation, but its migration can promote the efficiency of polarized vesicle trafficking and the targeting of apical membrane components to the AMIS. Interestingly, blocking cytokinesis in aggregated MDCK cells shows immovable centrosomes and pauses the polarized membrane trafficking. While, dividing MDCK cells that are cultured in suspension without extracellular matrix (ECM) could induce centrosome migration toward the cytokinetic bridge but result in inverted apical membrane. Our findings suggest that cytokinesis is sufficient to drive centrosome migration, but the decision of apical-basal orientation indeed relies on ECM signaling. Furthermore, Par3, which associates with dynein, first emerges at cytokinetic bridge before centrosome positioning and apical membrane formation. Depletion of Par3 results in a defects of centrosome migration. We thus speculate that the Par3-dynein complex at the cytokinetic bridge creates a pulling force for placing centrosomes near the site which will become apical region. Then the recruitment of apical membrane components to the centrosomes accompanied with centrosome migration during cytokinesis promotes the efficient transportation of apical membrane components to form the apical membrane. Our study provides an in-depth understanding the mechanism of centrosome migration and its roles in the promoting cell polarization during the development of epithelial-like tissues.

Differential Regulation of Cdc42 GTPase for polarity patch dynamics during mating in *S. pombe*

S. Saha, L. Merlini, S. G. Martin; Department of Fundamental Microbiology, University of Lausanne, Lausanne, SWITZERLAND.

Eukaryotic cells such as neurons, epithelial cells, developing embryo, yeasts etc. display a wide variety of polarized morphologies necessary for their particular functions. Despite the large diversity in cell types, establishment of polarity is often governed by highly conserved small GTPases like the Rho family GTPase Cdc42. In fission yeast *S. pombe*, active Cdc42 establishes cell polarity in mitotic cells. Cdc42-GTP zones are stabilized by a scaffold-mediated positive feedback and trigger cytoskeletal remodeling through effectors, such as formin and exocyst, to induce bipolar growth imparting a characteristic cylindrical shapes to the cells. Upon nitrogen starvation *S. pombe* cells of distinct P and M mating types secrete pheromones, P and M-factors respectively, to mate and produce dormant spores. During the mitotic to mating transition, Cdc42-GTP zones at cells tips become smaller and form dynamic patches that aid in partner searching by appearing and disappearing at different locations on cell's periphery. These dynamic patches function in both pheromone secretion, releasing a local signal, and perception, probing for strong pheromone gradients from the partner cell, a phenomenon called "cellular speed-dating". When dynamic patches of opposite mates come in contact, they stabilize and the cells extend a mating projection or "shmoo" towards their partner. Although Cdc42 GTPase governs cell polarization in both mitosis and mating, our knowledge of its regulation is largely limited to mitotic growth and we do not know what mediates its dynamics or stabilization during mating. Using genetic and imaging techniques, we are investigating if scaffold-mediated Cdc42 positive feedback also operates in mating and how negative regulation of Cdc42 promotes patch dynamics. Unexpectedly, we discovered that a scaffold mutant that blocks positive feedback during mitotic growth remains mating competent. We also observed that deletions of GTPase Activating Proteins (GAPs) and Guanosine Dissociation Inhibitor (GDI), which lead to vastly extended Cdc42-GTP zones during mitotic growth, do not prevent formation of patches of restricted size in mating cells. These findings indicate that Cdc42 regulation is significantly different in mating.

B375/P2762

Semaphorin Secretion by Endothelial Cells Stimulates Epithelial Polarization

P. Caceres; Hypertension and Vascular Research, Henry Ford Hospital, Detroit, MI.

The microvasculature has emerged as a local determinant of tissue homeostasis *via* secretion of paracrine factors. This notion is relevant for diseases characterized by microvascular alterations like cancer and diabetes, among others. How microvasculature dysfunction affects differentiation and homeostasis of surrounding tissues has received little attention. Given the close association between epithelia and microvascular beds throughout the body, the objective of this study is to determine whether two cell-cell communication proteins of the Semaphorin family, Sema3E and Sema3F, are secreted by endothelial cells and target epithelial cells, therefore stimulating epithelial polarization. Two epithelial cell lines, Calu-3 (lung) and RPTEC (kidney) were cultured in permeable support in monoculture or co-culture with Human Umbilical Vein Endothelial Cells (HUVEC) in the lower chamber. We measured tight junction maturation via trans-epithelial electrical resistance (TEER) and basolateral polarization of E-cadherin via domain-selective surface biotinylation. First, we determined by ELISA that HUVEC endothelial cells secreted Sema3E (7.8 ±1.8 pg/sq.cm/day) and Sema3F (205.8 ± 2.9 pg/sq.cm/day). High glucose (25mM) had no effect on Sema3F but increased Sema3E secretion 6-fold ($p<0.01$). Osmolality control 15mM mannitol had no effect. This suggests that high glucose, like in diabetes, could affect the endothelial-determined microenvironment. Next, we determined whether semaphorins either exogenous or from co-cultured endothelial cells, stimulated epithelial polarization. We found that exogenous recombinant Sema3E or 3F (300 ng/mL) accelerated TEER over two weeks ($p<0.01$) in Calu-3 and RPTEC cells. Similarly, co-culture with HUVEC cells stimulated TEER ($p<0.01$). However, silencing Sema3E or 3F in HUVEC cells prevented them from stimulating TEER in co-cultured epithelial cells. We observed the same when measuring progression of E-cadherin basolateral distribution. Equivalent co-culture experiments silencing semaphorin receptors Plexin-B1 or B2 in epithelial cells indicated that HUVEC cells could not promote epithelial polarization. We conclude that HUVEC endothelial cells secrete Sema3E and 3F, which may act as signals through Plexin receptors in epithelial cells to stimulate epithelial maturation and polarization.

Asymmetric cell division in human hematopoietic stem cells is regulated by cell-cell interaction

A. Candelas[1,2], B. Vianay[1,2], L. Blanchoin[2,1], S. Brunet[1,2], M. Thery[1,2]; [1]CytoMorpho Lab, Institut Pierre-Gilles de Gennes, PSL, Paris, FRANCE, [2]CytoMorpho Lab, LPCV, CEA, Grenoble, FRANCE.

The centrosome is pointed at the core of unique cellular structures such as the immune synapse, the cilia, the flagella or the mitotic spindle. These structures involve specific functions: communication, sensing, motility and division, respectively. In hematopoietic stem and progenitor cells (HSPC)s, the multipotent cells that generate all the blood cell lineages, centrosome has been described at the rear of the migratory cells. However, its behaviour and role in interaction remain unknown, despite its key presence in the cell-cell interaction of some differentiated hematopoietic lineages i.e. immune synapse of B-/T-cells.

To address this question, we co-culture human HSPCs with different cell types of the bone marrow, that form the niche of the HSPC. Using microwells, we confine both cell types in a restrictive space and maintain a continuous cell-cell interaction. We find that HSPCs polarize toward the interaction with the bone marrow cells, forming a single cellular protrusion called magnupodium. This protrusion presents a

dense actin network enriched in receptors and adhesion molecules. Remarkably, the centrosome localizes also at the core of this structure and together with it, the Golgi and proteins involved in cell-cell communication. In other stem cells, polarization can precede asymmetric cell division. This type of division drives a differentiation process by producing two daughter cells with different cell fates. To further investigate this hypothesis, we combine our microdevice setup with live staining and imaging to track consecutive (a)symmetric inheritance of fate determinants and the progeny identities. We find that HSPC polarization conditions increase perpendicular mitotic spindle orientation and the levels of asymmetric inheritance in the progeny, both indicators of asymmetric cell division.
Our data determine a novel centrosome-based structure of polarization upon specific cell-cell interaction and suggests that it is involved in the regulation of the asymmetric cell division of hematopoietic stem cells.

How Do Cells Determine the Timing and Rate of Polarized Growth?

W. Vickers, M. Das; Biology, Boston College, Chestnut Hill, MA.

Cells must be able to regulate the specific timing and position of growth to form the wide diversity of shapes and structures we see throughout biology. While the shape of the cell tends to be more important to the function of multicellular organisms, the basic pathways for the regulation of growth and polarity are also present in single-celled eukaryotes. After division, fission yeast initially grows only from the old end that was inherited from the previous generation. Later, in a process known as new end take-off (NETO) the cell transitions to bipolar growth. However, the rate of growth at the new end is slower than that of the old end. It is not fully understood what establishes this old end dominance or delayed new end growth. To answer this question, we investigated Rax1 as a potential regulator of NETO. *rax1Δ* cells begin new end growth prematurely and have a more symmetric distribution of Cdc42 activity between the two ends, as well as overall higher levels of active Cdc42. However, the growth rate of the new end after NETO remains similar to wildtype and the old end retains its dominance. Our findings suggest that the old end retains an advantage even when the new end grows earlier and that growth rate is not simply a function of the level of Cdc42 activation. We propose that the timing and rate of growth are regulated by at least two distinct regulatory systems.

B378/P2765

Role of the Galpha-MAPK interaction in mating in *Saccharomyces cerevisiae*

C. Robertson, D. Lew; Pharmacology And Cancer Biology, Duke University, Durham, NC.

Many cells direct their movement (chemotaxis) or growth (chemotropism) in response to chemical cues in their environment. This behavior involves translating spatial information from binding of cell surface receptors into cytoskeletal activity that directs movement or growth in a direction influenced by extracellular chemical gradients. The best understood model for gradient sensing is the budding yeast *Saccharomyces cerevisiae*, where the simple biology, lack of redundancy, and ease of manipulation has allowed investigators to identify molecular mechanisms whereby spatial information is conveyed to the cytoskeleton. Budding yeast cells are immobile and rely on chemotropism to mate with a nearby partner cell. Mating cells secrete pheromones that are sensed by cell surface G-protein coupled receptors (GPCRs) on potential partner cells. When these receptors bind pheromone, Gα is activated and dissociates from Gβγ, which then triggers a signaling cascade that activates MAPK to promote cell cycle

arrest, changes in gene expression, and polarization. Polarization is directed towards the partner via a scaffold protein, Far1, that connects Gβγ to activation of the polarity regulator Cdc42, which orients actin to promote directed growth. However, there are additional requirements for effective chemotropism whose mechanism has not been elucidated. The Gα subunit binds to the MAPK and disrupting the Gα-MAPK interaction (*gpa1*^{DSD} mutant) results in a mating defect (Metodiev et al., 2002). We found that the directionality of polarity site movement during partner search was partially defective in *gpa1*^{DSD} mutants, and that a subset of cells failed to recognize when polarity sites were aligned, leading to "kiss-and-run" encounters. One hypothesis to explain the role of the Gα-MAPK interaction is that it localizes active MAPK at the polarity site to phosphorylate its substrate Bni1, a formin that regulates actin (Matheos et al., 2004). Using bni1 temperature-sensitive mutants, we found that polarity site movement still occurred and allowed alignment of partner polarity sites in the absence of Bni1, although subsequent fusion was delayed. However, epistasis analysis showed that *gpa1*^{DSD} mutants still caused defects in polarity site directionality even in cells lacking Bni1. We conclude that the Gα-MAPK interaction regulates mating through Bni1-independent pathways. Other MAPK substrates enriched at polarity sites include Gβγ (Ste4 and Ste18, respectively) and Far1, and we are testing whether their phosphorylation may explain the need for Gα-MAPK interaction in mating yeast.

Control of cell polarity and exploratory Cdc42 dynamics by conserved NDR kinase Orb6 and Cdc42 GAP Rga3

L. Doyle, V. Mariani, D. D'Urso, F. Verde; University of Miami Miller School of Medicine, Miami, FL.

Cell polarization is crucial to cell function, and changes dynamically during the cell cycle and in response to environmental stress. Our work focuses on the conserved NDR kinase, which regulates cell morphogenesis from yeast to man, and has a role in the onset of disease in humans. In fission yeast cells, the NDR kinase Orb6 spatially controls the key morphology regulator Cdc42 GTPase. During interphase and in the presence of nutrition, Orb6 promotes Cdc42 function at the cell tips by increasing the activity of the upstream regulator Ras1. This pattern of Cdc42 activation during vegetative growth displays anticorrelated Cdc42 oscillations at the cell tips. Conversely, loss of Orb6 kinase activity leads to the emergence of an alternative, "exploratory" pattern of Cdc42 activation, where ectopic foci of Cdc42 activity dynamically appears and disappear throughout the cell membrane. We previously reported that this effect depends, at least in part, on the Cdc42 GEF Gef1, a substrate of Orb6, that moves to the cell membrane upon Orb6 inhibition. To better understand the emergence of these alternative Cdc42 dynamics, we undertook a mass spectrometry screen to identify novel Orb6 substrates. In this screen, we identified a Cdc42 GAP Rga3, as a substrate of Orb6. We found that loss of Orb6 kinase activity leads to a significant increase of Rga3 at the cell membrane, a phenotype mimicked by expression of Rga3-S683A, mutated in a single Orb6 phosphorylation site. The *rga3-S683A* mutation alters cell dimensions and decreases the rate of bipolar growth activation. Consistent with the idea that Rga3 has a role in promoting the emergence of alternative states of cell polarization, we found that *rga3* deletion prevents the ectopic Cdc42 activation observed during Orb6 inhibition. Further, we find that the *rga3-S683A* mutation promotes "exploratory" Cdc42 dynamics when introduced in a cellular background where the vegetative Cdc42 control axis has been attenuated, and the *gef1-S112A* mutation (mimicking Orb6 inhibition) has been expressed. In conclusion, we report that decreased Orb6 activity promotes the function of an alternative Cdc42 regulatory module, where Cdc42 GAP Rga3 functions in cooperation with Cdc42 GEF Gef1 to foster an exploratory pattern of Cdc42 dynamics. Since Orb6 kinase activity is

downregulated in response to nutritional and environmental cell stress, we discuss the function of this Cdc42 module in cell adaptation to stress.

Cdc42 Mobility and Membrane Flows Regulate Fission Yeast Cell Shape and Survival

D. M. Rutkowski[1], V. Vincenzetti[2], D. Vavylonis[1], S. G. Martin[2]; [1]Lehigh University, Bethlehem, PA, [2]University of Lausanne, Lausanne, SWITZERLAND.

Cdc42 activation directs cell growth by forming membrane associated patches which promote localized exocytosis. Secretion-driven in-plane membrane flow depletes peripheral proteins with low mobilities, including Cdc42 GAPs, away from the region of localized membrane addition/removal. To investigate the self-organizing properties of the Cdc42 secretion-polarization system, we developed a stochastic particle model implementing the reaction-diffusion of Cdc42. The model includes positive feedback by discretely modeled GEFs, hydrolysis by discrete GAPs, and flow-induced displacement by exo/endocytosis targeted towards regions of Cdc42 activity. Our simulations show how stable polarization of wild-type cells relies on flow-induced depletion of low mobility GAP when using Cdc42-GDP and Cdc42-GTP diffusion and membrane dissociation rates estimated from FRAP experiments. To probe the role of Cdc42 mobility, which is fast enough to not be strongly affected by membrane flow in WT cells, we changed its membrane binding properties by replacing its prenylation site with NxRitC, where N is the number of repeats of the Rit1 C terminal membrane binding domain. While Cdc42-3xRitC is inviable, surprisingly, Cdc42-1xRitC and -2xRitC cells survive and polarize, even though the unbinding and diffusion rates for these constructs (as measured from diploid cells also expressing WT Cdc42) are significantly lower than WT-Cdc42. By systematically varying Cdc42 mobility in our model, we find that GEF positive feedback and GAP flow-displacement allows polarization even when membrane flows are strong enough to displace Cdc42 itself away from its activation region. However, lower Cdc42 mobility in the model results in lower Cdc42 activation level and wider patches, in agreement with our experimental observations in haploid and diploid cells. The model predicts that GAP depletion increases Cdc42 activity at the expense of loss of polarization. Experiments confirm this prediction, as deletion of Cdc42 GAPs restores viability to Cdc42-3xRitC cells. Overall, our combined experimental and modeling studies demonstrate how membrane flows are an integral part of Cdc42-driven pattern formation.

B381/P2768

Endocytosis Regulates Negative Feedback to Promote Bipolar Growth in Fission Yeast

M. Harrell[1], Z. Liu[2], T. Hong[2], M. Das[1]; [1]Biology, Boston College, Chestnut Hill, MA, [2]University of Tennessee Knoxville, Knoxville, TN.

Precise regulation of polarized growth promotes specific cell shapes for optimal function. The Rho GTPase Cdc42 is highly conserved and is the major regulator of polarized growth in most eukaryotes. Cdc42 is localized to inner membranes but is only activated at specific sites for growth. Resources that activate Cdc42 are limited and must be properly shared among multiple sites of growth. In the bipolar yeast *S. pombe*, Cdc42 periodically cycles between active and inactive states at sites of growth. Periodic activation and inactivation of Cdc42 is regulated by positive and negative feedback loops. Thus, periodic Cdc42 activity at both cell ends allows sharing of limited polarity machinery resulting in bipolar growth. Positive feedback loops are established when active Cdc42 recruits Scd2 (a scaffold) which then recruits Scd1 (primary Cdc42 activator) to activate more Cdc42. This is the positive feedback loop. Active Cdc42

also recruits Pak1 kinase (inhibitor of Scd1 recruitment) to dismantle the complex via negative feedback. It is unclear how Cdc42 regulators are properly shared between both ends. To understand this, we built a mathematical model based on the positive feedback loop between Cdc42 & Scd1 at both ends of the cell. The model shows the essential roles of this feedback loop and the optimal removal rate of these molecules for bipolarity in *S. pombe*. We find, using genetic and chemical perturbations of only branched actin (required for endocytosis) but not actin cables (needed for vesicle transport) that growth sites no longer share resources. Instead, they accumulate at one end. This is consistent with the model which suggests that sharing of Cdc42 activity depends on endocytosis. Since endocytosis is known to recycle proteins from the membrane, we asked if a Cdc42 regulator accumulates in the absence of endocytosis. Contrary to our expectations and the model's prediction, Scd1 (Cdc42 activator) and Scd2 (scaffold) levels decrease at the cortex upon loss of branched actin. Therefore, we explicitly added Pak1 into the model then examined if altering Pak1 dynamics would explain the loss of sharing between sites of growth upon loss of branched actin. Our model indicates that the reduced removal rate of Pak1 (Scd1 inhibitor) from the cortex leads to loss of bipolarity and sharing as well as decreased Scd1 at the cortex. We then performed in vivo experiments and found that Pak1 did stabilize at a growth site when cells lost branched actin (endocytosis). Taken together, we propose that endocytosis promotes growth from multiple sites by mediating the sharing of polarity machinery via the removal of negative feedback proteins. Optimal removal of negative feedback proteins allows growth to re-establish at that site allowing for periodic activation and inactivation at each site.

B382/P2769

Loss of mechanical homeostasis drives epithelial acinar eversion

V. Narayanan[1], P. Purkayastha[2], B. Yu[3], R. Dickinson[3], **D. E. Conway**[4], T. P. Lele[2]; [1]Virginia Commonwealth University, Richmond, VA, [2]Texas A&M University, College Station, TX, [3]University of Florida, Gainseville, FL, [4]The Ohio State University, Columbus, OH.

Epithelial cells lining a gland and cells grown in a soft extracellular matrix polarize with apical proteins exposed to the lumen and basal proteins in contact with the extracellular matrix. Alterations to polarity, including an apical-out polarity, occur in human cancers. While some aberrant polarity states may result from altered protein trafficking, recent observations of an extraordinary tissue-level inside-out unfolding suggest an alternate pathway for altered polarity. Because mechanical alterations are common in human cancer including an upregulation of RhoA mediated actomyosin tension in acinar epithelia, we explored whether perturbing mechanical homeostasis could cause apical-out eversion. Acinar eversion was robustly induced by direct activation of RhoA or indirect activation of RhoA through blockage of β1 integrins, disruption of the LINC complex, oncogenic Ras activation, or Rac1 inhibition. Furthermore, laser ablation of a portion of the untreated acinus was sufficient to induce eversion. Analyses of acini revealed high curvature and low phosphorylated myosin in the apical cell surfaces relative to the basal surfaces. A vertex-based mathematical model which balances tension at cell-cell interfaces revealed a five-fold greater basal cell surface tension relative to the apical cell surface tension. The model suggests that the difference in surface energy between the apical and basal surfaces is the driving force for acinar eversion. Our findings raise the possibility that a loss of mechanical homeostasis may cause apical-out polarity states in human cancers.

B383/P2770

Cell-Cycle-Dependent Polarized Growth Inhibition in Fission Yeast

J. C. McDuffie, M. E. Das; Morrissey College of Arts & Sciences - Biology Department, Boston College, Chestnut Hill, MA.

Cells are defined by periods of division, interspersed by periods of growth. Precise coordination of the timing and position of this growth ensures proper cell division and is fundamental to the establishment of diverse cellular shapes and specialized functions. Highly conserved amongst eukaryotic organisms is the major regulator of polarized cell growth, the Rho-GTPase Cdc42. When activated by the binding of GTP, Cdc42 establishes sites of polarized growth via a positive feedback loop. The single-celled fission yeast employs a simple yet highly conserved Cdc42 regulatory system to maintain a bipolar rod-like growth pattern and to coordinate arrest of this growth during mitosis. Within this system, the membrane-associated Rga4 is a potent inhibitor of Cdc42. Rga4 localizes to the cortex of fission yeast cells in a punctate pattern during interphase, confined to the cell sides where it inhibits Cdc42 activity everywhere but the growing cell ends. Upon entrance into mitosis, Rga4 localization shifts to a more homogeneous distribution along the cortex and creeps up onto the cell tips, blocking growth until completion of division. How Rga4 localization is being regulated in a cell-cycle-dependent manner is currently unknown. To answer this question, we investigated Septins (Spns) as potential regulators of Rga4 localization. This filament-forming family of cytoskeletal proteins share a punctate cortical localization pattern with Rga4 during interphase. During mitosis, these Septins move off of the cell sides to form a ring at the middle of the cell. Our findings demonstrate that disruption of Septin filament formation via *spn1Δ* results in a more homogeneous distribution of Rga4 along the cell cortex, along with its mis-localization to the cell ends during interphase, a localization pattern normally associated with mitosis. Along with this mis-localization of Rga4, we observe changes in Cdc42 activity at the growing cell ends, disruptions in the feedback loop cycle of Cdc42 activity and changes in cell morphology. We propose that Septins regulate Rga4 localization in a cell-cycle-dependent manner by confining Rga4 to the cell sides during interphase, during mitosis the Septin filaments recede toward the division plane thus freeing Rga4 to spread out along the cell cortex.

B384/P2771

Defining the septin interactome and its role in appressorium-mediated plant infection by the rice blast fungus *Magnaporthe oryzae*

I. Eisermann, A. Foster, P. Derbyshire, F. Menke, N. Talbot; The Sainsbury Laboratory, Norwich, UNITED KINGDOM.

Rice blast disease, caused by the plant pathogenic fungus *Magnaporthe oryzae*, destroys rice to feed more than 60 million people every year. The disease is initiated by formation of a specialized dome-shaped infection cell called the appressorium. Turgor pressure of up to 8MPa is generated within the appressorium and enables the fungus to develop a rigid penetration peg to breach the rice cuticle. Cytoskeletal proteins called septins play a major role during appressorium-mediated plant infection by rigidifying the cortex of cells, scaffolding F-actin and localizing proteins, such as polarity determinants at the plasma membrane. *M. oryzae* possesses six septin GTPases. The four core septins, Sep3, Sep4, Sep5 and Sep6 form a large hetero-oligomeric ring structure at the base of the appressorium, while the two non-core septins, Sep7 and Sep8 are responsible for the formation of a range of membrane and cytoskeleton-associated structures in the cell. Interestingly the non-core septins Sep7 and Sep8 are

absent in mammals and belong to a unique class 5 group of septins. We have used a combination of approaches to determine the function of each septin during appressorium-mediated plant infection to define the dynamics of the septin interactome in so far unparalleled detail. We carried out Ultra-High-Throughput Yeast Two Hybrid analysis and combined the results with those of an *in vivo* immunoprecipitation tandem mass spectrometry (IP-MS-MS) approach using GFP-tagged septins. For each septins we have identified a wide range of interaction partners during appressorium development, including polarity determinants, cytoskeletal components, and a range of regulatory proteins. Interestingly we observed that Sep7 interacts with Sep3, Sep4, Sep5 and Sep6 specifically during early appressorium formation, 4h after conidial germination, forming a plasma membrane-associated complex. Sep8, which contains a transmembrane helix, also interacts with each septin and may link septins to the plasma membrane. Additional to the determination of the septin interactome, we gained knowledge about the regulation of the septins, by caring out a phosphoproteomic analysis. Our approaches define the septin interactome in unparalleled detail and determine how *M. oryzae* septin complexes organise the appressorium pore and deploy polarity determinants to facilitate cuticle rupture and invasive fungal growth.

B385/P2772

Spatiotemporal regulation of the Rho GTPase Cdc42

A. DAlessandro, K. Moran, D. Lew; Duke University, Durham, NC.

In *S. cerevisiae*, polarization of the actin cytoskeleton is regulated during the cell cycle by the main cell cycle regulator, cyclin dependent kinase (CDK). CDK activation promotes local clustering of the polarity regulator Cdc42, leading to actin orientation and bud emergence. How exactly CDK activity impacts Cdc42 behavior is not yet clear, but various studies have suggested that CDK controls polarity by regulating Cdc42-directed regulators (GEF, GAPs) or effectors.With respect to GEF regulation, CDK has been proposed to promote binding of the GEF Cdc24 to the scaffold protein Bem1 (Witte et al., 2009). This interaction would promote positive feedback by enabling recruitment of GEF to sites with active Cdc42. Using synchronized cell populations, we assessed whether Bem1-Cdc24 interaction (measured by co-immunoprecipitation) varied through the cell cycle. However, we detected a constitutive and unvarying interaction, inconsistent with the model.With respect to GAP regulation, CDK was shown to directly phosphorylate GAPs, and indirect assays suggested that phosphorylation might reduce GAP activity (Knaus et al., 2007; Sopko et al., 2007). To test this hypothesis, we probed Cdc42-GAP interaction by incubating extracts from synchronized cells with beads coated with GTP-locked $Cdc42^{Q61L}$. Epitope-tagged GAP proteins bound to the beads, and we are quantifying the degree of binding through the cell cycle. With respect to effectors, two related PAK-family kinases, Ste20 and Cla4, displayed differential localization through the cell cycle, with Ste20 localizing earlier than Cla4 (Moran et al., 2018). Effector localization requires both Cdc42 and membrane binding (Takahashi and Pryciak, 2007). As both effectors bind Cdc42 via a CRIB motif, but contain different membrane-binding domains (basic-rich amphipathic helix in Ste20 and PH domain in Cla4), we speculated that CDK activation might regulate membrane composition, enabling differential recruitment of these effectors. We constructed probes containing dimerized membrane-binding domains (without CRIB) from each effector and tested whether membrane localization varied during the cell cycle. Quantification showed no differences, suggesting that both domains bind membranes constitutively.In conclusion, two of the proposed mechanisms for cell cycle regulation of polarity (Bem1-Cdc24 association and effector-membrane interaction) are not

supported by our findings. Investigation of GAP regulation is ongoing. For now, the mechanism(s) by which CDK regulates Cdc42 remain mysterious.

SGEF, a RhoG-specific GEF, Regulates Lumen Formation and Collective Cell Migration in 3D Epithelial Cysts

M. Lovejoy, A. Rabino, G. Kreider-Letterman, V. Gangasani, R. Garcia-Mata; University of Toledo, Toledo, OH.

Most internal organs consist of a polarized epithelium surrounding a central lumen, which separates the interior of cells from the external environment. The establishment of polarity is essential for epithelial cells' function, and abnormalities in this process are a hallmark of many diseases, such as cancer. Polarization is initiated and maintained by the coordinated action of three protein complexes: Crumbs, Par, and Scribble. The Scribble complex is comprised of Scribble, Dlg1, and Lgl, and was primarily identified as a critical regulator for polarity. However, it was later shown to be involved in other related cellular processes, including cell-cell adhesion, asymmetric cell division, and vesicular trafficking. We previously showed that Scribble and Dlg1 can form a ternary complex with SGEF, which is a RhoG-specific guanine-nucleotide exchange factor (GEF) that also functions as a scaffolding protein. We also showed that SGEF is important in junctional stability and E-cadherin expression in a two-dimensional monolayer. Here we used single epithelial MDCK cells embedded in Matrigel, which develop into multicellular, polarized 3D cysts over time, to study the role of SGEF in regulating polarity and lumen formation in 3D. Using this model, we found that mature SGEF knockdown cysts have multiple lumens, which are often closed, decreased E-cadherin levels, and compromised tight junction barrier function. Multiple lumens can result from defects in proper mitotic spindle orientation, barrier function, or vesicle transport, whereas closed lumens may result from leakage due to the instability of tight junctions. Interestingly, when we followed cyst formation using live 4D spinning disc microscopy, SGEF KD cysts showed a surprising increase in collective motility. This was further confirmed in two-dimensional monolayers with a wound healing assay, where SGEF KD cells migrated much further at a higher velocity during migration to close the wound. Our results suggest that, because E-cadherin expression is reduced, there is a decrease in the strength of cell-cell adhesions. This phenotype has been observed in most cases of metastasis, suggesting that SGEF could play a role in maintaining epithelial stability in MDCK cells. We plan to grow cysts from several SGEF mutant rescue cell lines that isolate the catalytic and scaffolding role to further characterize the molecular mechanisms that control lumen phenotype, E-cadherin expression, junctional stability, and collective cell migration.

Mechanism of the transition from a Par-3- to Cdc42-bound Par complex

E. Vargas, K. Prehoda; BIology, University of Oregon, Eugene, OR.

The polarization of cell membranes into discrete domains is critical for the function of diverse animal cells. The Par complex (Par-6/aPKC), a central regulator of animal cell polarity, must localize in a spatially and temporally defined manner in order for proper polarization to occur. Two regulators of the Par complex, Par-3 and Cdc42, are responsible for the precise control of Par complex polarization and activity. Numerous *in vivo* studies propose that a key step in polarization is the transition from a Par-3- to a Cdc42-bound Par complex, as each regulator is thought to induce a distinct activity, yet limited

biochemical evidence exists to support these models. Utilizing a biochemical reconstitution approach with all purified components, we show that Par-3 and Cdc42 exhibit strong negative cooperativity for binding to the Par complex. We find that displacement of Cdc42 from the Par complex is mediated by the interactions between the second and third PDZ domains of Par-3 and the aPKC Kinase-PBM (PDZ binding motif). We also show that the epithelial specific protein, Crumbs, displaces Par-3 in a similar manner to Cdc42. Furthermore, Cdc42 and Crumbs work synergistically to displace Par-3 from the Par complex. These results provide a mechanistic framework for understanding how the Par complex can transition between different regulators and function in diverse polarized cell types.

Polarized cell plasma membrane compartment composition and protein sorting

C. Shurer, I. Levental; University of Virginia, Charlottesville, VA

Epithelial cell polarization is an essential biological process, serving many physiological roles including tissue morphogenesis and wound healing. A defining feature of polarization is the separation of cell plasma membrane lipids and proteins into apical and basolateral compartments between which molecular exchange is restricted. Decades ago, the apical membrane was found to be enriched in saturated lipids, glycolipids, and cholesterol. Mechanistic hypotheses to explain the biogenesis and unique composition of the apical membrane include self-assembling membrane domains (i.e., lipid rafts), specific protein sorting motifs, and post-translational modifications mediating protein sorting. However, neither the detailed composition nor the mechanisms of protein and lipid sorting between plasma membrane domains in epithelial cells have been resolved. Particularly, the lipid profile of the basolateral membrane remains unstudied, leaving doubts about the differentiation and lipid separation of the apical and basolateral membrane. We use advanced lipidomics and imaging techniques to characterize the changes in lipid organization, membrane composition, and membrane properties during the cellular polarization process. We observe that the apical membrane is enriched in highly saturated lipids and glycolipids relative to the basolateral membrane, with apical membrane biophysical properties reflecting a raft-enriched environment. Similar to lipids, the determinants of protein sorting between apical and basolateral domains are poorly understood, with past studies focusing on either specific proteins or trafficking machinery. Importantly, the apical membrane hosts an extensive extracellular glycocalyx consisting of glycolipids, glycoproteins, and polysaccharides. The role of these glycocalyx molecules on protein sorting has not been revealed, despite a major fraction of apical proteins being glycosylated. We systematically evaluate the structural determinants of apical versus basolateral sorting with a focus on transmembrane domain features, protein raft affinity, and glycosylation. We find that these protein features cooperatively direct protein sorting to the apical membrane.

Optimal inhibition by RasGAPs: the key for directed cell migration

Y. Lin, P. N. Devreotes; Johns Hopkins School of Medicine, Baltimore, MD

Directed cell migration, a process that cells migrate directional in response to various environmental cues, is critical to majority of biological processes, including embryogenesis, would healing, immune response and cancer metastasis. It can be dissected into three processes: directional sensing, motility and polarity, among which whether the cell can build the polarity memory is the key for long-term

directional migration. We addressed the issue by looking at Ras activity in social amoeba *Dictyostelium discoideum* and uncovered that two C2-domain containing RasGAPs have distinct functions. C2GAPA inhibits cell migration while C2GAPB polarizes cell and promotes directed migration. More strikingly, starved amoeba usually undergoes development and builds polarity within hours by the coordination of signal transduction and cytoskeletal events. However, we show that using optogenetics to manipulate Ras activities, we can either induce or break polarity in seconds. This study might provide new insights on how polarity is established and emphasize the importance of having optimal inhibitory regulation.

An Unexpected Function of P-cadherin is Required for Single Lumen Formation in Epithelial Cystogenesis

K. Fong-Ngern[1], S. Chang[1], A. S. Vijayakumar[1], R. Zaidel-Bar[2], P. Kanchanawong[3]; [1]Mechanobiology Institute, National University of Singapore, Singapore, SINGAPORE, [2]Department of Cell and Developmental Biology, Faculty of Medicine, Tel Aviv University, Tel Aviv, ISRAEL, [3]Mechanobiology Institute and Department of Biomedical Engineering, National University of Singapore, Singapore, SINGAPORE.

Cadherin-mediated adherens junctions are known to be essential for epithelial morphogenesis during development. While E-cadherin is by far the best characterized cadherin, other cadherin subtypes, such as P-cadherin, are often co-expressed. E-cadherin and P-cadherin are highly homologous type I classical cadherins with juxtaposed chromosomal loci in vertebrates. However, their specific and differential roles in epithelial morphogenesis are less clear. We used Madin Darby Canine Kidney II (MDCK II) cells, which express both E-cadherin and P-cadherin, to investigate the distinct contribution of each cadherin in self-organized cystogenesis in Matrigel after knocking out either E- or P-cadherin by CRISPR/Cas9. We found that E-cadherin KO MDCK cysts successfully generate a stereotypical single lumen, whereas P-cadherin KO MDCK cysts gave rise to multiple lumens, implicating P-cadherin in proper lumenogenesis. At the two-cell stage, P-cadherin KO doublets exhibited defects in both podocalyxin transcytosis and mitotic spindle orientation during the formation of the Apical Membrane Initiation Site (AMIS), a structure required for lumen positioning and lumen generation. During mitosis in cell doublet, E-cadherin remains on the cell surface and at the interface between adjacent cells, whereas P-cadherin localization is dynamically modulated. We found the accumulation of P-cadherin on the condensed chromosomes during prometaphase and at the spindle poles during metaphase, suggestive of a potential role of P-cadherin in mitosis and mitotic spindle orientation. In 2D monolayers, we observed both mitotic spindle misorientation as well as aberrant chromosome alignment. By probing various types of intracellular vesicles, including clathrin-, Rab5-, Rab11-, and Rab35-possitive vesicles, we identified Rab5-possitive vesicle as the major P-cadherin carrier mediating P-cadherin localization and function during mitosis. In conclusion, our findings reveal a distinct function and localization of P-cadherin in the morphogenesis of epithelial tissues by controlling the formation of the AMIS and the alignment of mitotic spindle, via a Rab5-vesicle mediated mechanism.

The *pam1* Suppressor *spam3* Rescues Polarity and Mitotic Defects in *C. elegans*

A. Durkan, B. Adams, K. Hryniszak, I. Marsh, R. Lyczak; Ursinus College, Collegeville, PA

Puromycin-sensitive aminopeptidase (PSA) is highly conserved across the animal kingdom. Moreover, PSAs are implicated in cell cycle regulation and seem to play a protective role in neurological disorders such as Alzheimer's. *Caenorhabditis elegans* have one PSA homolog called PAM-1 (puromycin-sensitive aminopeptidase), and PAM-1 is known to play a role in cell cycle regulation, especially in fertility, meiosis, and mitosis. PAM-1 plays a role in maintaining polarity by keeping centrosomes close to the cortex of the embryo. The first cell division in *C. elegans* is asymmetrical and is controlled by cortical flows and polarity proteins of the PAR class, localizing to the anterior and posterior domains of the cortex. When PAM-1 is inactivated, it disrupts the cortical flows and movement of PAR proteins by affecting the centrosome cortex contact. Though PAM-1 is highly conserved, little is known about its targets/interacting partners. Here, we identified one potential target/interaction of PAM-1 through a suppressor screen. This suppressor brings embryonic viability from ~12 % of a nonsense mutation in the *pam-1* gene to ~70% with the suppressor mutation dubbed *spam-3.* Through whole genome sequencing, we hope to identify the *spam-3* gene. For now, we are analyzing the phenotypes that *spam-3* mutant may resolve and why there is a significant increase in embryonic viability, by looking at mitosis and polarity. Looking at landmark phases in mitosis we have found that *pam-1* mutants lead to DNA segregation errors, such as DNA bridges or failed anaphase, which can lead to a deformed nuclear envelope. The *spam-3* suppressor mutant seems to resolve these issues in *pam-1* embryos. To analyze the polarity of the embryo PAR-1 protein localization and non-muscular myosin (NMY-2) puncta at the cortex are being analyzed. We have found that the *spam-3* mutant decreases the symmetrical cell division caused by mutant *pam-1.* Analyzing the PAR proteins will shed light on why there is a decrease in symmetrical cell division. NMY-2 is required for cytokinesis as well as for the establishment of asymmetry during embryogenesis. Analyzing NMY-2 will add to our understanding of why *pam-1* mutants undergo symmetrical cell division. A better understanding of how PAM-1 is functioning will broaden our understanding of cell cycle regulation and hopefully give insight into some neurological disorders.

3D reference map of retinal pigment epithelium during apical-basal polarization

D. Ortolan[1], P. Sathe[2], A. Volkov[1], D. Reichert[1], S. Sebastian[1], J. Ferrari Escoto[1], N. Lin[1], N. Schaub[3], G. Pegoraro[4], A. Maminishkis[1], R. Sharma[1], P. Bajcsy[2], K. Bharti[1]; [1]National Eye Institute, Bethesda, MD, [2]National Institute of Standards and Technology, Bethesda, MD, [3]National Center for Advancing Translational Sciences, Bethesda, MD, [4]National Cancer Institute, Bethesda, MD

The retinal pigment epithelium (RPE) is a monolayer of cells that faces two different environments - the retinal photoreceptors apically and the choroid basally. To perform different functions on each side, mature RPE cells polarize along the apical-basal axis. Failure to acquire a polarized phenotype leads to retinal degeneration, as seen in some ciliopathies.

In this study, we generated a three-dimensional reference map of RPE organelles and cytoskeletal structures during the process of cell polarization, using high-content imaging and object segmentation. RPE cells were derived from induced pluripotent stem cells reporter lines (iPSC-RPE), each expressing a fluorescently tagged protein to highlight specific intracellular structures. About 10,000 images of iPSC-

RPE were taken at different timepoints during polarization of each reporter line. iPSC-RPE cells treated with HPI4, a compound known to disrupt apical-basal polarity, were included as control. A machine-learning algorithm was trained to identify and segment cells and nuclei borders. These were used as reference to calculate organelle location. Each organelle or structure was segmented using a combination of classic segmentation algorithms and the quality of segmentation was verified by an imaging expert. Three rounds of segmentation with the human in the loop were carried out to ensure the accuracy of the results. The average organelle location and morphological properties were calculated for each condition. Cells became more compact horizontally and elongated on the vertical axis during polarization. At the same time, the nuclei became rounder and developed invaginations of the nuclear envelope. The volume of endoplasmic reticulum increased, while becoming more compact on the x and y axis, when compared to the HPI4 control. On the other hand, the volume of Golgi apparatus didn't change while becoming more compact horizontally. Similarly, lysosomes increased in volume and localized toward the center of the cell, while endosomes didn't appear to change volume or location. This work provides a three-dimensional reference map of organelle morphology and distribution during normal development of RPE apical-basal polarity. Abnormal RPE phenotypes occurring in different diseases can now be compared to this reference map to understand the underlying mechanisms of action.

Polarity in *Saccharomyces cerevisiae* spores

B. Cooperman, M. McMurray; University of Colorado Sch Med, Aurora, CO

The mechanisms responsible for establishing polarity have been studied in the budding yeast *Saccharomyces cerevisiae* for many decades. In mitotically dividing (vegetative) yeast cells the bud site selection process both requires and directs the placement of stable landmark proteins that mark the site of future buds. The cytoplasmic polarity machinery is recruited to these landmarks via direct interactions with components of the Ras-family GTPase Rsr1 module. This module is itself coupled to the Cdc42 GTPase module, linking downstream effector machinery to the previously marked bud site. While much progress has been made towards untangling the complicated web of molecular interactions underlying these pathways, many unknowns remain. Unlike vegetative cells, spores form when a diploid undergoes meiosis upon nutrient limitation. Four spores are created with *de novo* membranes and cell walls all contained within the original diploid cell wall, creating an ascus. When spores are exposed to nutrients and germinate, there is no previous bud site landmark to direct the placement of their future buds. We recently showed that despite the lack of traditionally placed landmarks, spores are indeed born polarized: they bud away from the center of the ascus. This finding provides a unique opportunity to improve our understanding of polarity by investigating how the molecular machinery functions in a system with different rules. We found that spores form a stable, polarized site and identified a variety of proteins that localize there, including the landmark protein Bud8 and Bud5, a GEF for Rsr1. The corresponding GAP for Rsr1, Bud2, is absent, suggesting that cycling of Rsr1 is not required. Upon germination, the site marks both the direction of budding and of early morphogenesis prior to reorienting towards a mating partner. Intriguingly, while Bud2 and Bud5 are both required to direct the budding machinery to the polarity site, loss of Rsr1 destabilizes the site, causing it to relocalize, together with the budding machinery. Unlike in vegetative cells, this occurs multiple times within the same bud, rather than stabilizing at a single, random site. Future experiments aim to further characterize this

system as well as the molecular interactions that occur upon germination in the hopes of understanding how, when, and why this site is marked.

B394/P2781

Visualizing the remodeling of planar cell polarity during cell division

D. Ouyang, L. Basta, D. Devenport; Princeton University, Princeton, NJ

To preserve tissue structure and function throughout life, stem cells must continuously divide and differentiate to replenish and replace aged or damaged tissue. The regenerative process of cell division requires elaborate morphological and internal reorganization whereby dividing cells round up, reorganize their cytoskeleton and organelles, and rearrange with their neighbors to incorporate daughter cells into the tissue. How epithelial stem cells maintain cell polarity, an essential architectural feature of all epithelial organs, during such elaborate cellular reorganization remains poorly understood. Polarity organizes along both the apicobasal and planar axes of epithelial tissues through the asymmetric partitioning of polarity proteins along the plasma membrane. In the skin epidermis, the core PCP proteins Vangl and Frizzled localize to the anterior and posterior sides of intercellular junctions where they partner with the atypical cadherin Celsr1. Our lab previously showed that when epidermal progenitors divide, PCP proteins are removed from the cell surface via bulk endocytosis resulting in a temporary loss of PCP. After division, PCP is restored but the mechanisms that direct PCP protein transport and repolarization are poorly understood. Here, using live-imaging and super-resolution microscopy of endogenously-tagged *Celsr1-3xGFP, Fz6-3xGFP*, and *tdTomato-Vangl2* proteins in murine embryonic epidermis, we characterize the differential internalization, partitioning, transport and delivery of PCP protein-containing vesicles over the course of mitosis and through developmental time. Our data suggest that mitotic internalization and repolarization of PCP proteins serves not only to preserve PCP asymmetry once it is established but may also function to enhance PCP asymmetry during its initial emergence.

Galectin-8 induces Epithelial-Mesenchymal Transition in Cysts of Fully Polarized MDCK cells

R. Santander[1], J. Cancino[1], F. Perez-Molina[1], C. Herrera-Cid[1], A. González[1], **A. Soza**[1,2,3]; [1]Universidad San Sebastián, Santiago, Chile, [2]P. Universidad Católica de Chile., Santiago, Chile, [3]Centro Científico y Tecnológico de Excelencia Ciencia & Vida., Santiago, Chile

Introduction: Epithelial cells undergo changes towards a more mesenchymal migratory phenotype during processes of organogenesis, tissue repair and cancer development and progression. Tumor cells co-exist with fully differentiated cells within their originating epithelia and therefore their secreted factors able to induce this epithelial-mesenchymal transition (EMT) entail great interest. Galectin-8 (Gal-8) is a carbohydrate binding protein that is overexpressed in several tumors and upon secretion by a nonconventional mechanism elicits a variety of cellular responses, interacting with different cell surface glycoproteins. Our previous studies show that Gal-8 promotes EMT in sub-confluent Madin-Darby Canine Kidney (MDCK) epithelial cells by trans-activating the epidermal growth factor receptor (EGFR) through integrin-mediated FAK activation. However, whether fully differentiated epithelial cells also undergo similar Gal-8-induced changes remain unknown. **Methods:** MDCK cells were grown in matrigel for 10 days to form three-dimensional (3D) cysts with their apical surfaces facing a central lumen and their basal surfaces contacting the extra cellular matrix and exposed to added recombinant Gal-8. Apical

(GP135) and basolateral (E-Cadherine) markers, cyst structure, and EMT marker Snail transcription factor were analyzed by confocal immunofluorescent microscopy. **Results:** Gal-8 promoted lumen loss and three-dimensional disorganization in 80% of cysts. Cysts that did not lose their lumen under these conditions were depolarized, according to the localization of E-cadherin and GP135. FAK activity was required to induce three-dimensional disorganization and polarity loss of the cysts. In contrast, EGFR activity was only required to induce three-dimensional disorganization. Lactose, which inhibits galectin binding to carbohydrates, prevented cyst three-dimensional disorganization and polarity loss. Gal-8 promoted the expression of Snail in the nucleus. **Conclusion:** Gal-8 has the potential to induce EGFR-mediated EMT in fully polarized epithelial cells and therefore might contribute to induce this process in epithelial cells adjacent to tumor cells overexpressing Gal-8. **Acknowledgements:** FONDECYT 1211829 and 1221374, ANID Centro de Envejecimiento y Regeneración, ACE210009, and Centro Ciencia & Vida, Basal FB 210008.

Neuronal Morphogenesis and the Cytoskeleton

B397/P2783

Coro1A role in TRIM67-regulated neuronal morphogenesis

C. T. Ho, E. B. Evans, S. Menon, S. L. Gupton; University of North Carolina At Chapel Hill, Chapel Hill, NC.

To establish functional neuronal circuitry, neurons progress through several developmental stages and shape changes, including neurite initiation, neuron polarization, axon branching and guidance, and synaptogenesis. The dramatic neuronal shape change during these morphological events depends on the cytoskeleton remodeling machinery. Previously, our lab discovered that the neuronally expressed E3 ubiquitin ligase TRIM67 is essential for appropriate neuronal morphogenesis. We found that TRIM67 localizes to the growth cone periphery and actin-rich filopodia structures, where it regulates filopodia number and stability. Interestingly, TRIM67 lacking neurons exhibit aberrant growth cone morphology, and have defects in netrin-dependent axon turning and branching. As E3 ubiquitin ligases typically have multiple substrates, and to further understand how TRIM67 regulates cytoskeleton dynamics during development, we conducted an unbiased proximity-dependent biotin identification (BioID) assay to identify putative TRIM67 substrates. **Coronin 1A**, which is a conserved actin binding protein crucial for the regulation of actin dynamics, was identified as a potential TRIM67 interactor/substrate from our proteomic study. Although Coronin 1A is neuronally expressed, and the gene lies in a chromosome locus where copy number variants are associated with various neurodevelopmental disorders, its role in neuronal development remains elusive. Through live-cell imaging and immunofluorescence staining, we discovered that Coronin 1A is enriched in the growth cones of developing neurons and localizes to the filopodia structures, particularly at the base region. In addition, using neurons from *Coro1A*$^{+/+}$ and *Coro1A*$^{-/-}$ littermates we discovered that Coronin 1A is crucial for netrin-dependent growth cone morphology and axon branching, which phenocopies neurons lacking TRIM67. Here we utilized microscopy and biochemical assays to show Coronin 1A and TRIM67 are binding partners, and have mapped out the domains that are required for TRIM67:Coronin 1A interaction. In addition, we discovered that Coronin 1A is ubiquitinated by immunoprecipitating Coronin 1A under denaturing conditions. Ongoing work is examining the impact of Coronin 1A knockout in axon turning *in vitro* and axon guidance *in vivo*, as well as testing whether Coronin 1A is ubiquitinated in a TRIM67-dependent or sensitive manner. These findings suggest a *novel role for Coronin 1A in regulating neuronal morphogenesis, and possibly functioning downstream of TRIM67-mediated pathway.*

B398/P2784

CKAP5 enables seeding of actin bundles by exploratory microtubules

J. Sabó, **M. Ždímalová**, Z. Lánský, M. Braun; Institute of Biotechnology of the Czech Academy of Sciences, Prague, CZECH REPUBLIC.

Neuronal growth cones are cellular structures responsible for neuronal guidance in a response to the cues presented to the cell from its surroundings. The function of the growth cones is heavily dependent on the cytoskeleton. Actin filaments in the form of networks and bundles are present at the periphery of the growth cone. Microtubule bundles are located in the central domain from which individual exploratory microtubules grow out towards the cell periphery. Recently, CKAP5 (in human, or its *Xenopus* and *Drosophila* equivalent, XMAP215 and MSMP, respectively) has been reported to play a role in mediating a cross-talk between microtubules and actin filaments in growth cones. However, the molecular mechanism of this process is unknown. Here, we found in an *in vitro* reconstituted system that CKAP5 enables seeding of prevailing actin bundles by dynamic microtubules. We observed that CKAP5 binds to microtubules with higher affinity than to single actin filaments. CKAP5 bound to the microtubule lattice can recruit actin filaments, which form bundles around the microtubules at concentrations insufficient for microtubule-independent actin bundle formation. When the microtubules depolymerize, the actin bundles prevail at the positions and orientations predetermined by the microtubules. This readily suggests a mechanism explaining how exploratory microtubules in filo- and lamellipodia set the positions of actin bundles, for example in neuronal growth cones.

B399/P2785

Biophysical regulation of axon morphology and plasticity

J. Griswold[1], C. Zhu[2], P. Rangamani[2], S. Watanabe[1]; [1]Johns Hopkins University Sch Med, BALTIMORE, MD, [2]University of California, San Diego, San Diego, CA.

Neurons are known for their intricate cellular morphology. Axons in particular are exceptionally long (100-1000 mm) and ultrathin (100 nm). Their cable-like morphology is essential for conduction of electrical signals, or action potentials, throughout the brain and body. Thus, it has been long assumed that axons are tubular structures with occasional synaptic varicosities. However, our work has challenged this assumption. Using high-pressure freezing and plunge freezing to preserves tissue morphology in a more native state, we performed ultrastructural analysis of axons in Caenorhabditis elegans motor neurons, mouse hippocampal neurons, and human cortical neurons. We discovered that axons are not simple tubes but rather exhibit a pearls-on-a-string morphology through their entire length, with the pearls being ~250 nm and the strings ~70 nm in diameter. This morphology is reminiscent of membrane tubes undergoing tension-driven instability. Consistent with this notion, the pearled area becomes smaller when hyperosmotic solution is applied and larger when hypoosmotic solution is applied. Interestingly, pharmacological perturbation of the cytoskeleton did not greatly alter axon morphology, suggesting that membrane mechanics drives axon morphology. In further support of this, increasing the membrane fluidity by cholesterol depletion from the plasma membrane led to a shrinking of the pearled membrane regions. Functionally, when axon morphology is altered with pharmacological cholesterol depletion, action potential velocity increases. Similarly, neuronal stimulation that induces plasticity increases action potential velocity by altering the pearled axon morphology. Our *in silico* modeling further supports the experimental data that membrane mechanics

can cause pearled axon morphology and that pearled morphology greatly impacts action potential conductance. These data have revealed for the first time that axons are pearled not tubular, and that pearled axon morphology has an important functional role in neuronal activity and plasticity.

B400/P2786

Investigating the role of netrin receptors in Trim9 and Trim67 dependent morphogenesis

S. Mutalik, S. L. Gupton; Department of Cell Biology and Physiology, University of North Carolina, Chapel Hill, NC.

Accurate axon guidance is crucial to form functional connections in the developing brain. The motile tip of axons, called growth cones sense various guidance cues in their surroundings through the surface receptors. Netrin-1 is a classic guidance cue essential for axonal guidance and neuronal development. Netrin-1 induces a diversity of responses through the regulation of multiple different receptors. In the current study, we investigate the role of netrin receptors DCC and UNC5C, which regulate attraction and repulsion, respectively. Over the years, our lab has established functions of neuronally enriched E3 ubiquitin ligases of the Tripartite motif (TRIM) family, TRIM9 and TRIM67 in neuronal morphogenesis and development. Consistent with previous work, we show that netrin-1 induces a concentration-dependent biphasic response in murine cortical neurons, attraction at lower concentrations and repulsion at higher concentrations. Previous work from the lab has established functions of TRIM9 and TRIM67 in attractive response. In the current study, we show that repulsive response is abolished in *Trim9*$^{-/-}$ and *TRIM67*$^{-/-}$cortical growth cones. Using TIRF-based live imaging, we show that TRIM9 ΔRING and TRIM67 ΔRING that lack the ligase activity colocalize with UNC5C in cortical growth cones, highlighting TRIM-dependent regulation of UNC5C in cortical growth cones. Using immunocytochemistry, we investigated netrin-dependent dynamic changes in receptor levels in cortical growth cones. We show that the surface level of DCC is increased and the total available pool of UNC5C is decreased in *Trim9*$^{-/-}$ growth cones. consistent with this, our preliminary results from the surface biotinylation assay show that the surface UNC5C levels are reduced while DCC levels are increased in Trim9$^{-/-}$ cortical neurons. The Previously published work has established TRIM9 and TRIM67 interaction with DCC. Further, TRIM9-dependent ubiquitination of DCC in the cytoplasmic domain including the UNC5C interacting domain has been predicted. Hence, we hypothesized that TRIM9 regulates DCC-UNC5C interaction. Using coimmunoprecipitation assay we showed that DCC-UNC5C interaction is not regulated by TRIM9. Collectively, the current work shows that altered baseline levels of DCC and UNC5C are likely to contribute to netrin unresponsiveness Trim9$^{-/-}$ and *Trim67*$^{-/-}$ cortical neurons.

B401/P2787

Shootin1-DCC Interaction Mediates Netrin-1-induced Axonal Haptotaxis

Z. Qiu, K. Abe, D. Aoki, T. Minegishi, N. Inagaki; Nara Institute of Science and Technology, Ikoma city, JAPAN.

During the development of the brain, neuronal axons are navigated to right destinations and connected with appropriate targets, the process called axon guidance. There are two types of axon guidance mediated by chemical cues, chemotaxis and haptotaxis. Chemotaxis is the movement directed by spatial gradients of soluble chemicals; haptotaxis is regulated by chemicals presented on adhesive substrates. Netrin-1 is one of the best-characterized axon guidance molecules; it is thought to attract commissural axons by chemotaxis. Recent studies reported that netrin-1 also functions as a haptotactic attractive

axon guidance molecule in hindbrain and spinal cord, but the mechanism underlying it is unknown yet. We previously reported that shootin1a is involved in neuronal polarization, axon outgrowth and guidance. In addition, shootin1a functions as 'clutch' molecule in laminin-induced axonal haptotaxis. However, involvement of shootin1a in netrin-1-induced axonal haptotaxis is not clear. Here, we analysed the molecular mechanism for netrin-1-induced axonal haptotaxis. First, we found that shootin1a was colocalized with the netrin-1 receptor DCC in axonal growth cones by immunostaining. Further co-immunoprecipitation analysis demonstrated the interaction between shootin1a and the intercellular domain of DCC. Next, we confirmed that neurons cultured on netrin-1-coated coverslips extended significantly longer axons than on polylysine, suggesting that axon outgrowth is promoted by substrate-bound netrin-1. Moreover, we compared shootin1 KO and WT neurons cultured on netrin-1-coated coverslips and microscale patterns. Shootin1 KO neurons extended shorter axons and did not undergo haptotaxis on microscale patterns. Those results demonstrate that shootin1a interacts with DCC-intercellular domain and mediates netrin-1-induced axonal haptotaxis. To further analyse the mechanism, we preformed speckle imaging using HaloTag-F-actin to determine the change of F-actin retrograde flow; the F-actin flow speed on netrin-1 was significantly slower than that on polylysine, indicating that the clutch linkage is promoted on netrin-1. In addition, traction force produced by growth cones was higher on netrin-1 than on polylysine, and shootin1 KO reduced the traction force on netrin-1. These data indicate that shootin1a-mediated clutch coupling is promoted by netrin-1 on the substrate. Furthermore, we preformed speckle imaging using DCC-HaloTag. Retrograde speed of DCC was slower on netrin-1 compared to that on polylysine; DCC-HaloTag underwent more stopped state and less flowing state on netrin-1 substrate, indicating netrin-1 promotes DCC-substrate clutch linkage. All our data suggest that shootin1-DCC interaction drives netrin-1 induced axonal haptotaxis.

How evolution diversifies specific protein recognition

G. Wiseglass, R. Rubinstein; School of Neurobiology, Biochemistry and Biophysics, George S. Wise Faculty of Life Sciences, Tel Aviv University, Tel Aviv, ISRAEL.

There has been great interest in studying the co-evolution of specific receptor-ligand interactions, as these interactions mediate the identification and incorporation of extracellular signaling, cell-cell recognition and adhesion. In some cases, and due to disruptive mutations, some co-evolving proteins undergo a non-interacting intermediate evolutionary stage, while others become promiscuous and form novel interactions with new partners. The Down syndrome cell adhesion molecule (Dscam1) provides an extreme example of receptors evolving strict homophilic interactions. In insects, exon duplications have led to the expansion of Dscam1 to tens of thousands of isoforms. Stochastic alternative splicing of Dscam1 results in a unique expression pattern in each neuron. These properties allow neurons to distinguish between interactions with neurites from the same cell and neurites from other cells, which is crucial for the correct formation of complex nerve architectures. The current study focuses on the evolutionary paths leading to the strict homophilic specificity exhibited by Dscam1. We use phylogenetics to analyze sequences of Dscam1 isoforms across species and identify the origins of exon duplication. Then, using ancestral reconstruction, we predict candidate intermediate sequences. We experimentally tested the binding specificities of these intermediates. Specifically, we tested whether their interactions are strictly homophilic, promiscuous, or whether they harbor disruptive mutations that prevent them from binding. Our results provide a detailed evolutionary pathway by which the Dscam family of proteins gains new recognition specificities. Our results indicate an evolutionary

pathway via “intermediate” proteins that form promiscuous interactions rather than non-interacting “intermediates”. Altogether, this work provides insights into protein families evolution and co-evolution of protein interfaces.

Neurexin and frizzled intercept axonal transport at microtubule minus ends via VAB-8 to control synapse formation

J. Park[1], S. Balseiro-Gomez[1], Y. Yue[2], C. Ding[1], L. Shao[1], S. Çetinkaya[1], C. Kuzoian[1], M. Hammarlund[3], K. Verhey[2], S. Yogev[1]; [1]Neuroscience, Yale, New Haven, CT, [2]Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, [3]Neuroscience/Genetics, Yale, New Haven, CT.

Neurons depend on the general polarity of microtubule population for the compartmentalization of dendrites and axons. Recent evidence has suggested that each end, plus (+) or minus (-) end, of a microtubule polymer plays an important role in determining how individual transport event terminates and thereby sculpting the precise synaptic connectivity of each neuron. Here, we report that VAB-8/KIF26, an immotile kinesin, as the downstream effector of anti- and pro-synaptogenic activities of frizzled and neurexin in *C. elegans*. We find that endogenous VAB-8 localizes to microtubule minus ends *in vivo* and its levels at synaptic microtubules are controlled by frizzled and neurexin. Loss of VAB-8 mimics frizzled hyperactivation or loss of neurexin, where posterior half of synapses in the tail of the worm are lost. VAB-8 is required for the synaptic localization of other minus-end binding proteins such as PTRN-1 and NOCA-1 although its effect on general microtubule dynamics and steady-state synaptic microtubule organization is minimal. Consistently with the possible role of VAB-8 at minus ends, we find that *vab-8* mutants show significantly shorter retrograde pause duration during synaptic vesicle precursor transport, which may affect synaptic cargo delivery at minus ends. Reducing retrograde transport, but not anterograde, rescues synapse loss in *vab-8* and neurexin mutants. Collectively, VAB-8 functions downstream of two separate signaling pathways to regulate retrograde transport and determine precise synaptic length of different neurons.

The kinesin-1 adaptor UNC-14 is required for synapse formation and microtubule polarity

M. Lyu; Yale University - New Haven, CT, New Haven, CT.

Synapse formation depends on long-range axonal transport on microtubule tracks. We identified the kinesin-1 binding protein UNC-14/RUSC2 as a regulator of microtubule organization and synapse formation in *C. elegans*. In *unc-14* mutants, we observe the loss of synaptic vesicle clustering and an ectopic accumulation of synaptic material in the dendrite. We speculate that these defects are due to misdirected transport of synaptic proteins, because *unc-14* mutants also show defects in microtubule polarity, with dendritic microtubules assuming an axonal-like organization and axonal microtubules showing dendritic features. We also hypothesize that microtubule defects underlie the previously observed axon guidance and animal locomotion defects in the mutant animals. We are currently working to elucidate how this pair of proteins control microtubules and synapses.

B405/P2791

Coordination of ion channel delivery and dendrite growth in Drosophila sensory neurons

J. Mitchell[1], I. Midillioglu[2], B. Wang[3], C. Han[3], **J. Wildonger**[2]; [1]University of Wisconsin-Madison, Madison, WI, [2]University of California, San Diego, La Jolla, CA, [3]Cornell University, Ithaca, NY.

Sensory neurons enable an organism to perceive external stimuli, which is essential for survival. The sensory capacity of a neuron depends on the elaboration of its dendritic arbor and the delivery of ion channels to the dendritic membrane. However, it is not well understood how ion channels are trafficked to morphologically complex sensory dendrites and whether their delivery is coordinated with dendrite growth. We investigated the trafficking of the DEG/ENaC/ASIC ion channel Pickpocket (Ppk) in peripheral sensory neurons in fruit fly larvae. We used CRISPR-Cas9 genome engineering to tag endogenous Ppk1 and visualize it live, including monitoring Ppk1 membrane localization via a novel secreted split-GFP approach. Strikingly, Ppk1 is present throughout the membrane of actively growing dendrites, and Ppk1 density scales in proportion to the dendritic membrane, even when dynein-mediated transport to dendrites is disrupted. Our data suggest that Ppk1 is integral to the membrane of growing dendrites and implicate the recycling endosome GTPase Rab11 in the forward trafficking of Ppk1 to dendrites. Together, our results suggest that Ppk channel transport is coordinated with dendrite morphogenesis, thus ensuring proper ion channel levels and distribution in sensory dendrites.

B406/P2792

Investigating the underlying mechanisms mediating dendrite pruning in *Caenorhabditis elegans*

P. Figueroa-Delgado[1], S. Yogev[2]; [1]Department of Cell Biology, Yale University, New Haven, CT, [2]Department of Neuroscience, Yale University, New Haven, CT.

Neurite remodeling is a highly conserved process that refines and establishes a mature nervous system. A failure in neurite remodeling leads to neurological and neurodevelopmental disorders. While developmental dendritic pruning, a means of neurite remodeling, has been extensively studied, the cell-biological mechanisms that control pruning remain poorly understood. Specifically, there is a *fundamental gap* in understanding the cell-biological mechanisms that mediate dendrite branch-specific pruning. The nematode *Caenorhabditis elegans* inner labial 2 (IL2) neurons, upon entering a developmental diapause, extend a stereotypical dendritic arbor that is pruned when development is resumed - leaving primary dendrites intact. The stereotypic remodeling of IL2 neurons allows experimental access to elucidate the cell-biological mechanisms that confer selective pruning. To identify IL2 dendrite pruning regulators, I conducted an unbiased forward genetic screen to isolate genes by selecting mutants that exhibited a pruning defect, such as loss of pruning or loss of pruning specificity. Among the nine (9) isolated mutants, mutant *shy87* showed a severe loss of pruning defect characterized by the remanence of the dendritic arbor into adulthood. Rescue experiments robustly show *sax-1*, a gene that encodes a highly conserved serine/threonine kinase, is the causal gene for the defective pruning observed in *shy87* mutants. In addition, to address if SAX-1 acts with known conserved scaffolding protein SAX-2 to mediate IL2 higher-order dendrite pruning, I tested a loss-of-function allele for *sax-2*, which phenocopies *shy87* mutants post-dauer exit. These findings suggest that SAX-1 and SAX-2 are important regulators of neuronal remodeling in IL2 neurons.

B407/P2793

Regulation of Human Neurofilament-light Assembly State by O-GlcNAc and Potential Hypoglycosylation of Charcot-Marie-Tooth Disease Mutants

D. T. Huynh[1], J. Hu[1], K. Tsolova[1], M. Zorawski[1], C. Lin[2], E. Soderblom[3], N. Linhart[1], D. Li[1], J. Chi[2], M. Boyce[1]; [1]Biochemistry, Duke University, Durham, NC, [2]Molecular Genetic and Microbiology, Duke University, Durham, NC, [3]Proteomics and Metabolomics Core Facility, Center for Genomic and Computational Biology, Duke University, Durham, NC.

Neurofilaments (NF) are cytoskeletal proteins composed of light, medium and heavy subunits that structurally support neurons. These proteins assemble in discrete states, from low-order oligomers to fully assembled filaments, and require the light subunit (NF-L) to form filamentous networks. NF-L dysregulation, such as mutants in a subtype of Charcot-Marie-Tooth (CMT), a neuromuscular disease, causes aggregations that also occur in various neurodegenerative disorders. In rodent brains, NFs are modified post-translationally by O-GlcNAc, an intracellular form of glycosylation on serine/threonine residues. However, how O-GlcNAc regulates human NF-L is unclear. In order to determine the impact of O-GlcNAc on NF-L functions, we first used immunoprecipitation to show dynamic O-GlcNAcylation of human NF-L. Then, we combined CRISPR-tagged endogenous human NF-L with mass spectrometry to find novel glycosites (S48, S431). To examine the effect of O-GlcNAc on NF-L assembly, we expressed wild type (WT) NF-L in NF-L$^{-/-}$ cells and biochemically fractionated discrete NF-L assembly states. Most of the total NF-L was in fully assembled filaments. However, elevating O-GlcNAc levels by expression of O-GlcNAc-transferase (OGT), which adds O-GlcNAc to substrates, significantly reduced this proportion, indicating a shift towards lower-order oligomers. Expression of WT NF-L in NF-L$^{-/-}$ neuroblastoma cells and immunofluorescence imaging revealed that OGT expression reduced NF-L full-length filaments and increased the prevalence of puncta, representing lower-order states. An unglycosylatable (S/T-to-A) NF-L mutant partially suppressed these phenotypes, demonstrating that site-specific glycosylation of NF-L itself is required for these effects. Interestingly, among CMT NF-L mutants, those near glycosites abolished NF-L O-GlcNAcylation. In immunofluorescence and fractionation assays, these mutants formed aggregates that were unaffected by increased O-GlcNAc levels. Therefore, our data indicate that increasing O-GlcNAcylation drives WT NF-L to lower-order assembly states, and NF-L may be hypoglycosylated in disease. We hypothesize that NF dysregulation found in other neurodegenerative diseases may involve perturbed NF-L O-GlcNAcylation, which we will test in future studies. This work advances our knowledge of the neuronal cytoskeleton and may inspire future efforts to rationally manipulate O-GlcNAc on NFs and other neuronal proteins for therapeutic benefit.

B408/P2794

Neuron Isolation on the Cyto R1 Platform: A Customized Workflow for Subpopulation Enrichment

K. E. Degen[1], J. D. Joyce[2], T. Harrell[2], A. S. Bertke[2], A. R. Hyler[1]; [1]CytoRecovery, Inc., Blacksburg, VA, [2]Department of Population Health Sciences, VA-MD College of Veterinary Medicine, Blacksburg, VA.

The isolation of primary neurons from peripheral ganglia of adult animals results in a dense mixture of axon debris, satellite glial cells (SGCs), and neurons. Conventional clean up techniques utilize density gradients, which achieve roughly 50-75% removal of SGCs and debris. Here, a novel workflow was developed using the Cyto R1 Platform to deplete debris and satellite glial cells to achieve more purified downstream neuron cultures. The Cyto R1 employs label-free, biophysical enrichment (dielectrophoresis) to separate live cells from debris by trapping cells with intact membranes. Using a

disposable microfluidic cartridge, Cyto Chip, neurons can be enriched in a sterile system in which trapping occurs at stationary pillars in the Chip. In order to generate the appropriate electrical fields for enrichment, we transferred samples into an ultra-low conductivity buffer, Cyto Buffer. For this workflow development, a customized buffer formulation was needed to support neuron viability. Murine trigeminal ganglia (TG) neurons were exposed to 6 novel buffers in suspension for 30 min at room temperature, plated on Matrigel and maintained in Neurobasal A medium with neurotrophic factors. Neuron viability was assessed immediately prior to plating, then 24 hours, 5 days and 14 days after plating. One buffer out-performed the others, maintaining neuronal viability on par with the control neurons in supplemented Neurobasal A media under the same conditions. Neurons exposed to this buffer were able to reestablish normal biophysical architecture once plated and remained viable for at least 14 days in post-exposure culture. With the adjusted formulation of buffer, additional TG suspensions were then enriched on the Cyto R1 Platform at 400 kHz and 640 Vpp in 5-minute batches. After enrichment, 85% recovery of purified neurons was achieved. Additionally, we observed variable trapping efficiencies as different flow rates, voltages, and frequencies suggesting that even finer sorts of cell subpopulations will be possible. The Cyto R1 provides a versatile platform for isolation of purified primary neurons from adult animal peripheral nervous system tissues for downstream culture or assays.

B409/P2795

Dual Roles of RBM8A in Neural Progenitors and Astrocytes

J. Mott, C. McSweeney, S. Asthana, Z. Pei, Y. Mao; Penn State University, State College, PA.

RBM8A, a core component of the exon junction complex, is located in the distal region of 1q21 (a prominent copy number variation associated with neurodevelopmental disorders). Studies have shown that *Rbm8a* modulates the balance between proliferation and differentiation of neural progenitors (NPs). Intricate balance between proliferation, differentiation, and migration of NPs is critical in cerebral cortical development. Here, we investigated the role of *Rbm8a* in interneuron development using a conditional knockout (cKO) mouse model. Additionally, RBM8A has been hypothesized to play regulatory roles in the radial glia. Dysfunction in the radial glia development may impair the development of the astrocytes, thus affecting synapse formation, leading to neurological disease. What role do astrocytes play in neurodevelopmental disorders? We explored the role of astrocytes in *Rbm8a*-deficient mouse phenotype.

We generated *Rbm8a* cKO mice by crossing homozygous floxed mice with *nestin-cre* mice to achieve heterozygous *Rbm8a* cKO selectively in NPs. Additionally, *Rbm8a*$^{fl/fl}$ mice were crossed with *Nkx2.1-cre* mice to selectively delete *Rbm8a* in interneuron progenitors. Then, *Nkx2.1-cre; Rbm8a*$^{fl/+}$ mice were crossed with *cre*-dependent *Ai9* reporter line to specifically trace progenies of *NKX2.1+* progenitors when *Rbm8a* expression is reduced in vivo. Furthermore, we generated astrocyte-specific *Rbm8a* cKO mice by crossing *Rbm8a* KO mice with B6.Cg-Tg(*Gfap-cre*)73.12Mvs/J mice, which features transgenic glial fibrillary acidic promoter driven expression of *Cre* Recombinase to selectively delete *Rbm8a* in the mouse astrocyte cell. We performed various behavioral tests to investigate motor and anxiety behavior in *GFAPCre; Rbm8a*$^{f/+}$ mice.

Our data reveal that *Rbm8a* haploinsufficiency in neural stem cells results in smaller body and brain size, as well as abnormal migration and cell size of cortical interneurons. This haploinsufficiency in *NKX2.1*-positive interneuron progenitor decreases cell proliferation and affects interneuron differentiation. Moreover, *GFAPCre; Rbm8a*$^{f/+}$ mice show significantly increased locomotor and mobility function and

altered anxiety state. Taken together, our study shows that *Rbm8a* plays a critical role in interneuron development and suggests that *Rbm8a* in astrocytes affects motor function and anxiety state.

Exposure of SHSY5Y cells with Tideglusib, Gallein, and Okadaic acid reveal that microtubule disruption but not Tau phosphorylation at ser 396 (ps396Tau) is key event in neurodegeneration.

D. Olivas, S. Roychowdhury; The University Of Texas At El Paso, El Paso, TX

BACKGROUND: As our elderly global population increases, so does the diagnosis of neurodegenerative diseases (ND), such as Alzheimer's disease (AD). The pathology of AD is characterized by extensive loss of neurons. Hyperphosphorylation of Tau (a microtubule-associated protein) leading to Tau aggregation and neurofibrillary tangles (NFT) formation has emerged as a major feature in the pathogenesis of AD and other taupathies. Due to this hypothesis, many inhibitors that decrease tau phosphorylation, such as Tideglusib (an inhibitor of GSK3β) have been targeted in clinical trial to treat AD and have failed suggesting that Tau phosphorylation may not be a key event in the pathogenesis of AD. Previously, we have shown that Gallein, an inhibitor of Gβγ decreased the expression of phosphorylated tau at the serine 396 sites (ps396 tau). However, it disrupted microtubules (MTs) and inhibited neuronal differentiation of human neuronal cells SHSY5Y suggesting that hypo-phosphorylation of Tau could also be linked to neurodegeneration similar to that observed with hyperphosphorylation of Tau. (doi: 10.1091/mbc.E21-11-0545). **GOAL:** In the current study, we used Tideglusib, Gallein, as well as Okadaic acid (a phosphatase inhibitor) to further understand the role of Tau phosphorylation in the pathogenesis of AD. **METHODS: To conduct the study, Retinoic acid (RA)-differentiated** SHSY5Y cells were treated with Tideglusib for 1 hr. To **induce a hyperphosphorylated Tau state,** cells were treated with OKA overnight. For comparison cells were also treated with Gallein. The samples were then subjected to confocal microscopy and whole cell lysis (WCL). **RESULTS: Confocal microscopic analysis showed that Tideglusib caused disruption of MTs and inhibited neuronal differentiation However, Tideglusib was more effective in disrupting structure of neurons compared to Gallein. In addition, neuronal cell numbers were decreased significantly in the presence of Tideglusib. As expected, immunoblot revealed a decrease in the expression of ps396 tau in the presence of Tideglusib. We found that OKA did not disrupt neuronal morphology. However, OKA treated cells had more short neurite projections than control. CONCLUSION: Although OKA induces the hyperphosphorylation of tau, OKA treatment did not disrupt the neuronal cytoskeleton. In the contrary, both Tideglusib and Gallein disrupted the neuronal structure but decreased the expression of ps396. Our result suggests that that the hyperphosphorylation of tau may not be the key event in the pathogenesis of AD, and therefore, the potential drugs against AD should be evaluated in neuronal cells for structural and morphological alterations which is reflective of neurodegeneration.**

B411/P2797

NeuroPAL: A "PAL" for Identifying hot Gene Neuron Identities within the Ly6 Family

S. Seth, K. Mali, R. Sung, **A. Petropoulos**; Carleton College, Northfield, MN.

The Ly6 protein family is highly conserved among multiple species including humans, mice, Drosophila, zebrafish, and C. elegans. Surprisingly, these endogenously expressed proteins also share significant structural similarities to alpha-neurotoxins (such as bungarotoxin) found in snake venom. Ly6 proteins have been observed to be involved in processes such as odor sensing, cell adhesion, and regulation of

receptor trafficking; however, despite this knowledge, little is known about the function of these proteins. In order to investigate the function of these proteins as a family, we are using C. elegans as a model organism, which has a manageable 10-member Ly6 family in comparison to larger Ly6 families in mammalian systems. Given that previous work has identified roles for Ly6 protein function in a variety of cellular processes related to neuronal activity, we hypothesize that Ly6 protein expression in C. elegans would occur in neuronal cell types. In order to deduce the expression of the Ly6 proteins, we are utilizing a tool called NeuroPAL in conjunction with transcriptional GFP reporters for each Ly6 gene of interest (known as the hot genes in C. elegans). NeuroPAL is a transgene that creates a color-coded atlas of the hermaphrodite C. elegans nervous system, and we have created a transgenic C. elegans model that contains both the NeuroPAL transgene and the GFP transcriptional reporter for hot-1 gene. Using confocal microscopy, we have begun examining hot-1 gene expression in hermaphrodites. We have tentatively identified hot-1 gene expression in the DD, RMDV, and AVE neurons.We plan to confirm our identification using additional reporter-lines for those specific cells. Lastly, we are in the process of generating additional transgenic lines containing NeuroPAL and other GFP transcriptional reporters for the other hot genes. Employing confocal microscopy, we are able to use this model to visualize the exact location of each GFP-tagged neuron for each hot gene. Moving forward, we hope to use this anatomical information to develop behavioral assays to assay the function of each hot gene in those specific tissues/cells.

B412/P2798

Co-exposure of Alcohol and Nicotine in Human Neuronal Cells SHSY5Y on Tau Phosphorylation and Microtubule alteration suggest a possible explanation of comorbidity of drug use

T. Poeschel, D. Olivas, S. Roychowdhury; University of Texas At El Paso, El Paso, TX

BACKGROUND: The use of alcohol and nicotine is common and show the most serious comorbidity. It is a major public health concern. Research has established that alcohol and nicotine addiction alter the ability for neurons to send and receive signals. Normal neuronal activities also heavily depend on microtubules (MTs), a major component of neuronal cytoskeleton. Recently, alcohol/nicotine was shown to alter microtubules (MTs). Tau is a MT-associated protein and is known to stabilize MTs, and critical for neuronal development. Tau proteins were found to be abnormally phosphorylated in neurodegenerative diseases. RESEARCH GOAL: The goal of this project is to understand the effect of alcohol/nicotine on the phosphorylation of several Tau sites that are pathologically relevant including Ser 396, Thr181, Ser404, and how MT organization and neuronal morphology is affected by alcohol/nicotine treatment. METHODS: To conduct the study, human neuronal cells SHSY5Y were exposed to nicotine [5uM] and ethanol [100mM] separately, and together for 24 hours. The samples were then subjected to immunoblotting and confocal microscopy using antibodies for tau, phosphorylated tau, and tubulin. RESULTS: The immunoblot analysis showed that ethanol caused an increase in phosphorylation of ps396Tau (~50%). While nicotine itself did not have any significance on tau phosphorylation, when co-treated with ethanol it reduced the ethanol effect by ~23% which could explain the cause behind the severe comorbidity. There was no significant difference in expression of pTau, Thr181 and Ser404 suggesting that the effect is site-specific. The results from confocal microscopy showed that when exposed to nicotine, no difference in neurite length was observed except that tubulin labeling appeared to be segmented along some neurites, indicating MT structure is disrupted by nicotine treatment. In the presence of ethanol, most neurites are significantly longer compared to control. In the presence of both nicotine and ethanol, the neurites were similar in length and morphology as seen in

the control. DISCUSSION: Overall, our result suggests that the exposure of alcohol and nicotine in neuronal cells alter Tau phosphorylation and microtubule organization. However, when co-exposed with nicotine and ethanol together, the individual effects were reduced which may explain the comorbidity among users.

B413/P2799
The Impact of DHA Supplementation on Neurogenesis in the Developing Embryo
G. Okros, M. DeLano-Taylor; Grand Valley State University, Allendale, MI

Differentiation and the rate of division of neural stem cells (NSCs) are regulated by various factors, including our diet. The impact of prenatal supplements, such as the omega-3 fatty acid docosahexaenoic acid (DHA) -a long chain polyunsaturated fatty acid (LCPUFA)- have shown to be important for the development of neuronal cell membranes. The impact of DHA and other LCPUFAs on neuronal stem cell differentiation in-vivo has not yet been tested. In this study DHA and other LCPUFAs were introduced into the developing neural tube of chick embryos to determine their effects on NSC development. By examining the number of neurons in LCPUFA treated embryonic NSCs compared to the vehicle control during different time periods of development, we found that DHA treated embryos had an increased number of neurons that persisted through development up to 72 hr after DHA injection. The persistent increase in neurons over the course of development suggests DHA is promoting neurogenesis without depletion of the stem cell pool, likely by promoting proliferation of stem cells or neuronal progenitors. The impact of this prenatal supplement on the developing nervous system in vivo provides some insight of how it could shape neurogenesis in the course of development.

Synaptogenesis

B414/P2800
Structural Analysis of Glutamategic Synapse Auxiliary Protein Neto Isoform
S. Chen; NIH, Bethesda, MD.

The synapse is a fundamental communication unit of the nervous system that connects neurons and other non-neuronal target cells to govern complex cognitive processes and behavior. A functional synapse requires the assembly of the pre-and postsynaptic structures and continuous trans-synaptic communication between them. *Drosophila melanogaster* neuromuscular junction (NMJ) is a powerful genetic model system to study glutamatergic synapse development. Previous studies established that Neto, an auxiliary protein for glutamate receptors, is essential for the recruitment of postsynaptic receptors and proper NMJ functionality. *Drosophila* neto encodes two isoforms, Neto-α and Neto-β, with the same extracellular domains but distinct cytoplasmic domains. Mutations in Neto-β result in failure to accumulate and stabilize a particular subtype of glutamate receptors (Type A) at the synapses. To determine which specific domains of Neto-β are essential for its function, we have embarked on a series of structural function analyses in which we removed specific domains and conducted loss of function studies. The current project utilizes the ALFA system, a novel epitope/nanobody pair, for the in vivo detection of tagged Neto-β. CRISPR-Cas9 was used to insert ALFA-tag in all Neto-β variants to standardize the detection of various truncated Neto-β proteins. Immunohistochemistry showed modified Neto-β and tagged β-AT with the same synaptic distribution when stained with a previously described Neto-β antibody. This work will inform us of the molecular mechanisms underlying the

recruitment and organization of the pre-and postsynaptic components crucial in gaining insights into neural circuit formation and plasticity necessary for normal brain development and function.

B415/P2801

Engineered *in vitro* models based on selective neuronal adhesion to study synapse formation

N. Piette, P. Strale, M. Munier, M. Sainlos, I. Chamma, O. Thoumine, V. Studer; IINS -CNRS Bordeaux, Bordeaux, FRANCE.

Information transfer in the brain is ensured by a complex network of specialized interconnected neurons responding to environmental cues. The proper functioning of this network relies on the establishment and maintenance of synaptic connections, nanoscale organization of their molecular components, and plasticity of their architecture. It is well known that these mechanisms are regulated by specific trans-synaptic adhesion proteins linked to membrane receptors or scaffolding proteins.
We present here two cell based *in vitro* models that we have specifically engineered to study the biophysical properties of trans-synaptic adhesion proteins and their role in the nanoscale organization of synapses during development. These models rely on micropatterns of synaptic proteins printed on glass coverslips. They were fabricated with a commercially available contactless and maskless UV projection system which allows us to reproducibly control the shape and the protein density of the microcontact areas.
In the first model, recombinant Fc-tagged neuronal protein (e.g. Neurexin1β) are anchored to 5µm wide patterned lines and presented to COS-7 cells expressing fluorescent tagged paired protein (e.g. Neuroligin1) providing highly selective recognition. By using fluorescence recovery after photobleaching and single particle tracking we are able to measure the diffusion coefficient and the interaction rate of trans-synaptic adhesion complexes, respectively. We also show how to use this model to measure the interaction between trans-membrane synaptic proteins and cytosolic partners (e.g. PSD95).
The second model consists in surfaces micropatterned with arrays of small dots (5µm diameter) coated with Fc-tagged neuronal ligands. When cultured on these substrates, primary neurons form thousands of standardized hemi-synapses after 14 days *in vitro*. We show that we can precisely locate patches of pre or post synaptic markers as well as the cytoskeleton within micropatterned areas. By averaging the super-resolved STORM (Stochastic Optical Reconstruction Microscopy) image of hundreds of these standardized hemi synapses for each developmental stage, we hope to get a new insight on the sequence of events leading from the creation of an initial contact to the formation of stable synapses. Together, these two *in vitro* models will allow us to screen and characterize the role of synaptic proteins in the context of synaptogenesis. We also hope to get a better understanding of the role of synaptic adhesion proteins in the nanoscale organization of the synapse during development.

B416/P2802

Multilayered control for subcellular distribution and functional properties of KaiR1D autoreceptor

W. Hsieh, T. Han, R. Vicidomini, P. Nguyen, Z. Li, M. Serpe; National Institutes of Health, HHS, Bethesda, MD.

At excitatory synapses, autoreceptors provide a feedback mechanism that modulate neurotransmitter release and ensure stable neuronal networks. Disruptions to this feedback have been linked to various neuronal disorders. Autoreceptors localize on presynaptic membranes and respond to neurotransmitter released by the cell on which they sit. However, detection of these low abundant proteins has been

challenging. At *Drosophila* NMJ, an autoreceptor containing the KaiR1D glutamate receptor has been implicated in the control of glutamate release; *KaiR1D* mutants have basal neurotransmission reduced to half of the normal levels. We and others previously showed that KaiR1D requires at least two auxiliary proteins, Neto-α and Sol1. Here, we focus on the roles of Neto-α in modulating KaiR1D properties and distribution. Neto-α limits KaiR1D *in vivo* activities: Basal neurotransmission is reduced by 50% in *neto-α^{null}*. Neuronal overexpression of KaiR1D cannot rescue this defect. Using fast perfusion on outside-out patches of HEK cells transfected with KaiR1D alone or with Neto-α, we found that Neto-α modulates the gating properties of KaiR1D channels, decreasing the desensitization and deactivation rates. Neto proteins have conserved extracellular domains, including two CUB domains and a LDL motif, and variable intracellular domains (CTD). We found that CUB1 is required for modulation of KaiR1D gating properties as well as *in vivo* autoreceptor activities. The CTD contributes to modulation of KaiR1D gating properties but is dispensable *in vivo*. This difference may be reconciled by the presence of Sol1 *in vivo* but not in reconstituted systems.To search for a role for Neto-α in the subcellular distribution of KaiR1D, we examined KaiR1D localization in primary rat hippocampal neurons. KaiR1D localizes to dendrites, with or without Neto-α, but cannot efficiently enter the axon by itself even when overexpressed. Neto-α or ΔCUB1, but not ΔCTD, promote KaiR1D axonal localization. Neto variants distributed at both neurites and formed puncta largely colocalizing with KaiR1D. Finally, Neto-α and KaiR1D colocalize in the proximity of the active zones suggesting that Neto-α may stabilize KaiR1D at the site of autoreceptor function. Our data indicate that multiple layers of modulation ensure proper autoreceptor activities and reveal potential new targets for pharmacological interventions.

The fly Neuropilin, Neto, mediates presynaptic homeostasis through Plexin-dependent and Plexin-independent mechanisms

R. Vicidomini[1], T. Han[1], W. Hsieh[1], E. Giniger[2], M. Serpe[1]; [1]NIH/NICHD, Bethesda, MD, [2]NIH/NINDS, Bethesda, MD.

Homeostatic mechanisms ensure stable neuronal circuits function by maintaining constant synaptic strength during development and learning. *Drosophila* neuromuscular junction is a powerful genetic system to study molecular mechanisms underlying homeostasis at glutamatergic synapses: Chronic depletion of postsynaptic receptors or acute inactivation with philanthotoxin trigger a robust compensatory increases of neurotransmitter release, bringing the evoked response to normal levels. This presynaptic homeostatic potentiation (PHP) requires active zone cytomatrix remodeling to increase release probability. Previous studies implicated the flavoprotein monooxygenase (Redox) enzyme Mical, an actin regulator, in PHP. Mical is activated by binding of muscle secreted Semaphorin2b (Sema2b) to PlexinB (PlexB) on the motor neurons. Our previous work demonstrated that the Neuropillin and Tolloid-like protein, Neto, functions as an effector of PHP. More specifically, genetic null mutants lacking the presynaptic Neto-α isoform show no chronic or acute PHP response; this phenotype is rescued by neuronal overexpression of full length Neto-α but not Neto-ΔCTD, a Neto variant lacking the intracellular domain. Here we examine how Neto-α controls the PHP response. Using genetics and electrophysiology approaches, we found that *neto-α* interacts genetically with the *Sema2b/PlexB* pathway components, including *Mical*. Our epistasis analyses indicate that Neto-α functions together with Sema2b to relieve PlexB autoinhibition and thus enabling signaling downstream PlexB. These results suggest that *Drosophila* Neto-α resembles the vertebrate Neuropilins which promote binding of secreted Semas to Plexin receptors and activate Sema/Plex signaling. *Drosophila* genome does not contain a *neuropilin*

gene; instead, Neto-α seems to be the functional fly orthologue. Surprisingly, excess Neto-α activates the PHP response in the absence of PlexB but not in the absence of Mical, suggesting that Neto-α could activate Mical independently of PlexB. Interestingly, a Neto-α variant lacking the putative SH3 binding motif can restore the PHP response in *neto-α^{null}* but not in *PlexB* mutants. The SH3 binding motifs have been implicated in the activation of Abelson kinase (Abl) which phosphorylates and hyperactivates Mical in other contexts. We found that Abl is also required for the PHP response and its kinase activity is critical for this function. Neuronal overexpression of *neto-α* can only partly rescue the PHP deficits of *abl* mutants, highlighting the key role of Abl in PHP. Our data support a model whereby Neto-α engages both the the Sema/Plex pathway as well as its amplifier, Abl, to deploy a rapid and robust compensatory response and buffer fluctuations in synaptic activity.

Endocytic machinery are primed at neuronal synapses through enrichment of PI4P and PS at endocytic zones

B. Goulden, Y. Imoto, T. Ogunmowo; Johns Hopkins, Baltimore, MD.

Synaptic vesicle proteins used in neurotransmitter release are retrieved within 50 milliseconds. This rapid membrane internalization, called ultrafast endocytosis is mediated by a splice variant of dynamin 1 (Dyn1xA) and a BAR domain containing protein Syndapin 1. Dyn1xA and Syndapin 1 are primed at endocytic zones in synapses to accelerate the kinetics needed for ultrafast endocytosis. However, it is currently unclear how they are targeted to the endocytic zone membrane. Here we show that plasma membrane lipids, phosphatidylinositol-4-phosphate (PI4P) and phosphatidylserine (PS), are enriched at endocytic zones and mediate recruitment of endocytic protein machinery Dyn1xA and Syndapin 1. Using genetically encoded lipid biosensors and super-resolution imaging with STED microscopy, we analyzed nano-scale organization of membrane lipids. We demonstrate that PI4P and PS are colocalized with Dyn1xA at endocytic zones, which is devoid of other membrane signaling lipids such as PIP2. To keep endocytic zones devoid of PIP2, synapses utilize the endocytic 5-phosphatase synatojanin-1 to maintain its enrichment of PI4P. The lipid localization of PI4P and PS at endocytic zones are used by the lipid interacting domains in endocytic machinery. We showed that the BAR domain of Syndapin 1 recognizes PS at the endocytic zone, whereas Dyn1xA does not require its Pleckstrin Homology (PH) domain, but instead is localized to endocytic regions through protein-protein interactions in a phase condensate by interreacting with Syndapin 1. Together, these data indicate an entirely novel method of lipid regulation for endocytosis of synaptic vesicle proteins, and allowing for the high temporal and spatial precision needed for endocytic protein machinery recruitment in synapses.

Formation of neuronal synapses through phase separation is activated by the SAD-1 kinase

N. McDonald[1], L. Tao[1], M. Dong[2], K. Shen[1]; [1]Stanford University, Stanford, CA, [2]National Institute of Biological Sciences, Beijing, CHINA.

The formation of synapses by neurons is essential to establish nervous systems. Molecularly, a conserved core “active zone” structure is assembled in all synapses. We recently found that two core active zone scaffold proteins, SYD-2/Liprin-α and ELKS, form liquid phase-separated condensates during synapse formation. These condensates are required for the assembly of active zone components, clustering of synaptic vesicles, and synaptic function - suggesting phase separation is a critical

mechanism of synapse formation.
Here we investigate how neurons initiate active zone phase separation in order to build synapses at the appropriate place and time. We find that the neuronal kinase SAD-1 phosphorylates C. elegans SYD-2/Liprin-α in order to activate its phase separation and presynaptic active zone formation. The SAD-1 kinase localizes to presynaptic sites and has been previously implicated in the functional maturation of synapses and neuronal polarity, but its substrates and mechanisms of action are unknown. We identified phosphorylation sites in SYD-2 *in vivo* with mass spectrometry and confirmed direct phosphorylation by SAD-1 on specific residues within SYD-2's C-terminal SAM domains with *in vitro* kinase assays. *In vivo*, we introduced an endogenous SYD-2 mutant that blocked SAD-1 phosphorylation and imaged individual synapses at single-cell resolution. This phosphomutant inhibited the assembly of active zone proteins and resulted in animal-wide synaptic transmission defects. Furthermore, at developing synapses, the SAD-1 phosphomutant lost the ability to form dynamic condensates, indicating SAD-1 phosphorylation may directly regulate SYD-2's phase separation activity. Supporting this notion *in vitro*, we find SYD-2's SAM domains inhibit the protein's phase separation when unphosphorylated. We find the unphosphorylated SAM domains directly bind SYD-2's N-terminal coiled-coil domains, revealing an autoinhibitory mechanism where the interaction of C- and N-terminal folded domains inhibit the phase separation of an intervening intrinsically disordered region. As SAD-1 localizes to presynaptic sites, this mechanism may constrain SYD-2's phase separation elsewhere in the neuron until it is properly located to build an active zone. We conclude that SAD-1 phosphorylation of SYD-2/Liprin-α activates its phase separation to build presynaptic active zones in neurons.

B420/P2806

The Effects of alpha-Synuclein on the Phase Separation at Synapses

D. Milovanovic[1], R. Sansevrino[1], **D. Milovanovic**[2], C. Hoffmann[1,2], B. Rankovic[1], A. Condric[1], G. Aguilar Perez[1], J. Tromm[1]; [1]Molecular Neuroscience, German Center for Neurodegenerative Diseases (DZNE), Berlin, GERMANY, [2]Marine Biological Laboratory (MBL), Woods Hole, MA.

To sustain neurotransmission, synapses must maintain a proper supply of neurotransmitter-filled synaptic vesicles (SVs). Hundreds of SVs form biomolecular condensates through the interaction with synapsins, the highly abundant family of synaptic phosphoproteins. Another major family of disordered proteins at the presynapse includes synucleins, most notably alpha-synuclein. The precise physiological role of alpha-synuclein in synaptic physiology remains elusive, albeit its role has been implicated in nearly all steps of the SV cycle. To determine the effect of α-synuclein on the synapsin phase, we employ the reconstitution approaches using natively purified SVs from rat brains and the heterologous cell system to generate synapsin condensates. We demonstrate that synapsin condensates recruit alpha-synuclein, and while enriched into these synapsin condensates, alpha-synuclein still maintains its high mobility. The presence of SVs enhances the rate of synapsin/ alpha-synuclein condensation, suggesting that SVs act as catalyzers for the formation of synapsin condensates. Notably, at physiological salt and protein concentrations, alpha-synuclein alone cannot trigger the phase separation of SVs. The excess of alpha-synuclein attenuates the kinetics of synapsin/SV condensate formation, indicating that the molar ratio between synapsin and alpha-synuclein is important in assembling the functional condensates of SVs. alpha-Synuclein can be depleted from synapsin condensates by synphilin 1, another intrinsically disordered, scaffold protein at the presynapse implicated in Parkinson's Disease. Interestingly, synphilin 1 can form fluid condensates by itself, and alpha-synuclein shows the ability to fully wet synphilin condensates in a salt-dependent manner. Understanding the molecular mechanism of alpha-synuclein

interactions at the nerve terminals is crucial for clarifying the pathogenesis of synucleinopathies, where alpha-synuclein, synaptic proteins, and lipid organelles all accumulate as insoluble intracellular inclusions.

B421/P2807

Synaptic vesicle proteins and ATG9A self-organize in distinct vesicle phases within synapsin condensates

D. Park[1,2], Y. Wu[1,2], A. Baublis[3], P. De Camilli[1,2]; [1]Departments of Neuroscience and of Cell Biology, Yale University, New Haven, CT, [2]Howard Hughes Medical Institute, Yale University, New Haven, CT, [3]Harvard Chan Advanced Multi-omics Platform, Harvard T.H. Chan School of Public Health, Boston, MA.

A defining feature of presynaptic nerve terminals is the presence of tight clusters of synaptic vesicles anchored to active zones of the presynaptic plasma membrane. We have provided evidence that principles of liquid-liquid phase separation (LLPS) may explain the formation of these vesicle clusters (PMID: 28279363 and 29976799). Recently, we have shown that ectopic expression in fibroblasts of synapsin1, a peripheral synaptic vesicle-associated protein, and just an integral synaptic vesicle membrane protein, synaptophysin, is sufficient to generate clusters of small vesicles (a separate cytosolic phase or condensate) highly reminiscent of synaptic vesicle clusters at presynapses and with liquid like properties (PMID:33431828). We have now followed-up these studies by investigating the fate of other synaptic vesicle proteins when expressed in fibroblasts. We found that, unlike synaptophysin, other major integral synaptic vesicle membrane proteins, such as synaptobrevin2 (VAMP2), synaptotagmin1, SCAMP5, vGlut and vGAT fail to form condensates with synapsin but can coassemble into the vesicle clusters formed by synaptophysin and synapsin. Another vesicle protein present in nerve terminal, ATG9 (the only transmembrane protein of the core autophagy machineries), was recently shown to undergo activity-dependent exo-endocytosis at synapses in parallel with synaptic vesicle proteins (PMID: 35065714), raising questions about the overlap of the traffic of this protein with the traffic of synaptic vesicles. We have found that ATG9 does not coassemble into the synaptophysin and synapsin condensates but assembles with synapsin into a distinct phase. Our findings suggest that ATG9 undergoes differential sorting relative to synaptic vesicle proteins and also point to a dual role of synapsin in controlling the clustering at synapses of bona fide synaptic vesicles and ATG9 vesicles.

B422/P2808

The E3 ubiquitin ligase TRIM9 regulates actin dynamics and synapse formation

L. E. McCormick, L. Herring, N. G. Brown, G. H. Diering, S. L. Gupton; University of North Carolina At Chapel Hill, Chapel Hill, NC.

In neurons, actin-rich filopodia are critical at many stages of morphogenesis, including neuritogenesis, axon guidance, and dendritic spine formation. Defects in these critical developmental processes can result in improper synaptic connectivity, neurodevelopmental disorders, and psychiatric syndromes. Previously, we have demonstrated the E3 ubiquitin ligase TRIM9 localizes to growth cone filopodia and regulates axon pathfinding downstream of the guidance cue netrin. *Trim9*$^{-/-}$ mice have overt spatial learning memory deficits, yet the role of TRIM9 in synapse formation and maintenance is unknown. Here we show TRIM9 is enriched in the post-synaptic density following differential centrifugation, suggesting a role for TRIM9 in dendritic spines. We find Netrin-dependent increases in dendritic spine number, synapse maturation, and neuronal firing in vitro, and all these responses are abrogated in

Trim9$^{-/-}$ neurons. Furthermore, neurons over-expressing TRIM9 show defects in spine maturation but not dendritic spine number. In vivo, we demonstrate that loss of *Trim9* alters the proteome of the post-synaptic density. In particular, we observe changes in numerous cytoskeletal proteins, including the Arp2/3 complex. Ongoing work is investigating the functional consequence of these changes to Arp2/3 accumulation in dendritic spines and neurotransmitter receptors on the neuronal surface.

Presynaptic dTACC controls NMJ growth through regulation of microtubule dynamics in *D. melanogaster*

S. A. Johnson[1], V. Chou[2], J. Long[2], D. Van Vactor[2]; [1]Simmons University, Boston, MA, [2]Harvard Medical School, Boston, MA

Growth of the neuromuscular junction (NMJ) is a tightly controlled process that requires many separate factors working together. Errors in synaptic development in which growth is either to great or small are linked to neurological disorders including autism spectrum disorder (ASD) and Parkinson's disease. We have identified a new protein which regulates NMJ growth in *Drosophila melanogaster*, dTACC, previously established as a microtubule associated protein (MAP) responsible for stabilizing microtubules (MTs) particularly during mitosis. dTACC is found decorating MTs within the presynaptic neuron at the NMJ as well as in a punctate pattern that closely juxtaposes the active zone marker BRP. Loss of dTACC within motoneurons produces an overgrowth phenotype characterized by a loss of presynaptic tubulin and an abundance of diffuse MT within synaptic boutons, a pattern consistent with boutons that are actively growing. Taken together, our results suggest that regulation of presynaptic MT dynamics as controlled by dTACC represent an important mechanism to control NMJ growth.

Mitochondrial Homeostasis and Quality Control

B427/P2810

Mitochondrial RNA and RNA biogenesis factors are nucleoid components linked to mitochondrial genome replication

J. Smolka, S. Lewis; Department of Molecular and Cellular Biology, University of California, Berkeley, Berkeley, CA.

Human mitochondria contain a genome (mtDNA) coding for 13 mitochondrial inner membrane proteins, as well as ribosomal and transfer RNAs (tRNAs), that support cellular respiration and ATP production. There can be hundreds to thousands of mtDNA copies per cell, and each genome can form supramolecular complexes, or nucleoids, with nuclearly encoded proteins imported into mitochondria. These proteins organize, propagate, and express mtDNA, and nucleoids heterogeneously and asynchronously engage in replication and transcription throughout a cell cycle. However, how replication and transcription of a population of mitochondrial genomes could be regulated to attain homeostatic genome copy numbers and gene expression levels remains elusive. This gap in knowledge stems from an incomplete understanding of the steady state protein composition of nucleoids and how discrete, variable, or dynamic that composition can be. To address this gap in knowledge, we bioinformatically inferred a human mitochondrial nucleoid protein network using publicly available proteomic and genetic interaction data from proliferative cell culture models. This analysis suggests that mitochondrial nucleoids are an amalgam of DNA, RNA, and proteins that bind both, and that

mitochondrial tRNA synthetases, which aminoacylate mitochondrial tRNAs, associate with proteins that replicate mtDNA. Using untransformed human fibroblasts, live imaging of mitochondrial RNA and a well-established nucleoid protein, TFAM, indicates nucleoids do contain, and physically associate with, RNA. Furthermore, treatment of cells with compounds targeting the mitochondrial RNA polymerase and a mitochondrial tRNA synthetase acutely perturb mtDNA replication. These data suggest that mitochondrial RNA and RNA biogenesis factors are constituents of nucleoids, and that mtDNA replication is potentially integrated with both mitochondrial transcription and translation via regulation by tRNA metabolism.

Mitochondrial phospholipids regulate mitochondrial-derived compartment biogenesis

T. Xiao, A. M. English, A. L. Hughes; Department of Biochemistry, School of Medicine, University of Utah, Salt Lake City, UT.

Mitochondrial protein homeostasis is necessary for cellular health during pathogenic cellular stresses. In recent studies, our lab identified a pathway that regulates the mitochondrial proteome in response to amino acid overabundance stress, called the Mitochondria-Derived Compartment (MDC) pathway. MDCs are membrane structures generated from mitochondria that selectively sequester a subset of mitochondrial proteins upon formation. Importantly, in cells with elevated intracellular amino acid levels, failure to form MDCs compromises cell health and impacts amino acid metabolism. Both in yeasts and mammalian cells, MDCs form at ER-mitochondria contacts, and proteins at the contact sites are required for this process. However, the mechanism(s) that regulate MDC biogenesis remains poorly understood. To uncover factors that control MDC formation, we conducted a microscopy-based genome-wide screen of yeast non-essential deletion collection. We identified 977 individual gene deletions that impair MDC biogenesis, and 68 gene deletions that enhance MDC formation. Among these gene hits, *UPS1* and *UPS2*, which encode for two mitochondrial proteins that transfer substrates for cardiolipin (CL) or phosphatidylethanolamine (PE) synthesis from the mitochondrial outer membrane to inner membrane, respectively, have opposing effects on MDC biogenesis. In the absence of Ups1, MDC formation in response to amino acid stress is blocked. In contrast, cells with *UPS2* deletion constitutively form MDCs. We further assessed MDC biogenesis in mutants lacking other components of the CL and PE synthesis pathways. Similar to *UPS1*, genes that govern CL synthesis, including *GEP4* and *CRD1*, are required for MDC formation, and consistent with *UPS2*, deletion of *PSD1*, the decarboxylase that catalyzes mitochondrial PE synthesis, leads to constitutive MDC formation. These results suggest that mitochondrial CL and PE levels regulates MDC biogenesis opposingly. In addition, we investigated the lipid profiles of cells treated various agents that increase cellular amino acid pools and trigger MDC formation. Interestingly, under numerous known MDC-inducing conditions, total cellular PE levels were decreased. Preventing MDC formation by the removal of amino acids from the medium attenuates the drop in PE level caused by MDC activating agents, and depleting mitochondrial PE by *PSD1* deletion re-activates the MDC pathway. Our data indicate a critical role of mitochondrial phospholipids in MDC biogenesis, potentially as a signal to initiate MDC formation downstream of amino acid stress. We are currently characterizing how mitochondrial phospholipids are regulated in cells experiencing MDC-inducing stresses, and how this contributes to MDC formation.

A spatial map of hepatic mitochondria uncovers functional heterogeneity and plasticity at the tissue scale

S. Kang[1], R. P. Cunningham[1], C. Cultraro[1], A. Lobanov[2], M. Cam[2], N. Porat-Shlion[1]; [1]Thoracic and GI Malignancies Branch, NCI, National Instituts of Health, Bethesda, MD, [2]CCR Collaborative Bioinformatics Resource (CCBR), National Instituts of Health, Bethesda, MD.

Hepatocytes in the liver are organized in hexagonal units called lobules. Blood flows directionally within each lobule, resulting in gradients of nutrients along the periportal (PP) - pericentral (PC) axis. These gradients, in turn, drive spatially distinct gene expression and metabolic functions, a phenomenon that is known as liver zonation. At the cellular level, mitochondria continuously adjust their metabolic output to match nutrient supply. However, how liver zonation impacts mitochondrial functions was never investigated. Here, we used a combination of protein mass spectrometry and light microscopy to spatially characterize hepatic mitochondria. Our analysis reveals great diversity between PP and PC mitochondria in protein composition, respiration, morphology, and turnover. In response to acute fasting, PC mitochondria undergo substantial remodeling. This adaptive response is prominent in PC hepatocytes and conferred by upregulation of translation and phosphorylation to simultaneously increase mitochondrial oxidative capacity and decrease pericentral pathways that may not be immediately required during fasting. Collectively, our data provide tissue scale insights into mitochondrial spatial diversification and their phospho-proteome remodeling in response to changes in nutrient supply. This work begins to capture the complexity of mitochondria heterogeneity and plasticity in intact tissue and during physiological metabolic transitioning.

B430/P2813

Quantitative mitochondrial proteome analysis differentiates the specific vs general mitochondrial effects caused by Drosophila mutants affecting three different critical pathways for mitochondrial function

A. Sen[1], R. T. Cox[2]; [1]Uniformed Services University/Henry M. Jackson Foundation, Bethesda, MD, [2]Uniformed Services University, Bethesda, MD.

Dysfunctional mitochondria affect almost all major organs in the body. About 1 in 4300 people in the United States are affected by mitochondrial diseases and they are often hard to diagnose. Although mitochondria have their own genome, they need hundreds of proteins encoded by nuclear genome for proper functioning. Mutations in one of these genes can cause a wide spectrum of abnormalities in animals. Despite the challenges in studying the mitochondrial proteome due to the dynamic nature of mitochondria, it holds the potential to identify both the specific and general mitochondrial damages caused by single gene mutations. In this study we have analyzed and compared the effects of three Drosophila mutants, *clueless* (*clu*), *Superoxide dismutase 2* (*Sod2*) and *PTEN-induced putative kinase 1* (*Pink1*), which are associated with mitochondrial dysfunction and changes to the mitochondrial proteome. Clueless (Clu) is a nucleus-encoded ribonucleoprotein that forms mitochondrion-associated particles. Sod2 scavenges mitochondrial free radicals and mutants have increased oxidative damages. Pink1 is a component of the mitophagy pathway used to cull damaged mitochondria. After performing quantitative tandem mass tag mass spectrometry analysis from mitochondrial extracts from these mutants, we identified changes to protein classes that were unique for each mutant as well as shared between them. Our analysis indicates that some changes in the mitochondrial proteome are due to

general mitochondrial damage whereas others are gene-specific. While all three mutants induce a general mitochondrial stress response, *clueless* mutants predominantly affect mitochondrial respiratory chain protein. For the first time, we have directly compared the in vivo steady-state levels of mitochondrial proteins in mutants affecting three pathways critical for mitochondrial function. These data could be useful to better understand the etiology of mitochondrial diseases, and articulate better therapeutic aspects based on specific proteomic changes as opposed to changes due to generalized mitochondrial damage.

B431/P2814

Genome-wide screen reveals novel regulators of PINK1-Parkin pathway and Mitofusin-2 expression

J. Thayer[1], X. Huang[1], J. Hawrot[1], D. Ramos[2], A. Subramaniam[1], M. Ward[1], D. Narendra[1]; [1]National Institute of Neurological Disorders and Stroke, NIH, BETHESDA, MD, [2]National Institute of Aging, BETHESDA, MD.

We sought to identify novel regulators of the PINK1-Parkin mitochondrial quality control (MQC) pathway and Mitofusin-2 (MFN2) expression using a novel flow cytometry reporter in a genome-wide CRISPRi (GWCi) screen. Mitochondrial dynamics and quality control are critical for neuronal health. Loss of the PINK1-Parkin MQC pathway is the leading cause of recessive Parkinson's disease. Also, dominant mutations in the mitochondrial fusion protein MFN2 are the leading cause of Charcot-Marie Tooth 2A. MFN2 is the preferred substrate of Parkin's E3 ubiquitin ligase activity, linking the PINK1-Parkin MQC pathway and mitochondrial dynamics. MFN2 in HeLa cells co-expressing mCherry-Parkin and dCas9-KRAB was endogenously tagged (HaloTag). Cells were transduced with a pooled dual guide GWCi library. Oxidative phosphorylation (OXPHOS) inhibitors were used to activate the PINK1-Parkin pathway. Treated and untreated cells were sorted into high and low MFN2-Halo populations by fluorescence activated cell sorting (FACS). Guide counts from each population were calculated after next generation sequencing of extracted genomic DNA. We verified by microscopy that endogenous MFN2-Halo was expressed on mitochondria. Also, we demonstrated that activation of the PINK1-Parkin pathway by OXPHOS inhibition causes degradation of MFN2-Halo by flow cytometry and immunoblotting. Next, we completed two FACS-based GWCi screens of MFN2-Halo in duplicate: one under basal conditions and one with OXPHOS inhibition. Under basal conditions, we identified genes increasing or decreasing MFN2 expression (with 795 reaching genome-wide significance). The top mitochondrial hit increasing MFN2 levels was SLC25A46, a known negative regulator of MFN2, validating this approach. Additionally, we identified four components of a transcriptional complex not previously linked to MFN2 regulation, ranked 1, 5, 6, and 11, respectively. Under OXPHOS inhibited conditions, PINK1 was the top hit opposing MFN2-Halo degradation, validating this approach. Novel hits (among 330 reaching genome-wide significance) have suspected roles in promoting PINK1 expression, facilitating autophagic capture of impaired mitochondria, mediating fusion of the mito-autophagosome with the lysosome, and promoting mitochondrial degradation in the lysosome. Surprisingly, the HOPS complex and the V-ATPase were among the factors most limiting for MFN2 degradation by the PINK1-Parkin pathway. In a GWCi screen of a MFN2-Halo FACS reporter, we identified novel regulators of the PINK1-Parkin MQC pathway and MFN2 expression. While requiring additional study, these regulators may have far-reaching implications for modulating mitochondrial quality control and dynamics for the treatment of neurodegenerative disorders.

B432/P2815

Mitochondrial fission and fusion maintain mitochondrial genome integrity by different mechanisms

B. T. Wisniewski, L. L. Lackner, First; Molecular Biosciences, Northwestern University, Evanston, IL.

Mitochondria exist as an interconnected and dynamic network of membrane tubules within cells. Mitochondrial network morphology contributes to proper organelle function and cell health. Two opposing processes: mitochondrial fission and mitochondrial fusion maintain mitochondrial morphology. Mitochondrial fission and fusion are also required to maintain the integrity of mitochondrial DNA (mtDNA)—chromosomes within mitochondria that encode components of the respiratory chain. Intact mitochondrial DNA is required for proper mitochondrial function and defects are associated with multiple disease states. The mechanism by which fission and fusion maintain mitochondrial DNA integrity is not fully understood. We use live-cell imaging to localize mtDNA to mitochondrial fission and fusion sites. We find that a minimal, but balanced, amount of fission and fusion are required to maintain functional mtDNA. Finally, we introduce a model in which increased mtDNA copy number buffers the loss of functional mtDNA in the absence of both fission and fusion. Current work is expanding our model to include the molecular mechanism by which mtDNA mutation is caused by the simultaneous disruption of fission and fusion.

B433/P2816

Identification of a novel negative regulator of BNIP3/BNIP3L-dependent receptor-mediated mitophagy

M. Gok, J. Friedman; UT Southwestern Medical Center, Dallas, TX.

Mitochondria play critical roles in cellular metabolism and are functionally maintained by several quality control pathways. During hypoxia, the outer mitochondrial membrane proteins BNIP3 and BNIP3L are upregulated and promote receptor-mediated mitophagy, whereby autophagy machinery is directly recruited to facilitate the selective turnover of a subset of mitochondria. Constitutive low levels of BNIP3/BNIP3L are found under normoxic conditions, but it is unclear how they are regulated and whether they contribute to low levels of basal mitophagy that occur independently of the well-characterized PINK1/Parkin pathway. In exploring the role of the poorly characterized mitochondrial morphology regulator TMEM11, we unexpectedly find that it localizes to the outer membrane and forms a complex with BNIP3 and BNIP3L. We find that the mitochondrial morphology defects that occur in the absence of TMEM11 are caused in a BNIP3/3L-dependent manner. Using a fluorescence-based assay to monitor mitophagy in live cells, we find that BNIP3/3L-dependent mitophagy is hyper-active in both normoxic and hypoxic conditions in the absence of TMEM11. Additionally, our data reveal that BNIP3 is indeed required for basal mitophagy in certain cell types. In addition to interacting with BNIP3/3L, TMEM11 interacts with the mitochondrial inner membrane cristae-organizing MICOS complex. We observe that TMEM11 bridges the BNIP3/3L and MICOS complexes and that depletion of MICOS triggers BNIP3/3L-mediated mitophagy during normoxia. Our data are consistent with a model that TMEM11 serves as a “brake” against mitophagy by directly binding and inhibiting BNIP3 and that a MICOS/TMEM11/BNIP3/3L axis coordinately regulates mitochondrial quality control by sensing and responding to mitochondrial dysfunction. We thus uncover a non-canonical role for TMEM11 as a novel regulator of BNIP3/3L-mediated mitophagy.

B434/P2817

Mechanism of mitochondrial cholesterol import is via an intermembrane space cholesterol shuttle: STAR

P. P. Koganti, A. H. Zhao, M. C. Kern, A. Guo, S. Wasti, V. Selvaraj; Cornell University, Ithaca, NY

Cholesterol import into mitochondria is an essential first step in the production of all steroid hormones. CYP11A1 localized to the matrix-side of the inner mitochondrial membrane (IMM) converts cholesterol to pregnenolone, the first steroid in the biosynthetic pathway. Acute regulation of IMM cholesterol availability via the synthesis, function and degradation of the steroidogenic acute regulatory protein (STAR) has been well documented. Nevertheless, the precise mechanism of STAR action remains undefined. We recently refuted the two-step model that purported cooperation of STAR and the mitochondrial translocator protein/TSPO. The fallback was another model that portrayed STAR as a molten globule at the outer mitochondrial membrane (OMM) apposing the IMM. However, this model has remained at odds with the need for a cholesterol-binding domain that is present in STAR. By generating STAR-deleted Leydig cells we evaluated functional reconstitution using different STAR mutants and fusion proteins with ultrastructural localization as means to uncover its mechanism of action. Truncation of the STAR mitochondrial targeting sequence (MTS; ΔN36, ΔN42, ΔN50, ΔN54 and ΔN62) or anchoring STAR to the OMM using a TOM20 fusion (TOM20-ΔN62.STAR), resulted in a complete loss of steroidogenic function; a result that was in direct contrast to that previously reported to support the molten globule model. Use of the MTS of cytochrome C1 (CYC1) that is known to target proteins into the intermembrane space (IMS) in the place of the STAR MTS (CYC1.MTS-ΔN62.STAR) could completely restore import indicating the resident site of STAR function as the IMS. Ultrastructural localization using ascorbate peroxidase (APEX2) fusion proteins to evaluate both STAR (STAR.APEX2) and CYC1 targeting (CYC1.MTS-APEX2) confirmed an IMS localization in steroidogenic mitochondria. Structural analysis revealed a C-terminal amphipathic α4-helix, truncation of which (STAR.ΔC261) or site-directed mutagenesis of residues that formed the hydrophobic face to hydrophilic amino acids (I264T, F266W, A267S and L270T) resulted in complete loss of function. These results indicated STAR actions in membrane docking, cholesterol extraction, and diffusion, as an IMS cholesterol shuttle. As such, our findings resolve a core steroidogenic regulatory mechanism that has baffled the field of steroid endocrinology for decades.

B435/P2818

A novel cytoskeleton-based pathway regulates mitochondrial dynamics and energetics in skeletal muscle

K. Voos[1], J. Tzeng[2], T. Pharr[2], G. Choi[2], D. Lorenzo[1]; [1]University of Pennsylvania - Philadelphia, PA, Philadelphia, PA, [2]University of North Carolina- Chapel Hill, Chapel Hill, NC.

Regulation of mitochondrial fission-fusion dynamics is key for maintaining bioenergetic homeostasis, especially in cell types with high energy demand. Changes in the balance between mitochondria fission and fusion events in skeletal muscle (SKM) promote metabolic deficits associated with impaired energetic capacity, muscle atrophy and diabetes. Previous studies have identified the actin cytoskeleton as a key modulator of mitochondria fission-fusion events. However, the cytoskeletal factors and mechanisms that regulate mitochondria dynamics are poorly understood. Ankryin-B (AnkB) is a ubiquitously expressed actin cytoskeleton-associated protein that scaffolds and stabilizes submembrane protein complexes. Human variants in 220-kDa AnkB, the most abundant isoform in SKM, have been

identified as risk factors for cardio-metabolic disease, and shown to cause age-dependent metabolic syndrome in mice. In SKM, AnkB stabilizes the dystrophin-dystroglycan axis to provide structural support. However, the metabolic role of AnkB in SKM has not been characterized. Using a conditional knock-out mouse model that selectively lacks 220-kDa AnkB in SKM (SKM-AnkB-KO mice), we identified a novel role of AnkB in regulating SKM energetics through its association with mitochondria. SKM-AnkB-KO mice exhibit deficits in glucose metabolism that worsens with age, impaired activity and exercise capacity, and reduced levels of oxidative phosphorylation proteins in mitochondria-rich muscle. In addition, Transmission Electron Microscopy (TEM) evaluations of muscle sections show the presence of enlarged mitochondria in SKM-AnkB-KO mice, which suggests alterations in mitochondria dynamics that likely contribute to energetic stress. In support of this idea, we found that critical regulators of mitochondria fission-fusion, including dynamin-like protein 1 (DRP1) and Optic Atrophy 1 (OPA1) were reduced at the protein and transcript levels. Importantly, AnkB co-fractionates with mitochondria in control SKM. Also, interactome and biochemical analysis identified the DRP1-receptor Mitochondrial Fission Factor (MFF) as an AnkB-interactor in SKM. Here, we will discuss our findings that support a model in which AnkB transiently interacts with DRP1 and scaffolds the DRP1-MFF to promote mitochondrial fission and homeostasis. We propose that this pathway is critical for bioenergetic balance in SKM.

NME3 and PLD6 Mediate Mitochondrial Tethering for Selective Fusion

C. Sung, Y. Su, H. Chiu, Y. Chang, Z. Chang, Y. Liu; National Taiwan University, Taipei City, TAIWAN.

Mitochondria are dynamic organelles regulated by the fission and fusion processes. The fusion of biomembranes requires elaborative coordination of proteins and lipids, and is crucial for mitochondrial quality control. It is known that phosphatidic acid (PA) generated from cardiolipin (CL) by PLD6 is essential for the fusion of mitochondria. However, how PA promotes the fusion process of mitochondrial outer membrane remains unclear. Here, we show a mitochondrial outer membrane protein, NME3, is required for PLD6-induced mitochondrial tethering. Live-cell microscopy reveals that NME3 is enriched at the contact interface of two closely positioned mitochondria by activation of PLD6. Biochemical analysis indicates that NME3 is capable of binding directly to PA-exposed lipid packing defects via its N-terminal amphipathic helix. The PA binding function and the hexamerization confer NME3 tethering the PLD6-remodeled mitochondrial membrane. Given externalized CL is a signal of unhealthy mitochondria, our findings suggest that the membrane tethering function of NME3 has the selectivity to the damaged mitochondria targeted by PLD6 that promotes fusion process for the quality control. To explore this hypothesis, we utilized UV or mitochondrial damaging agent to induce mild mitochondrial stress and observed higher enrichment of NME3 to the mitochondria contact increased. In conclusion, we discover that NME3 and PLD6 play critical roles in mitochondrial fusion via promoting tether between damaged mitochondria.

Interrogating neurodegeneration-linked CHCHD2 and CHCHD10 and their mitochondrial interaction network

T. Huang, N. Randolph, X. Huang, B. Wu, D. Narendra; NIH-NINDS, Bethesda, MD.

Objective: To identify endogenous protein-protein interactions (PPIs) with CHCHD2 and CHCHD10 in cultured cells and mouse tissues by affinity purification mass spectrometry (AP-MS).
Introduction: Dominant mutations in the paralogs *CHCHD2* (*C2*) and *CHCHD10* (*C10*) cause neurodegenerative disease. These nuclear genes code small proteins localized to the intermembrane space side of mitochondrial cristae. Their functions are crucial for maintaining cristae structure and oxidative phosphorylation (OXPHOS). However, the detailed molecular mechanism for their action has not been fully characterized.
Methods: Using a novel antibody and C2/C10 double knockout cell lines and mouse models, we will establish authentic endogenous interactors of C2 and C10 in cell culture and *in vivo* by AP-MS.
Results: In the first comprehensive study of C2/C10 endogenous PPIs, we confirm several previously published PPIs and establish that OXPHOS subunits are major interactors. Using KO cell lines for individual PPIs, we find that most PPIs are independent of one another, suggesting transient association of C2/C10 with multiple inner mitochondrial membrane complexes. Unexpectedly, we find substantially increased C2/C10 PPIs following cristae disruption (due to KO of TAZ, MIC60, and STOML2 KO), suggesting a role for C2 and C10 in maintaining cristae proteostasis. Finally, we find that a myopathy/cardiomyopathy-causing mutation in C10, which causes C10 misfolding, strongly increases C2/C10 binding to an intermembrane space protease, HTRA2/OMI, in the affected mouse heart. This suggests that HTRA2/OMI may protect against pathogenic C10 misfolding.
Conclusion: In the first comprehensive study of C2/C10 endogenous interactors we identify dynamic changes in PPIs following cristae disruption and a protease that may selectively associates with mutant C10 *in vivo*.

YME1L1 Knockdown Induces Mitochondrial Fragmentation and Dysfunction during Porcine Embryonic Development

D. ZHOU, X. Cui; Aminal Science, Chungbuk National University, Cheongju, KOREA, REPUBLIC OF.

YME1L1, a member of the AAA family of ATPases, is a nuclear genome-encoded ATP-dependent metalloprotease embedded in the IMM. Its protease domain faces the IMS (also termed i-AAA protease). YME1L1 is also a mitochondrial metalloprotease responsible for the cleavage of the mitochondrial GTPase OPA1. However, how YME1L1 regulates mitochondrial function in porcine embryos is still obscure. In the present study, we knock down the mRNA level of *YME1L1* by the microinjection with dsRNA of *YME1L1* at the 1-cell stage. Immunofluorescence and western blot were used for detecting the localization and expression of YME1L1 and related proteins. Embryo cleavage rates, blastocyst diameter, and total cell number were measured to assess the YME1L1 knock-down effect. Firstly, we found that endogenous YME1L1 locates at punctate structures of mitochondria and is highly expressed in the BL stage. Knock-down of YME1L1 in porcine embryos results in mitochondrial fragmentation and leads to significantly decreased quality of blastocyst. Knock-down of YME1L1 induced an increase in ROS and reduced mitochondrial membrane potential and ATP level. In addition, YME1L1 knock-down also caused a significant release of cytochrome c from mitochondria, which is a pro-

apoptotic signal. Taken together, YME1L1 plays a critical role in embryo development by regulating mitochondrial morphology, function, and apoptosis in pigs.

Mitochondrial-derived compartments are stress-induced multilamellar whorls that sequester mitochondrial outer membrane cargo

Z. N. Wilson[1], A. M. English[1], M. West[2], G. Odorizzi[2], A. L. Hughes[1]; [1]University of Utah, Salt Lake City, UT, [2]University of Colorado Boulder, Boulder, CO.

Preserving the functional health of the mitochondrial network is critical to cell viability and longevity. To do so, cells employ mitophagy to remove dysfunctional mitochondria or remove select portions of the organelle through a variety of mechanisms, including mitochondrial-derived vesicles, structures positive for the outer membrane, or mitochondrial-derived compartments (MDCs). For these latter mechanisms, it remains unclear what features they share in common or the characteristics and functional roles that distinguish them. To further define MDCs, we performed electron tomography on MDCs in the budding yeast *Saccharomyces cerevisiae.* We show that MDCs consist of multilamellar whorls derived from the mitochondrial outer membrane that form concentric spherical compartments with up to eight membrane bilayers. Time-lapse super-resolution microscopy of MDC biogenesis revealed that the mitochondrial outer membrane repeatedly extends and fuses to form these multilamellar compartments. As such, MDCs strongly enrich and sequester portions of the mitochondrial outer membrane and encase cytosolic material within the MDC lumen. Remarkably, subunits of the translocase of the outer membrane (TOM) complex are excluded from MDCs unless assembly of the TOM complex is inhibited, suggesting that criteria also exists within the mitochondrial outer membrane for selecting cargo that incorporate into MDCs. Considering that overloading the outer membrane with membrane proteins constitutively induces MDC formation, we propose that one functional role of MDCs is to segregate and sequester excess hydrophobic cargo through mitochondrial outer membrane expansion and enclosure to maintain mitochondrial homeostasis during stress.

The Role of *C. elegans* Metaxins in Mitochondrial Homeostasis

J. Dietz, E. Park, N. Salazar-Vasquez, N. Kane, C. Nowlen, C. Rongo; Rutgers University, Piscataway, NJ.

Mitochondria are critical for neuronal function and health, as they are the primary supplier of energy and calcium storage for neurons. Mitochondria are also dynamic organelles - undergoing fusion and fission in response to various stimuli. In neurons, which have elaborate morphology, mitochondrial dynamics also includes transport to specific sub-compartments, where they supply energy and buffer calcium for the local cellular environment. Disturbances in mitochondrial function or dynamics contribute to various neurological neurodegenerative disorders, including Alzheimer's disease, Parkinson's disease, ALS, Huntington's disease, and Leigh syndrome. Using a forward genetics screen in *C. elegans* searching for novel mutants defective in neuronal mitochondrial dynamics, we found that mutations in metaxin 1 (MTX-1), metaxin 2 (MTX-2), and VDAC-1 resulted in fewer mitochondria in *C. elegans* interneuron dendrites. Homologs of MTX-1 and MTX-2 (the metaxins) in *S. cerevisiae* and mammals interact with SAM50 to form the sorting and assembly machinery (SAM) complex, which mediates β-barrel protein assembly in the mitochondrial outer membrane (MOM). VDAC-1 is a highly conserved SAM complex substrate that acts as a channel for metabolites (ATP/ADP, Ca^{2+}, NAD^{+}/NADH)

to move across the MOM. We are testing the hypothesis that the metaxins promote mitochondrial motility along *C. elegans* interneuron dendrites by mediating β-barrel assembly of VDAC-1 in the MOM. MTX-1, MTX-2, and VDAC-1 mutants are viable; however, their lifespans are reduced compared to WT. To determine the impact of the metaxins and VDAC-1 on mitochondrial homeostasis in *C. elegans*, we measured mitochondrial unfolded protein response (UPRmt) activation using a fluorescent reporter (HSP-6::GFP) in strains lacking MTX-1, MTX-2, and VDAC-1. We found that HSP-6::GFP expression was increased in *mtx-2* and *vdac-1* mutants, suggesting basal UPRmt activation and mitohormesis, and resulting in heat stress resistance. We are currently investigating the role of *C. elegans* MTX-1 and MTX-2 in mitochondrial outer membrane β-barrel protein (VDAC-1) assembly and how that impacts neuron integrity. Our results will provide key insights towards the impact of mitochondria on neurodegeneration.

Zebrafish TMEM11 Localizes to Mitochondria and Interacts with Rhot2

S. S. Tadesse[1], P. Collado Cordon[2], S. Walsh[1]; [1]Life Sciences, Soka University of America, Aliso Viejo, CA, [2]Biology, Trinity College of Arts and Sciences, Duke University, Durham, NC.

Mitochondria are capable of moving around the cell, and this function is critical for cell function and viability. In addition, damaged mitochondria can produce toxic reactive oxygen species and therefore, must be removed from the cell through the protein-mediated process of mitophagy. These processes of motility and mitophagy are linked by common proteins, and failure of either can result in the cell death associated with neurodegenerative diseases. One important protein is Miro, and we sought to identify novel zebrafish proteins that might interact with the zebrafish orthologs of Miro using a zebrafish yeast two hybrid library. We identified 13 proteins that strongly interact with zebrafish Miro2/Rhot2 in this heterologous system, and one interactor was transmembrane protein 11 (TMEM11), also known as Pantagruelian Mitochondrion I (PMI) in fruit flies. We initially dismissed this interaction, given Miro's localization to the mitochondrial outer membrane (OM), and previous data demonstrating that PMI localized to the mitochondrial inner membrane. However, a more recent preprint stated that the human ortholog of TMEM11 localized to the OM, suggesting that Miro and TMEM11 might be more likely to interact. Thus far, we have tagged the zebrafish ortholog of TMEM11 on either the C-terminus or the N-terminus with Cherry or GFP, respectively. Based on structure predictions which indicate that the C-terminus is likely part of a transmembrane helix, the C-terminally tagged TMEM11-Cherry does not localize to mitochondria, but the N-terminally GFP-tagged protein does colocalize with mitochondrial markers when overexpressed in HeLa cells. Initial studies isolating mitochondria followed by treatment with Proteinase K further suggest that zebrafish TMEM11, like its human counterpart, may localize to the mitochondrial OM. Overall, these studies will provide new insights into the complex protein network that mediates mitochondrial physiology.

Identification of a mitochondrial intermembrane space protein required for the completion of organelle fission

O. Connor, S. Matta, **J. Friedman**; UT Southwestern, Dallas, TX

Mitochondria are highly dynamic organelles that maintain their shape through the conserved processes of organelle fission and fusion. These mitochondrial dynamics are required for numerous functions,

including controlling the spatial positioning of the organelle, maintenance of the mitochondrial genome, regulation of organelle quality control, and regulation of cell death. Mitochondrial fission is performed by the dynamin-related protein Drp1 (Dnm1 in yeast), a large GTPase that constricts and divides the mitochondria in a GTP hydrolysis-dependent manner. Despite over 20 years of research into the mechanisms of mitochondria fission, it has remained controversial whether factors inside mitochondria help coordinate the process and if Dnm1/Drp1 activity alone is sufficient to complete fission of both mitochondrial membranes. In the process of studying poorly characterized mitochondrial intermembrane space proteins, we have identified a new factor required for mitochondrial division in yeast, which we name Mitochondrial Division Intermembrane Space 1 (Mdi1). We find that deletion of Mdi1 leads to hyperconnected mitochondria networks, similar to loss of Dnm1. Using a combination of temperature-dependent inhibition of mitochondrial fusion and pharmacological approaches, we find that Mdi1 is required for promoting mitochondrial division. Then, using live cell fluorescence microscopy, we spatially link Mdi1 to sites of mitochondrial constriction and fission. Unlike all other known division machinery, loss of Mdi1 does not inhibit Dnm1 recruitment to mitochondria. Even under conditions that promote fragmentation of mitochondria, we find Dnm1-mediated mitochondrial constriction is not sufficient to complete division of the organelle in the absence of Mdi1. Finally, we show that the requirement of Mdi1 for Dnm1 to complete mitochondrial division is conserved in fission yeast. Thus, we have identified the first internal mitochondrial factor absolutely required for mitochondrial division and provide evidence suggesting it works after Dnm1-mediated mitochondrial constriction to complete fission of the organelle.

B443/P2826

Targeted fission as a quality control mechanism for asymmetric inheritance of mitochondrial protein aggregates

G. Sun, C. Hwang, T. Jung, J. Liu, R. Li; Johns Hopkins University, Baltimore, MD

In budding yeast, mitochondria form intricate reticulated structures capable of undergoing fission and fusion. This process is thought to aid in efficient distribution throughout the cytoplasm. During the cell budding cycle, prior research indicates mother yeast preferentially pass more reductive parts of their mitochondria network to their daughters through asymmetric inheritance. While expressing a mitochondria targeted misfolded protein capable of aggregation, we similarly observe mother cells retaining aggregate containing mitochondria at a high probability while preferentially passing down non-aggregate containing mitochondria to their buds. Using this aggregate system, we identify the characteristics of mitochondrial fission/fusion and motion as a quality control mechanism for enforcing asymmetric inheritance. In aggregate-expressing cells, we observe the presence of a two-class system of mitochondria characterized by differential fission/fusion probabilities, fission site placement, and motility. Using experimentally measured physical and mitochondrial dynamic attributes, we develop a computational model of mitochondrial network dynamics and inheritance to identify targeted fission as a mechanism for accelerating consolidation of multiple aggregates into one mass while simultaneously reducing the probability of inheriting aggregate containing mitochondria. Experimental examination of mitochondrial fission machinery furthermore indicates a localization preference of fission machinery close to aggregate inclusions and suggests a possible positive feedback loop driving fission machinery accumulation. Finally, we demonstrate knockout of mitochondrial fission machinery results in aggregate buildup in specifically mitochondrial nets.

Insulin-like Growth Factor 1 Signaling in Mitochondrial protection

J. Murray, S. Riis, **R. O'Connor**; University College Cork, Cork, Ireland

IGF-1 is essential for normal cell, organ and organismal growth but also supports oncogenic pathways that mediate initiation and progression of cancer. Although IGF-1signalling promotes mitochondrial metabolism and oxidative phosphorylation, this is modulated by nutrient availability, hypoxia, or cellular stresses that can lead to dysfunction and release of reactive oxygen species or DNA. We have previously described a mitochondrial protective role for IGF-1 through the induction of a PGC1beta-activated mitochondrial biogenesis programme that is coordinated with induction of the mitophagy receptor BNIP3 through Nrf2 and HIF-1α activation. Inhibition of IGF-1 signalling impairs this mitochondrial protection, suggesting that it is amenable for therapeutic co-targeting in cancer.In this study we sought to investigate whether IGF-1-induced BNIP3 is engaged in basal homeostatic mitophagy, and under which metabolic conditions, considering that IGF-1-activated mTOR is a potent suppressor of global cellular autophagy, including mitophagy. To address this we investigated BNIP-3 mediated mitophagy and autophagy flux in cells that were cultured in complete medium, serum starved or stimulated with IGF-1 and either exposed to bafilomycin or not. The results demonstrate that in serum-starved cells, although IGF-1 induced BNIP3, it did not promote association of BNIP3 with LC3 and overall suppressed mitophagy. In these serum-starved cell cultures the PINK1-Parkin axis was observed to engage in mitophagy. However, BNIP3 was associated with mitophagy flux in cells that were cultured in complete medium. Furthermore, in cells where the IGF-1 receptor was knocked out, autophagy flux was lower than in complete medium than in serum-depleted cultures, suggesting that IGF-1 signalling is required for maintaining basal mitophagy/autophagy. These findings support a mito- protective function for IGF-1 signalling in cancer cells that may be mediated by Hif-1a in normoxic conditions. The data further suggest that targeting this mito- protective function would augment current cancer therapies that target the IGF signalling pathway.

A balanced distribution of mitochondria is required to maintain mtDNA integrity over generations

M. Ray, W. Chen, K. Krueger, A. Jacob, E. Rosario, L. L. Lackner; Northwestern University, Evanston, IL

A conserved feature of Eukarya's defining organelle, the mitochondrion, is a reticular network that dynamically rearranges. The cell maintains this network through mechanisms that are also conserved—division/fusion, tethering, and motility. Given that mitochondria cannot form *de novo*, these mechanisms ensure that an adequate amount of mitochondria is partitioned during mitosis. In the absence of such inheritance, cells die. To maintain viability over generations, the inherited compartment must also be expanded by biogenesis. Budding yeast serves as a historical and tractable model to study these processes; many of the molecular players and phenotypes of mitochondrial inheritance and biogenesis are well described in this species. Studies have shown that mitochondrial volume scales with cell size in yeast. Interestingly, the mitochondrial genome (mtDNA), required for the role of mitochondria in oxidative phosphorylation, is packaged into protein-DNA complexes called nucleoids that themselves scale with and are evenly distributed along the mitochondrial network. Our work supports a model in which the proper distribution of mitochondrial volume during mitosis is required to maintain the integrity of mtDNA. We find that a fundamental requirement for the maintenance of mtDNA is the inheritance of an adequate volume of mitochondria. Synthetically altering the partitioning

of mitochondria during mitosis to varying degrees results in gradated defects in mtDNA maintenance that are predicted by our model. Current work is addressing the specific mechanism by which inheritance of mitochondrial volume impacts mtDNA maintenance. One hypothesis is that network expansion and mtDNA replication compete for a limiting factor, such as phosphate. In this hypothesis, the more essential of the two—compartment propagation—wins at the cost of mtDNA integrity. Given the conserved nature of mtDNA spacing and mitochondrial positioning, we predict that our work will describe universal features of mtDNA regulation.

The effects of *SHE9* deletion on *S.cerevisiae* mitochondrial function.

S. Kowaleski, N. A. Najor; University of Detroit Mercy, Detroit, MI

The model yeast organism Saccharomyces cerevisiae has roughly 10% of genes that remain as uncharacterized. To attempt to understand these genes of unknown function, genomic databases were mined to attempt to provide a potential function to these unknown genes. Data from Phobius and GeneMania databases, provided putative information suggesting the gene of unknown function SHE9 is a potential transmembrane protein in the inner membrane of the mitochondrion and is expressed with genes involving DNA Synthesis, DNA transcription/translation, and mitochondrial fission. While some data exists to support its expression and localization, the molecular function for the She9 protein is unknown. We ran a series of fitness tests on various yeast media or conditions with *she9* deletion mutants. The results indicate that the she9 deletion mutant was viable and resistant to both NaCl and Sorbitol osmotic stressors and was less viable under ultraviolet exposure compared to the wild-type Saccharomyces Cerevisiae strain. We hypothesize that She9 could be involved in maintaining mitochondrial DNA during mitochondrial fission. Since the genomic homology between yeast and humans is significant, uncovering these yeast genes of unknown functions, such as She9, have the potential to reveal undescribed pathways that could be implicated in human diseases.

B447/P2830

Eliminating mitochondrial import stress is independent of ATAD1 function

M.-C. Hsu[1], R. J. Youle[2]; [1]National Taiwan University, Taipei, Taiwan, [2]National Institutes of Health, Bethesda, MD

In eukaryotes, most mitochondrial proteins are encoded in nuclear genome; these proteins are synthesized in the cytosol and further imported into mitochondria across single or double organelle membranes. Maintaining the capability of mitochondrial protein import is a key for mitochondrial protein renewal and mitochondrial biogenesis, and also indirectly affects cellular physiological functions. Msp1, a yeast mitochondrial outer membrane AAA ATPase, has been shown to eliminate the excess precursor proteins from the mitochondrial translocases when the cells encounter the import stress by overexpressing bipartite signal-containing proteins. ATAD1 is a predicted human homologue of Msp1 and is shown to extract the mislocalized peroxisomal proteins from the outer mitochondrial membrane, however, the role of ATAD1 in protecting the mammalian cells from import stress has not been established. We aimed to determine whether ATAD1 is involved in eliminating the proteins that plugged on the mitochondrial import channel in the human cells. To test the hypothesis, we first developed a doxycycline-inducible mitochondrial import blocking system using dihydrofolate reductase (DHFR) fused to the N-terminus of human MIC60 in the HeLa cell. Upon adding methotrexate (MTX) which stabilizes

DHFR domain, this chimeric protein could clog translocase of outer membrane (TOM) channel and the part of N-terminus would be anchored on the mitochondrial inner membrane. Localization of MTX-DHFR domain complex on the mitochondrial outer membrane had been confirmed in both proteinase K protection assay and the immunofluorescent stain. In addition, the un-cleaved precursor of endogenous COX5A was accumulated in the cells, which clearly indicated the decrease in import efficiency. Based on this blocking approach, we further generated the cells with ATAD1 knockdown or CMV-driven overexpression. Manipulating ATAD1 expression level did not affect the removal of blocking chimeric protein, the clearance of COX5A precursor, and the cell viabilities. This work demonstrates that human ATAD1, unlike the protective role of Msp1 in yeast, couldn't ameliorate the mitochondrial import stress. However, the import blocking approach provides a platform for better understanding of other machinery in mitochondrial quality control.

B448/P2831

Identifying Domains of the Drosophila Ribonucleoprotein Clueless Critical for Clueless Particle Dynamics and Assemb

H. Hwang, R. T. Cox; USUHS, Bethesda, MD

Clueless (Clu) is a highly conserved ribonucleoprotein whose loss causes abnormal mitochondrial morphology and malfunction. Previous studies from our lab and others have shown that Clu is required for physiological functions such as energy production, metabolic pathways, stress responses, and mitochondrial quality control in various species. Drosophila *clu* mutants live less than a week, are sterile, and have mislocalized mitochondria. Remarkably, Clu forms highly dynamic cytoplasmic particles juxtaposed to mitochondria. Clu particles are formed or dispersed depending on the nutrient state of the cell or in response to various stressors. As we showed that Clu associates with ribosomes in mitochondrial fractions and others showed it appears to be involved in mitochondrial co-translational import in Arabidopsis, these particles could be involved in mRNA regulation. Clu has multiple domains: DUF727, CLU, and tetratricopeptide repeats (TPR). We previously demonstrated that Clu can self-associate. However, whether this happens as a dimer or multimer and which domains of Clu contribute to forming Clu particles is not known. To answer this question, we utilized confocal live-imaging with *Drosophila* expressing Clu deletion mutant constructs. We generated fly stocks expressing ectopic full-length or domain-deleted Clu tagged with mScarlet-i at the C-terminus under the control of the *UASp-Gal4* system. We then generated flies ectopically expressing mScarlet-I constructs in germ cells in the background of Clu GFP trap. We will present data from live-imaging demonstrating which domains are critical for interacting with endogenous Clu and which domains are important for forming particles. As mitochondrial co-translational import is poorly understood in metazoans, and Clu appears to play a role regulating transcripts of mitochondrial proteins encoded in the nucleus, these finding will shed light on how mitochondria regulate protein import during metabolic shifts in the cell. Understanding this important process is relevant to many different cell types, including germ cells and neurons.

B449/P2832

Mitophagy in heteroplasmic bivalve mollusks with DUI

H. Hosseini Khorami, S. Breton, A. Angers; University of Montreal, Montreal, QC, Canada

Mitochondrial heteroplasmy, the presence of more than one mitochondrial DNA in a cell or an individual is considered as a major factor in mitochondrial diseases. Strict maternal inheritance (SMI), by which

only the mother's mitochondria are passed to the offspring is regarded as an important mechanism to insure the maintenance of homoplasmy. In species with SMI, mitophagy is thought to play a major role in limiting heteroplasmy by elimination of paternal mitochondria in embryos and degradation of defective mitochondria in adults. Unlike most animal species, several bivalve mollusks pass the paternal mitochondrial genome to the offspring through a system called double uniparental inheritance (DUI). The molecular mechanisms behind this peculiar transmission that implies high degrees of heteroplasmy are largely unresolved. To gain insight into this phenomenon, we have established a system of primary cell culture from *Mytilus edulis* tissue dissociation that allow us to keep proliferating cells in vitro for several weeks. We showed that cultures established for dissociation of male mantle cells maintain a high degree of heteroplasmy, with germline progenitors showing the highest proliferation rate. Cells obtained from female tissue show a similar degree of germ cell proliferation but remained largely homoplasmic whereas male and female gill cells showed low heteroplasmy and only modest proliferation of unknown cell types. We induced mitophagy in these cultures by treatment with 100 uM CCCP (Carbonyl cyanide m-chlorophenyl hydrazone) for different times. We examined response to CCCP by probing Beclin1, a core component of autophagosome nucleation. We found that cells of male and female origin responded differently to the treatment. Female cells showed increased mitophagy after 2h of treatment, whereas male cells dose not respond or showed decrease beclin1 fluorescence. Further investigation into the nature of this compensation mechanism is likely to shed light in a possible involvement of mitophagy in the maintenance of heteroplasmy in species with DUI.

Receptors, Transporters, and Channels

A novel ammonium transporter functions as a lysosomal detoxifier

R. Levin Konigsberg[1], A. Nigam[2], K. Mitra[3], K. Spees[1], P. Hivare[3], Y. Krishnan[3], M. C. Bassik[1]; [1]Genetics, STANFORD SCHOOL OF MEDICINE, Stanford, CA, [2]Computer Science, STANFORD UNIVERSITY, Stanford, CA, [3]Chemistry, University of Chicago, Chicago, IL.

Ammonia is a ubiquitous toxic by-product of cell metabolism. While systemic ammonia detoxifying mechanisms are well understood, only a small subset of cell types —mainly in the liver— express the necessary machinery to perform these reactions. Thus, how ammonia affects cell physiology and the molecular mechanisms whereby most cells tolerate and detoxify physiological levels of ammonia are incompletely understood. Our work describes a lysosomal co-transport mechanism whereby lysosomes export "ion-trapped" ammonium —along with chloride— to the cytosol, preserving the physiology and function of these organelles. Through a genome-wide CRISPR screen for regulators of macropinocytosis, we found SLC12A9 to be critical for membrane trafficking homeostasis. We show that SLC12A9 —previously reported as a plasmalemmal protein without ion transport capacity— is a lysosomal ammonium transporter. SLC12A9 KO cells showed a vacuolation phenotype with abnormally large lysosomes and increased levels of cellular ammonia. These phenotypes were rescued upon removal of a metabolic source of ammonium, inactivation of the lysosomal proton pump (vATPase) or exogenous expression of WT-SLC12A9. SLC12A9-mediated ammonium transport was dependent on the presence of chloride and on conserved chloride-binding residues among the SLC12A family of transporters. This was further supported by molecular dynamics simulations using the predicted structure of SLC12A9. Our findings suggest that SLC12A9 is an ammonium - chloride co-transporter that functions at the endo-

lysosomal level. Functionally, SLC12A9 inactivation impaired lysosomal osmolarity, cargo delivery, and fission, highlighting its critical role in the fundamental physiology of this organelle

B451/P2834

Investigating the C-terminal of KCNT1 to see its regulatory effects on K^+ and Ca^{2+} homeostasis, inspired from a patient with Brugada syndrome

P. Tsai[1], C. Pan[2,3], Y. Liao[4], J. Juang[5,6], F. Tsai[1,6]; [1]Department and Graduate Institute of Pharmacology, College of Medicine, National Taiwan University, Taipei, TAIWAN, [2]Department of Life Science, College of Life Science, National Taiwan University, Taipei, TAIWAN, [3]Graduate Institute of Brain and Mind Sciences, College of Medicine, National Taiwan University, Taipei, TAIWAN, [4]Department of Life Sciences, College of Health Sciences and Technology, National Central University, Taoyuan, TAIWAN, [5]Department of Medical Genetics, National Taiwan University Hospital, Taipei, TAIWAN, [6]Department of Internal Medicine, National Taiwan University Hospital, Taipei, TAIWAN.

Potassium sodium activated channel subfamily T member 1 (KCNT1) is a Na^+-activated K^+ channel known to carry an enormous cytoplasmic tail. In 2014, Dr. Jyh-Ming Juang and his colleagues identified a mutation, *KCNT1:R1106Q*, from a patient diagnosed with Brugada syndrome (BrS), which is an inheritable sudden cardiac death disease. Besides KCNT1's ability of K^+ current modulation, we found that the store-operated Ca^{2+} entry (SOCE) is also enhanced, which can be further increased with the point mutation of R1106Q. On the other hand, with the truncation of its C-terminus, KCNT1 lost its capability of SOCE promotion, suggesting C-terminus' importance in maintaining Ca^{2+} homeostasis. By performing patch clamp, the result shows that the change in SOCE intensity cannot simply be attributed to the difference in K^+ outward current. Since the amplified K^+ current may not be the only reason for SOCE increase, we are seeking the underlying mechanism. Stromal interaction molecule 1 (STIM1) resides on the endoplasmic reticulum (ER), which is crucial for SOCE assembly, we found that its puncta density is increased with KCNT1 overexpression, this may be another proof that the KCNT1 tail can regulate SOCE intensity independently. The aforementioned results suggested that besides electrostatic balance, KCNT1 might alter cellular Ca^{2+} homeostasis with a distinct, K^+-independent mechanism, thus may bring up some innovative treating strategies of KCNT1-related disease.

B452/P2835

The effects of Phosphatidylinositol 3,5-bisphosphate on the interdependent transport of $Ca^{2+}$and H^+on yeast vacuoles

C. Zhang; Biochemistry, University of Illinois At Urbana–Champaign, Urbana, IL.

Yeast vacuoles are acidified by the vacuolar type H+-ATPase (V-ATPase), a protein complex comprised of the membrane embedded VO complex and the soluble cytoplasmic V1 complex. The assembly of the V1-VO holoenzyme on the vacuole is stabilized in part through interactions between the VO a-subunit ortholog Vph1 and the lipid phosphatidylinositol 3,5-bisphospate (PI(3,5)P2). PI(3,5)P2 also affects vacuolar Ca2+ export through the channel Yvc1, and the Ca2+ importing pump Pmc1. Here we asked if H+ and Ca2+ transport activities were connected through PI(3,5)P2. We found that overproduction of PI(3,5)P2 by the hyperactive fab1^{T2250A} mutant led to augmented vacuole acidification, whereas the kinase inactive fab1^{EEE} mutant attenuated the formation a H+ gradient. Separately, we tested the effects of extraluminal Ca2+ on vacuole acidification. Adding Ca2+ blocked vacuole acidification, whereas chelating Ca2+ accelerated acidification, illustrating that affecting Ca2+ transport alters vacuole

acidification. The effect of adding Ca2+ on acidification was eliminated when the Ca2+/H+ antiporter Vcx1 was absent. Together this shows that the H+ gradient across the vacuole membrane can collapse during Ca2+ stress is Ca2+ through Vcx1 activity. To see if the link between Ca2+ and H+ transport was bidirectional we examined Ca2+ transport when V-ATPase activity was inhibited with Bafilomycin. When added at the start of the experiment Bafilomycin blocked Ca2+ uptake whereas adding the inhibitor after establishing a H+ gradient caused a rapid release of Ca2+. Together, these data illustrate that Ca2+ transport and V-ATPase efficacy are connected.

B453/P2836

Structural and functional insights into a peroxisomal fatty-acid transporter

M. Gupta[1], M. Dickinson[2], A. Myasnikov[3], R. M. Stroud[4]; [1]Department of Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA, [2]University of Washington, Seattle, WA, [3]École polytechnique fédérale de Lausanne, Lausanne, SWITZERLAND, [4]Department of Biochemistry and Biophysics, University of California, San Francisco, CA.

Objective: To elucidate mechanism of fatty-acid transport using biochemistry and structural biology Methods: We expressed the membrane protein in insect cells (SF), extracted the protein using detergent and purified using affinity tags. We performed biochemical characterization of the protein and used cryoEM to determine high-resolution structures in various conditions. Summary: Peroxisomes are ubiquitous eukaryotic organelles that form a focal point for multiple metabolic pathways. Lipid metabolism, and in particular, fatty acid transport related to it, depend heavily on peroxisomal membrane proteins that have specifically evolved for such purposes. The ATP-dependent cassette (ABC) transporters of 'D' subfamily' reside in the peroxisomal membrane and are responsible for fatty acid import into the peroxisomes, defects in which process are related to various metabolic disorders. Mutations in ABCD1 cause X-linked adrenoleukodystrophy (X-ALD) which manifests as mild to severe central nervous system (CNS) demyelination. Dysfunction of ABCD3 and/or peroxisome biogenesis factors (PEXs) may cause Zellweger syndrome (ZS), a heterogeneous group of peroxisome assembly disorders. In addition to inherited diseases, reduced peroxisomal function is associated with aging and pathogenesis of age-related acquired diseases like diabetes, neurodegenerative disorders. Key gaps in understanding the function of ABCDs in metabolism and disease are due to lack of structural details, particularly of their conformational plasticity during substrate transport, and how this is compromised during aging and disease. Using CryoEM, we determined the first high-resolution structures of any human peroxisomal ABC transporters (ABCD3). We show that the purified protein in the detergent is active in vitro. With the help of the structures and biochemical assays, we propose a mechanism of fatty-acid transport through these transporters and identify a potentially new substrate. We are also exploring interaction among peroxins and PMPs (peroxisomal membrane proteins) and have noteworthy results which help us comprehend PMP recruitment on peroxisomal membranes and peroxisome biogenesis. Conclusion: ABCD3 is a homodimer with fatty-acid (phytanoyl-CoA) as a primary substrate. The protein possibly splits fatty-acid and CoA moiety of the fatty-acyl ester using thioesterase activity as part of the transport mechanism. ABCD3 associates with Pex19 at the N-terminus and may serve as the initial step of membrane protein recruitment of the membrane proteins.

Cryo-EM structures of the Inward Rectifier K+ channel Kir7.1 .

A. Peisley, first, C. Hernandez, M. Su, R. Cone; Life Sciences Institute, University of Michigan, Ann Arbor, MI.

Inward rectifier potassium (Kir) channels are a class of K+ channels responsible for maintaining membrane potential and extracellular K+ concentrations. Kir7.1 is localized to a variety of ion-transporting epithelia including the apical membranes of retinal pigmented epithelium (RPE). Functional studies have established the involvement of Kir7.1 in maintaining subretinal K+ concentration and the RPE monolayer integrity. Patients diagnosed with adult onset retinitis pigmentosa, a progressive loss of photoreceptors, have been found to carry heterozygous missense mutations resulting in Arg-to-Gln (R162Q) and Glu-to-Ala (E276A) mutants of Kir7.1. We sought to understand the impact of these mutations on the structure of Kir7.1 channels using cryo-electron microscopy (cryo-EM).
Kir7.1 is the most divergent inward rectifying K+ channel whose structure has yet to be determined. Here we present the first high-resolution cryo-EM structures of full-length human Kir7.1 with phosphatidylinositol 4,5-bisphosphate (PIP2) and that of the retinopathy associated mutants R162Q and E276A. Each subunit of the Kir7.1 tetrameric channel consists of two transmembrane domains, a pore-forming loop containing the selectivity filter, and two cytoplasmic polar tails. To gain insight into the structural organization that governs the gating mechanism of Kir7.1 channels, we complexed Kir7.1 with PIP2 known to stabilize the open conformation of Kir channels. The structures of Kir7.1-PIP2 showed that PIP2 faces hydrophobic pockets of lipids of the transmembrane domain on the cytoplasmic side, and favors the rotation of the cytosolic domain that is relatively independent of the pore-forming domain, to adopt a conductive conformation of the channel. To understand mechanistically how the retinopathy associated mutations affect channel function we also determined their structures by cryo-EM. The R162Q mutant is located at the interface of the cytosolic and transmembrane domains in the PIP2 binding site. The channel harboring this mutation was found to be in a subconductance state and stabilized in an extended confirmation with a constricted pore. The E276A mutation is located in the highly conserved G-loop gate. We observed a rotation of the cytosolic domains relative to the transmembrane domains of the channel to a state reminiscent of the polyamine blocked conformation. Our results provide evidence of stabilization of channel conformations by Kir7.1 mutants as an underlying cause of disease.

A common mechanism of Sec61 translocon inhibition by small molecules

S. Itskanov[1], **L. Wang*[2]**, T. Junne[3], R. Sheriff[2], L. Xiao[4], N. Blanchard[5], W. Q. Shi[6], C. Forsyth[4], D. Hoepfner[7], M. Spiess[3], E. Park[2,8]; [1]Biophysics Graduate Program, University of California, Berkeley, Berkeley, CA, [2]Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, [3]Biozentrum, University of Basel, Basel, SWITZERLAND, [4]Department of Chemistry and Biochemistry, The Ohio State University, Columbus, OH, [5]CNRS, LIMA, UMR 7042, Université de Haute-Alsace, Université de Strasbourg, Mulhouse, FRANCE, [6]Department of Chemistry, Ball State University, Muncie, IN, [7]Novartis Institutes for BioMedical Research, Novartis Pharma AG, Basel, SWITZERLAND, [8]California Institute for Quantitative Biosciences, University of California, Berkeley, Berkeley, CA.

*The first two authors contributed equally to this work.
The Sec61 complex forms a protein-conducting channel in the endoplasmic reticulum (ER) membrane

that is required for secretion of soluble proteins and production of many membrane proteins. Several natural and synthetic small molecules specifically inhibit the Sec61 channel, generating cellular effects that are potentially useful for therapeutic purposes, but their inhibitory mechanisms remain unclear. Here we present near-atomic-resolution structures by cryo-EM of the human Sec61 channel inhibited by a comprehensive panel of structurally distinct small molecules—cotransin, decatransin, apratoxinF, ipomoeassinF, mycolactone, cyclotriazadisulfonamide (CADA)and eeyarestatin I (ESI). All inhibitors bind to a common lipid-exposed pocket formed by the lateral gate and plug domain of the channel. Mutations conferring resistance to the inhibitors are clustered at this binding pocket. The structures indicate that Sec61 inhibitors stabilize the plug domain of Sec61 in a closed state, thereby preventing the protein-translocation pore from opening. Our study reveals molecular interactions between Sec61 and its inhibitors in detail and offers the structural framework for further pharmacological studies and drug design.

PALM combined with ExM and advanced analysis show novel spatiotemporal organization of the AT1 receptor

C. Andersen[1], Y. M. Zulueta Díaz[1], C. Lagerholm[2], P. Wiseman[3], **E. C. Arnspang**[1]; [1]University of Southern Denmark, Odense, DENMARK, [2]University of Oxford, Oxford, UNITED KINGDOM, [3]McGill Unversity, Monteral, QC, CANADA.

Investigation of spatiotemporal interactions between a ligand and a receptor in the plasma membrane (PM) at the nanoscale, is a challenge [1]. Specially, the mechanisms by which Angiotensin II type 1 Receptor (AT1R) is distributed and diffused in the PM remains unclear, despite their crucial role in cardiovascular homeostasis [2,3]. Super-resolution techniques and images analysis are powerful tools to investigate protein dynamics in complex cellular environment [4,5]; however, there is only a limited number of approaches that combine super-resolution imaging and measurement of dynamics in the presence of spatially and temporally heterogeneous structures [6,7]. The aim of this study is to obtain quantitative information about dynamics and organization of AT1R, and their corresponding receptor-ligand complexes in living cells. For this purpose, Photoactivated localization microscopy (PALM) combined with image spatial-temporal correlation analysis were used. To study the organization of the receptor at the nanoscale, Expansion Microscopy (ExM) combined with PALM was performed.
This study revealed that AT1R lateral diffusion increased after binding to the agonist, Angiotensin II (Ang II) while no change for either the biased agonist, SII-Ang II or the antagonist, Losartan, was observed. The receptor diffusion was found to be transiently confined in the PM. Additionally, ExM showed that AT1R form nano clusters at the PM, and the cluster size significantly decreased after Ang II treatment. These results show that Ang II interaction cause reorganization and changes in the dynamics of AT1R at the PM. We here present quantitative data that helps explain AT1R distribution and dynamics in mammalian cell and contributes to a better understanding of receptor mechanism.

Lysosomal-dependent remodeling of endoplasmic reticulum-plasma membrane contacts drives neurodegeneration

M. Casas[1], K. Hino[2], N. Vierra[1], S. Simó[2], J. Trimmer[1], R. Dixon[1], E. Dickson[1]; [1]Department of Physiology and Membrane Biology, University of California, Davis, Davis, CA, [2]Department of Cell Biology and Human Anatomy, University of California, Davis, Davis, CA.

Lysosome dysfunction is associated with the pathogenesis of a variety of neurodegenerative disorders. Thus, linking lysosome abnormal mechanisms to disruption of neuronal fidelity offers opportunities to understand the molecular basis of neurodegeneration and to potentially identify novel therapeutic targets. One mechanism that lysosomes use to communicate and receive instruction is via transfer of cholesterol at ER-lysosome membrane contact sites (MCSs) where the Niemann Pick C1 cholesterol transporter (NPC1) is a key gatekeeper that facilitates cholesterol flux from the lysosome to the ER, where it is further distributed to other cellular membranes. Briefly, loss of NPC1 function leads to the fatal neurodegenerative disorder, NPC disease, which is characterized by the progressive neurodegeneration of several brain regions. Despite altered ER contacts with lysosome, Golgi and Mitochondria membranes, in addition to a gross Ca^{2+} handling defect being reported in NPC1 deficient cells, the molecular mechanism(s) linking NPC1 loss of function to NPC disease associated neuropathology are still poorly understood. Giving the importance of ER MCSs, we wanted to study if molecular contents of other ER junctions are also altered and contribute to neurodegeneration observed in the NPC disorder. In neurons, a prominent ER-PM contact site forming protein is the $K_V2.1$ ion channel, which tunes lipid and Ca^{2+} nanodomains. Using super-resolution TIRF nanoscopy, high-speed fluorescence imaging, biochemistry, and animal models of NPC disease, we determined that NPC1 loss of function increases ER-PM MCSs and the area, density, and number of PM $K_V2.1$ channels in neurons. Moreover, interactions between $K_V2.1$ and Ca_V1 voltage-gated Ca^{2+} channels are elevated and result in significantly increased Ca_V1 clustering and activity, leading to elevated neuronal Ca^{2+} entry. A critical consequence of such enhanced $K_V2.1$-dependent Ca_V1 Ca^{2+} entry is neurotoxic elevations in mitochondrial Ca^{2+} concentrations. Noteworthy, reducing $K_V2.1$ phosphorylation with a Cyclin-dependent kinase 5 inhibitor or disrupting $K_V2.1$-Ca_V1 interactions using a synthetic peptide rescues the increases in Ca_V1 clustering, mitochondrial Ca^{2+} and neurotoxicity seen in NPC neurons. Collectively, these data demonstrate that NPC is a nanostructural ion channel clustering disease with altered ion channel distribution/activity and ER-PM remodeling that contribute to neurodegeneration.

Characterization of zebrafish ABCG2 homologs

J. R. Thomas[1], R. Robey[1], W. Frye[1], C. Inglut[1], A. Warner[2], D. Butcher[2], J. Matta[2], E. Edmondson[2], M. Gottesman[1]; [1]Center for Cancer Research, National Cancer Institute, Bethesda, MD, [2]National Cancer Institute, Frederick, MD.

A principal component of the blood-brain barrier (BBB) is the expression of high levels of the ATP-binding cassette (ABC) transporters P-glycoprotein (P-gp, encoded by ABCB1) and ABCG2 (encoded by ABCG2) on the apical surface of brain microvascular endothelial cells (BMECs). ABC transporters at the BBB efflux toxins and a wide range of therapeutic drugs back into the bloodstream, preventing brain access. Zebrafish have emerged as an advantageous model for studying the BBB, however little information exists regarding zebrafish ABC transporters which comprise the BBB. We recently identified

and characterized the zebrafish homologs of P-gp (Abcb4, Abcb5), and now seek to advance this by characterizing the zebrafish homologs of ABCG2 (Abcg2a, Abcg2b, Abcg2c, Abcg2d). In situ hybridization with RNAscope™ probes was used to selectively detect expression of *abcg2a-d* in adult zebrafish tissues. The most widely expressed homolog was *abcg2a* which was detected in BMECs of the BBB, the intestine/GI tract, liver and ovaries. We noted *abcg2b* expression in the intestine/GI tract, *abcb2d* was detected in the liver, and all four homologs were detected in the ovaries. We stably expressed human ABCG2 and zebrafish *abcg2a-d* homologs in HEK293 cells to determine substrate overlap using known ABCG2 substrates in efflux and cytotoxicity assays. Abcg2a, -b, and -c, transported pheophorbide a, and only Abcg2a transported mitoxantrone. In agreement, only Abcg2a also conferred resistance to mitoxantrone and the additional cytotoxic substrates CUDC-101 and NMS1286937. Abcg2a has the greatest and Abcg2d has the least substrate overlap with ABCG2. In conclusion, our data indicate *abcg2a* is most phenotypically similar to ABCG2 and is likely the relevant homolog for BBB studies in zebrafish. We are developing a transgenic zebrafish model which expressing luciferase in the brain parenchyma. If the BBB is perturbed for example by ABC transporter inhibition or physical disruption, BBB impermeable luciferase substrates will be able to cross the BBB, resulting in a bioluminescent signal. We tested the substrates coelenterazine native, coelenterazine h and furimazine, and found they are substrates of both ABCG2 and Abcg2a. This indicates our transgenic model will be capable of detecting Abcg2a-mediated BBB disruption, allowing for a high-throughput method of screening zebrafish BBB integrity.

Electric stress opens a transmembrane route in Na,K-ATPase alpha subunit

G. Silkuniene, U. Mangalanathan, A. G. Pakhomov, O. N. Pakhomova; Frank Reidy Research Center for Bioelectrics, Old Dominion University, Norfolk, VA.

Several studies reported that electric fields could form a pore in a lipidic portion of the membrane and could suppress the function of ion channels, possibly by electroconformational changes in the channel proteins. The structural alterations in channel proteins likely impact membrane permeability, providing pathways for transporting ions and molecules across the plasma membrane. Therefore, this work aimed to identify ion channels and pumps affecting membrane permeabilization after cell injury by electric pulses using high-throughput screening (HTS). We generated gene knock-outs (KOs) in human cell monocytes U937 using CRISPR/Cas9 gene editing approach and obtained a total of 328 derivatives with KO for a single gene. Each KO was exposed to 20 electric pulses of 300 ns duration, all delivered at 7 kV/cm and 20 Hz. In 50 min, cells were imaged for YoPro-1 (YP) uptake on an Olympus IX83 microscope configured for HTS. It was found that KO of the ATP1A1 gene coding for the alpha-1 subunit (ATP1A1) of Na,K-ATPase (NKA) had reduced YP uptake by up to 30%. The effect of lower YP uptake was confirmed under the different conditions. YP uptake was measured within 5 min after application of electric field (10 pulses of 300ns, 7 kV/cm, at 5Hz) by timelapse imaging on a scanning confocal microscope. YP fluorescence in ATP1A1 KO cells was ~20% lower than in control cells, thus confirming the results of HTS. Next, ATP1A1 expression was suppressed using shRNA lentiviral particles. The YP uptake reduction in ATP1A1 knock-down (KD) cells was up to 25% in HTS and confocal setups. Additionally, it was noticed that the initially strong reduction effect in YP uptake tended to weaken with time after transduction. It was hypothesized that the function of the ATP1A1 gene was compensated by paralog genes typically low expressed in U937 cells. The expression levels of other NKA α subunits were determined. Results revealed that ATP1A4 expression was upregulated in ATP1A1 KD cells. Therefore, upregulation of NKA paralog genes can compensate for inhibited ATP1A1. Finally, it was tested if inhibition of NKA with

ouabain affects the YP uptake after electric pulses. It was found that the presence of ouabain did not reduce YP uptake but increased it by 21%. This result showed that reduced YP uptake after electric pulse injury in ATP1A1 KOs is not related to NKA physiological function as an ion pump but instead linked to modification in protein conformation. Overall, the study identified ATP1A1 as a potential protein target (or one of the protein targets) for cell membrane permeabilization by electric fields. Support: AFOSR MURI grant FA9550-15-1-0517 to AGP.

A structural and functional analysis of Nematostella vectensis major intrinsic proteins in Saccharomyces cerevisiae

J. Grissom, J. Taylor, O. Mikula, M. Shahani, A. M. Reitzel, R. Chi; Biological Sciences, The University of North Carolina At Charlotte, Charlotte, NC.

There is currently a major gap in understanding tissue grade organisms from early diverging phyla, particularly within the context of understanding placatory responses to osmotic variabilities that can result from salinity fluctuation due to global climate change. A key protein family essential for the regulation of intracellular water and solute concentrations are the Major Intrinsic Proteins (MIPs), these include aquaporins (Aqps) and aquaglyceroporins (Glps). Here, we report the identification and functional analysis of MIPs in Nematostella vectensis, a member of the early diverging phyla that represents a unique group of tissue grade organisms. Using a molecular evolution approach, we successfully identified each MIP node in *N. vectensis*. Putative MIPs were cloned and recombinantly expressed in budding yeast, *Saccharomyces cerevisiae* and tested for functionality. *N. vectensis* MIPs displayed varying degrees of functionality, ranging from no effect to lethality, suggesting a phylogenetic approach paired with an in vivo functionality assay is critical for their characterization. Total N. vectensis MIP transcripts were also quantified during acute and long-term salinity exposure which also support our functional yeast results. Furthermore, based on high confidence protein structure homology modeling, we demonstrate a significant correlation between biophysical pore properties that can accurately predict functionality.

Host Nucleotide Manipulation StrategiesImplemented by an Intracellular Bacterium

L. Blanchet, A. Subtil; Institut Pasteur, Paris, FRANCE.

The obligate intracellular bacteria *Chlamydia trachomatis* are auxotrophic for nucleotides. The expression of unique transporters enables capture of nucleotides from the host cell. However, to reach the bacteria, host-derived nucleotides need to cross the membrane of the vacuole in which the bacteria multiply, called the inclusion. We investigated the mechanism(s) by which nucleotides reached the inclusion lumen, and whether *Chlamydia* modulated nucleotide metabolism in the host.Overexpression of tagged forms of host nucleosides/nucleotides transporters indicate that two such transporters, ENT1 and AXER, are relocated to the inclusion membrane upon infection. Furthermore, silencing of the expression of either one of the corresponding genes using siRNA leads to an about 2-fold decrease in the generation of infectious bacteria, bringing additional support for their implication in nucleoside/nucleotide transport to the *Chlamydia* inclusion. We implemented click-chemistry coupled to quantitative microscopy to directly measure the transport of two nucleotides, ATP and CTP, to the inclusion. Preliminary data support the hypothesis that ATP transport to the *Chlamydia* vacuole uses

AXER, while CTP transport uses a different mechanism. Finally, we identified a post-translational modification triggered by infection on the enzyme that engages purine biosynthesis in the host. Biochemical assays are ongoing to test its incidence.In conclusion, completion of this work will answer the longstanding question of nucleotide transport to the *Chlamydia* inclusion and bring mechanistic insight on the modulation of nucleotide biosynthesis in the host. By doing so, it might identify novel targets for therapeutic intervention against *Chlamydia* infection. It will also shed light on the regulation of purine biosynthesis, and thereby help improving nucleoside-based chemotherapeutic strategies.

Membrane stretching activates putative ion channel Pkd2 to promote calcium spikes during cytokinesis

A. Poddar[1], Y. Hsu[2], F. Zhang[1], A. Shamma[3], Z. Kreais[3], C. Muller[1], M. Malla[1], A. Ray[3], A. Liu[2], Q. Chen[1]; [1]Department of Biological Sciences, The University of Toledo, Toledo, OH, [2]Department of Mechanical Engineering, University of Michigan, Ann Arbor, MI, [3]Department of Physics and Astronomy, The University of Toledo, Toledo, OH.

During cytokinesis of many animal embryos, calcium transients accompany two crucial events, the initiation of cleavage furrow ingression and the separation of daughter cells. We have recently discovered similar transients, termed cytokinetic calcium spikes, in the unicellular model organism fission yeast. These spikes promote cleavage furrow ingression and maintain the integrity of separating cells in yeast. However, as in the embryonic cells, it remains unclear how such calcium spikes are generated. Here, we focused on the likely role of an essential fission yeast channel Pkd2. This plasma membrane protein translocates to the equatorial plane during the cleavage furrow ingression and remains there throughout the cell separation. It promotes cell separation but modulates the furrow ingression through unknown mechanisms. In this study, we first employed a genetically encoded calcium indicator GCaMP to measure the intracellular calcium level throughout the cytokinesis of the *pkd2* mutants. Both *pkd2-81KD* and *pkd2-B42* reduced the separation calcium spikes by 60%, compared to the wild-type. Surprisingly, they also increased the constriction spikes by more than two-fold. Next, to determine how Pkd2 is activated in cytokinesis, we reconstituted this putative channel in vitro. Pkd2 was translated in a cell-free expression system and inserted into giant unilamellar vesicles. It permeated calcium when the membrane was mechanically stretched. Consistent with this result, depletion of Pkd2 in vivo reduced the calcium spike triggered by the hypoosmotic shock by 59%, compared to the wild type. We concluded that membrane stretching activates Pkd2 to promote the calcium influx during cell separation, suggesting that the cytokinetic calcium transients are partially contributed by mechanosensitive channels.

SLC-30A9 is required for zinc homeostasis, zinc mobilization, and mitochondrial health

H. Deng[1], X. Qiao[2], C. Chen[2], X. Wang[2], K. Shen[1]; [1]HHMI-Stanford, Stanford, CA, [2]Institute of Biophysics, Chinese Academy of Sciences, Beijing, China

The trace element zinc is essential for many aspects of physiology. The mitochondrion is a major Zn^{2+} store, and excessive mitochondrial Zn^{2+} is linked to neurodegeneration. How mitochondria maintain their Zn^{2+} homeostasis is unknown. Here, we find that the SLC-30A9 transporter localizes on mitochondria and is required for export of Zn^{2+} from mitochondria in both *Caenorhabditis elegans* and

human cells. Loss of *slc-30a9* leads to elevated Zn^{2+} levels in mitochondria, a severely swollen mitochondrial matrix in many tissues, compromised mitochondrial metabolic function, reductive stress, and induction of the mitochondrial stress response. SLC-30A9 is also essential for organismal fertility and sperm activation in *C. elegans*, during which Zn^{2+} exits from mitochondria and acts as an activation signal. In *slc-30a9*-deficient neurons, misshapen mitochondria show reduced distribution in axons and dendrites, providing a potential mechanism for the Birk-Landau-Perez cerebrorenal syndrome where an SLC30A9 mutation was found.

A "Hot" Date with Capsaicinoids: Molecular Networking meets TRPV1

J. Smith, H. Gaustad, P. Sacha, T. Pluskal; UOCHB, Praha, Czech Republic

Chili plants are known for their production of capsaicinoids, specialized metabolites defined by their vanilloid head and the C9-C11 carbon long tail (acyl moiety). The most well studied capsaicinoid, capsaicin, is a well-characterized agonist of the human pain and heat receptor, TRPV1, and has been used in a wide range of medicinal applications. Despite capsaicin's significant role in medicine, other capsaicinoids remain relatively uncharacterized, with about only 20 capsaicinoid structures roughly reported throughout the literature. Furthermore, most studies exploring capsaicin's biological relevance have not been expanded to capsaicinoids. Utilizing UPLC-HRMS and modern MS computational tools for the analysis of different Capsicum sp. varieties; I have already identified capsaicinoids with an undescribed structure by utilizing feature-based molecular networking. Over 30 different varieties of chilis have been collected for supercritical CO2 extraction and subsequent capsaicinoid library building. In addition to, capsaicinoids biological effects on glucose metabolism are being investigated using a stably transfected cell line expressing rTRPV1. Current experiments to investigate the effects of capsaicinoids are a mixture of calcium influx, western blot, cytotoxicity, and glucose uptake assays. The goal is to create the most complete library of capsaicinoids with corresponding biological information on its activation of TRPV1 and subsequent effects on glucose metabolism. Current experiments show that capsaicin cytotoxic effects trump any therapeutic benefit during excess exposure. Experiments are still being completed regarding the effects of capsaicin on glucose metabolism.

Analysis of endocytic structures and B cell receptor clustering in Diffuse Large B cell Lymphoma Cell lines

A. Roberts[1], A. Arnold[1], S. Scheich[2], X. Zhuang[2], L. Staudt[2], J. Taraska[1]; [1]National Heart Lung and Blood Institute, Bethesda, MD, [2]National Cancer Institute, Bethesda, MD

The B cell receptor (BCR) is the primary receptor on the B cell plasma membrane that interacts with foreign antigens and transmits downstream signaling events that lead to cell activation and antibody production. A necessary first step in the production of antigen specific antibodies is the endocytosis of the receptor-antigen complex. The BCR may be endocytosed through the classical clathrin-mediated pathway or less well characterized clathrin independent mechanisms. Our previous work identified smooth raised membrane structures at the plasma membrane that co-localize with BCR clusters upon activation and mediate endocytosis of large membrane clusters through an actin-dependent hybrid endocytosis pathway. Here, we have extended our analysis of endocytic structures at the plasma membrane in four human B cell lymphoma cell lines: HBL1, TMD8, FL318, and WSU-FSCCL. Using

platinum replica electron microscopy, we identified an increased number of clathrin and smooth raised membrane structures in Diffuse Large B Cell Lymphoma (DLBCL) cell lines compared to control B cells. We also observed differences in density of different types (flat, domed, or sphere) of clathrin structures present on the plasma membrane. Finally we found differences in the rate of BCR recycling from the plasma membrane in germinal center and activated B cell like DLBCL cell lines.

The role of salt bridge networks in the stability and function of the Hxt1 glucose transporter

L. Mailloux, D. Bloor, B. Maddox, J. Humble, J.-H. Kim; Liberty University, Lynchburg, VA

Glucose transport across the plasma membrane is tightly controlled by hexose (glucose) transporters. The yeast *S. cerevisiae* possesses 17 different hexose transporters that belong to the sugar porter subfamily of the major facilitator superfamily (MFS) of transporters. In this study, using homology modeling and site-directed mutagenesis, we identified conserved salt bridge networks within and between the two 6-transmembrane (TM) spanning segments of the yeast glucose transporter 1 (Hxt1) and constructed 15 derivatives of the transporter. Genetic and biochemical analyses show that the disruption of these bridges causes destabilization of the Hxt1 transporter and consequently abolishes transport activity. Of note, the Hxt1 transporters predicted to be locked in either an inward-facing or an outward-facing conformation are unable to complete the transport cycle and are targeted for degradation by cellular quality control machinery. Interestingly, the corresponding mutations in the Rgt2 glucose-sensing receptor are also predicted to arrest the receptor in inward-facing conformations, but do not reduce the stability of the protein; rather, they render Rgt2 constitutively active. This suggests that the salt bridge-forming residues in Hxt1 and Rgt2 may have different structural and functional roles. Taken together, our results provide insight into the role of salt bridge networks in the stability and function of Hxt1 as well as a framework for studying the structure-function relationship of yeast and other fungal glucose transporters, as high-resolution crystal structures are not currently available for them.

Elucidating transport mechanisms of membrane protein variants that confer Alzheimer's risk in African Americans

A. Sekhar[1], K. Stepler[1], R. Robinson[1], **J. Davis**[2]; [1]Vanderbilt University, Nashville, TN, [2]Meharry Medical College, Nashville, TN

Alzheimer's disease (AD), the most common cause of dementia in older adults, disproportionally affects African Americans with an incidence rate as much as three times higher, compared to other racial/ethnic groups. Multiple factors contribute to this racial disparity however, an in-depth understanding of the biological or genetic contributions does not exist. Compelling evidence indicate that genetic variants of the lipid transport protein, ABCA7, is more strongly associated with AD in African Americans. To understand how ABCA7 contributes to AD on the molecular level, we used a combination of structural and cell biology techniques. We have found that the ABCA7 T319A variant, that confers risk in African Americans, is expressed, localizes to the plasma membrane and has reduced ATPase activity when expressed in human cell lines. Proteomic studies indicate reduced levels of the phospholipase C eta (PLCH1) protein in cells that expressed ABCA7 T319A compared to wild-type. PLCH1 plays a key role in the metabolism of phosphoinositol bisphosphate, PIP_2. The ABCA7 T319A protein variant displays

reduced binding with PIP_2. Our results suggest that this ABCA7 variant may contribute to AD by reducing the levels of PIP_2, a phospholipid reported to be decreased in the AD brain. These results provide a framework for targeting mechanisms that can increase PIP_2 levels as an effective strategy mitigating AD disparities.

Tetraspanin CD82 regulates Epidermal Growth Factor Receptor signaling by modulating molecular organization and dynamics

S. Restrepo Cruz, E. A. Burns, K. A. Lidke, D. S. Lidke, J. M. Gillette; University of New Mexico, Albuquerque, NM

Molecular interactions on the plasma membrane significantly influence the outcomes of signaling events fundamental to cell function in both normal and disease states. Tetraspanins, a superfamily of transmembrane proteins, play a vital role as scaffolding proteins on the membrane, forming structural platforms termed Tetraspanin-Enriched Microdomains (TEMs). By facilitating compartmentalization, tetraspanins have been shown to act as regulators of cellular signaling, enhancing the recruitment of intracellular signaling proteins to the membrane, and modulating the organization of transmembrane proteins. Signaling by the Epidermal Growth Factor Receptor (EGFR), a receptor tyrosine kinase, has been shown to depend on the dimerization, auto- and cross-phosphorylation, and internalization of the receptor; these processes are dependent on the dynamics and landscape of the plasma membrane. While disruption of EGFR signaling has been implicated in the development and progression of several cancers, the efficacy of EGFR-targeting drugs remains limited. Genetic and biochemical studies have previously shown that specific tetraspanins can directly and indirectly influence EGFR signaling and internalization. However, the molecular mechanisms by which tetraspanins modulate EGFR signaling are not fully understood. Here, we assess the role of tetraspanin CD82 in the regulation of EGFR signaling. Using multiple Super Resolution (SR) microscopy techniques to achieve sub-diffraction limit resolution, we evaluate the molecular organization of EGFR and CD82 on the plasma membrane of cells under basal and EGF-activated conditions. Clustering analysis of reconstructed SR images reveals that expression of CD82 enhances ligand-independent clustering of EGFR but restricts ligand-dependent changes in EGFR organization. Moreover, EGF treatment is also found to alter the molecular organization of the CD82 scaffold. Additional biochemical analyses show that while CD82 can attenuate EGFR signaling, this attenuation is specific to discrete EGFR phosphorylation sites. Furthermore, single-particle tracking and receptor internalization analyses show that CD82 expression modulates EGFR dynamics, resulting in altered receptor mobility and enhanced internalization. Ongoing mutational studies of CD82 provide mechanistic insight into key residues responsible for the CD82-mediated regulation of EGFR signaling. Collectively, these studies suggest that the CD82 scaffold regulates EGFR signaling through modulation of molecular organization and receptor dynamics and implicate CD82 as a potential target for improving EGFR-directed therapies.

UNIQUE responses of lens epithelial cells induced by nuclear cataract formation in AQP0 mutant mice

W.-K. Lo, S. Biswas; Morehouse School of Medicine, Atlanta, GA

Objective: A single epithelial layer is located anteriorly over the entire underlying fiber-cell mass of the lens. AQP0 water channel protein is distributed in the fiber cell membrane whereas AQP1 is in the

epithelial cell membrane. In the AQP0-KO mice, a distinct cataract is consistently formed in the fiber cells of the lens core. This study investigated unique responses in the lens epithelium induced by cataractogenesis in lens fibers of AQP0-KO mice. Methods: Immunolabeling of AQP1, Cx43, and EMT markers, and cell biology techniques were used to examine lenses from WT and AQP0-KO mice (P4-12wks old). Results: In WT, strongly labeled AQP1 was mainly observed in the equatorial epithelial cells (~250 μm along the epithelial layer) on frozen sections and wholemount samples. Only a trace or absence of AQP1 labeling was seen in the central epithelium. In contrast, the AQP0-KO lenses showed significant upregulation of strong AQP1 labeling in the entire anterior epithelial cells at various ages. Furthermore, epithelial-mesenchymal transition (EMT) was also induced by AQP0 deficiency. Using EMT markers, all WT lenses showed negative labeling for α-actin (α-SMA), fibronectin, and vimentin antibodies. In contrast, α-actin was strongly labeled in the entire epithelial layer in AQP0-KO lenses at P8 and older. Several distinct clusters of labeled epithelial cells in multiple layers were seen overlying the anterior lens fiber sutures. Strongly labeled fibronectin was regularly seen in the clusters of migrating EMT cells in the fiber-cell mass. Interestingly, at 2 weeks old, the migrated clusters of labeled mesenchymal cells had reached the lens core, seemingly passing through the enlarged anterior lens suture spaces. These EMT cells showed positively labeled α-actin, fibronectin, Cx43, and AQP1 in the disorganized lens nuclear cell region. By TEM analysis, 10 nm vimentin filaments were seen extensively distributed in EMT cells in the epithelium. Conclusions: AQP1 was significantly overexpressed in the anterior lens epithelium of AQP0-KO mice. This would cause a large increase in water influx from the epithelium into underlying fibers and result in further damage to the cataractous fiber cells. Due to the concomitant induction of EMT by AQP0 deficiency, some epithelial-mesenchymal cells eventually migrate into damaged nuclear fiber cell regions to form a large cataractous mixture containing both epithelial and fiber cell materials.

Mitochondrial Structure and Morphology

B470/P2853

Uncovering the mysterious role cardiolipin plays in shaping mitochondrial structure

K. Venkatraman, I. Budin; Chemistry and Biochemistry, University of California, San Diego, La Jolla, CA.

Cardiolipin (CL) is a unique phospholipid exclusively localized and synthesized in the inner mitochondrial membrane (IMM). In mammalian systems, CL plays numerous mitochondrial roles in optimizing ATP synthesis and shaping cristae formation. However in yeast, it has been a long-standing mystery as to why knockouts of cardiolipin synthase (Crd1p) or CL remodelling enzymes (Taz1p and Cld1p) do not result in any differences in mitochondrial morphology or function. Here we show that CL becomes essential for mitochondrial structure in more saturated lipid environments, as shown via genetic modification of the lipid desaturase, Ole1p, and through microaerobic growth conditions, the latter of which is a hallmark for natural yeast environments. Our results also demonstrate the importance of CL remodelling in increasing the intrinsic curvature and membrane bending capabilities of CL molecules, and thus accentuates the mechanical role CL plays in bending of stiffer membranes. Together, our findings demonstrate that mitochondrial structure is dependent on physical contributions of CL and its interaction with the lipid environment.

B471/P2854

Molecular mechanism of TIM23-mediated mitochondrial protein import revealed by cryo-EM structure and crosslinking analysis

S. I. Sim, Y. Chen, E. Park; Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA.

The identity of membrane-bound organelles in eukaryotic cells depends on their protein composition. The targeting and transport of proteins across membranes is thus critical for organelle function and cellular homeostasis. While protein translocation at the endoplasmic reticulum is relatively well understood, the mechanisms of protein import into mitochondria are poorly defined. Mitochondria are essential organelles that have important roles in oxidative respiration, metabolism, and cell signaling. Approximately 99% of mitochondrial proteins are synthesized as precursors in the cytosol and must be imported into the organelle. Mitochondrial protein import is enabled by membrane-bound translocases, which thread hydrophilic polypeptides through the hydrophobic lipid bilayer during transport. The TIM23 (Translocase of the Inner Membrane 23) complex recognizes presequence-containing precursor proteins (preproteins) and mediates their translocation into the mitochondrial matrix and inner membrane. Though the subunits of TIM23 have been identified through biochemical and genetic studies, the organization of the complex and the molecular basis of its activity remained unclear due to a lack of structural information. Here, we present a 2.7 Å cryo-EM structure of the core TIM23 complex (Tim17-Tim23-Tim44) from *Saccharomyces cerevisiae* accompanied by in-depth biochemical analysis to define the preprotein translocation path in TIM23. Contrary to prevailing models, the membrane protein subunits Tim17 and Tim23 do not form an aqueous pore, but instead have separate, lipid-exposed cavities that face in opposite directions. Using mutational analysis and site-specific crosslinking, we show that the cavity of Tim17 forms the translocation path, while Tim23 plays more of a structural role. In addition, the non-essential subunit Mgr2 acts in coordination with Tim17 to seal the lateral opening of this cavity during active preprotein translocation. Our work forms the structural foundation to understand the mechanism of TIM23-mediated protein import in atomic detail.

Linkage of Myosin 19 to the Mitochondrial Intermembrane space Bridging (MIB) complex

S. Shembekar, A. Attia, P. Nikolaus, U. Honnert, K. Topp, B. Lohmann, M. Bähler; Institute of Integrative Cell Biology and Physiology, WWU Muenster, Muenster, GERMANY.

The actin-based motor myosin 19 (Myo19) localizes to mitochondria and regulates the intracellular distribution of mitochondria in interphase and their inheritance during cell division. The outer mitochondrial membrane (OMM) proteins Miro1/2 that serve as receptors for microtubule-based motors interact directly with Myo19 and stabilize it. In absence of Myo19, mitochondrial inner membrane cristae architecture is disturbed along with impaired OXPHOS and enhanced ROS production. Cristae structure is regulated by the MICOS complex that is essential for cristae junction formation. The MICOS complex is part of a larger Mitochondrial Intermembrane Bridging (MIB) complex that connects the outer and inner membranes of mitochondria. A Turbo-ID screen with full-length Myo19 demonstrated that in addition to Miro1/2, metaxin-3 (Mtx3), a MIB component, and Mic60, a MICOS component, are in close contact to Myo19 *in vivo*. Immunoprecipitation experiments showed that Mtx3 and Mic60 co-precipitated with Myo19, supporting the notion that Myo19 interacts with the MIB complex to maintain structural stability of cristae. To elucidate further how Myo19 couples to the inner mitochondrial membrane (IMM) and regulates cristae structure, we generated Miro1KO, Miro2KO and

Miro1/2DKO cells. Because the lack of Miro1/2 leads to the degradation of Myo19 as mentioned above, we will supplement these cells with mutated Miro1/2 constructs to assess their potential involvement in the linkage of Myo19 to the MIB/MICOS complex. As stated previously, Mtx3 is a potential interactor of Myo19, whose role in MIB/MICOS complex is largely unknown. We will determine the functional significance of Mtx3, especially the role it might have in linking Myo19 to the MIB complex, by using Mtx3KO cells. To understand the formation of cristae architecture, a detailed characterization will be needed of how Myo19 transduces its directed force produced along actin filaments collectively to the outer and inner membranes of mitochondria.

B473/P2856

Identification of a functional metazoan ortholog of a fungal mitochondrial morphology regulator

A. R. Edington, J. Friedman; University of Texas Southwestern Medical Center, Dallas, TX.

Mitochondria are elaborately shaped and highly dynamic organelles whose function is dependent upon their ability to maintain proper morphology. Mitochondrial morphology is maintained in part through the conserved processes of division and fusion. Aberrant mitochondrial morphology is associated with organelle dysfunction and an underlying feature of numerous diseases, including neurodegeneration. While unbiased screens in budding yeast have identified many proteins that are required for normal mitochondrial morphology, many of these factors are not conserved in metazoans and/or have not been functionally characterized. One such protein, which we rename Mitochondria Division Regulatory Protein 1 (Mdp1), has been suggested to regulate mitochondrial morphology by facilitating phospholipid homeostasis and aiding in efficient mitochondrial division. However, Mdp1 lacks a sequence-conserved ortholog in metazoans and its specific functional role is poorly understood. Here, we use Alphafold2 to identify a potential structural analog in humans, which we name MIDP. Depletion of MIDP leads to the formation of lamellar mitochondrial structures, similar to those found in yeast Mdp1 deletion cells. Furthermore, we found that overexpression of human MIDP fragments the mitochondria in a DRP1-dependent manner, akin to Mdp1 in budding yeast, suggestive of a conserved role in mitochondrial division. Consistent with this, using live cell confocal microscopy, we find both MIDP in humans and Mdp1 in yeast can be spatially linked to sites of mitochondrial division. Interestingly, we find that acute depletion of MIDP in human cells causes the mitochondria network to become hyperfused prior to lamellae formation, further implicating the proteins in the regulation of mitochondrial division. Finally, we find that MIDP can rescue the mitochondrial morphology defects of yeast Mdp1 deletion cells, indicating these proteins are indeed functionally conserved. Together, our data suggests that Mpd1 and its structural ortholog MIDP play analogous roles in the regulation of mitochondrial division.

B474/P2857

Novel role for HSPE1 in OPA1 cleavage independent of co-chaperonin HSPD1

N. Yeung, D. Murata, M. Iijima, H. Sesaki; Johns Hopkins University School of Medicine, Baltimore, MD

The majority of the proteins in the mitochondria are imported from the cytoplasm, which requires the protein to be in an unfolded state. A series of chaperones/chaperonins are needed to ensure these proteins are correctly refolded within the mitochondria. The chaperonin, HSPD1, and co-chaperonin, HSPE1, are responsible for ensuring correct folding of proteins in the mitochondrial matrix and defects in this complex are implicated in cancer and neurodegenerative disorders. Our study aims to address how disruption to the HSPD1 and HSPE1 complex results in dysfunctional mitochondria. The depletion of

HSPD1 or HSPE1 leads to mitochondrial fragmentation indicating that these chaperonins could be important in mitochondrial fusion. We observe that only the depletion of HSPE1 results in the inactivation of OPA1, a dynamin related GTPase that is critical for mitochondrial fusion. We demonstrate that this inactivation is mediated by OMA1 which is a stress-activated metalloprotease. The data here suggests a novel role for HSPE1 in regulating mitochondrial morphology that is independent of its chaperonin activity with HSPD1.

Kinases and Phosphatases 2

The mechanism of Cdc14-regulated Rim4-mRNA complex formation during meiosis

W. Feng[1], **R. Zhang**[2], S. Qian[2], F. Wang[2]; [1]Department of Cell Biology, Harvard Medical School, Boston, MA, [2]Department of Cell Biology, UT Southwestern Medical Center, Dallas, TX.

Meiotic gene expression was regulated posttranscriptionally by RNA binding proteins (RBP), e.g., yeast Rim4, that bind meiotic transcripts to ensure their timely translation during meiotic divisions. At the same time, the mechanism that controls general RBP-mRNA dynamics during meiosis remains unclear. Using genetic, biochemical, and cell imaging approaches, we identified a *bona fide* Cdc14 docking site in Rim4's C-terminal low complexity domain (LCD) region, near Rim4's RNA recognition motif. Mutating this site (Rim4[PxLm]) alone causes severe nuclear retention of Rim4 due to impaired nuclear Rim4(PxLm)-mRNA assembly that consequentially drives Rim4 nuclear export. Using a systematic mutagenesis approach, we identified several Cdc14-targeted phosphorylation sites (P-sites) on Rim4. Upon alanine replacement mimicking dephosphorylation on these P-sites, the nuclear retention of Rim4(PxLm) was rescued, indicating that Cdc14 dephosphorylate Rim4 to facilitate Rim4-mRNA assembly in the nucleus. In addition, we discovered that phosphorylated (Rim4-p) forms a complex with Bmh1/2 (14-3-3 family proteins) heterodimer in a phosphorylation-dependent manner, while Bmh1/2-Rim4 excludes mRNAs. Thus, dephosphorylation facilitates Rim4-mRNA assembly with a dual mechanism, i.e., by modulating RRM-mRNA interface with site-specific negative charges and freeing Rim4 from Bmh1/2 to stimulate the Rim4-mRNA complex. Our data further show that Bmh1/2 protects Rim4 from autophagic degradation, as mRNA binding does. The mRNA- and Bmh1/2-free Rim4 stimulates Atg1, resulting in its selective degradation by autophagy during meiotic divisions. Thus, we demonstrate that the cell cycle phosphatase Cdc14 is a master regulator of Rim4's subcellular localization, meiotic functions (Rim4-mRNA complex formation), and stability, and thereby a modulator of meiotic translation.

***Ocrl* mutation leads to reduced neuronal excitability and astrocyte dysfunction in an induced pluripotent stem cell model of Lowe Syndrome**

Y. Sharma, R. Padinjat; National Center for Biological Sciences NCBS-BLR-20121272, Bangalore, INDIA.

Objective: Mammalian brain development is a complex process that involves generation of neural stem cells, followed by their timely maturation into neurons, astrocytes and oligodendrocytes. Perturbations in any of these key events can result in neurodevelopmental disorders. Lowe Syndrome (LS) is an X-linked recessive disorder that presents in patients with brain defects such as delayed cognitive milestones, seizures, hypotonia and gliosis. LS is caused by mutations arising in *OCRL* that encodes for a

phosphoinositide 5-phosphatase enzyme that catalyzes the removal of the 5' phosphate from PI(4,5)P2 to generate PI4P. However, the mechanism by which absence of *OCRL* results in alterations in the brain remains to be elucidated.
Methodology: To address this, we identified a south-Indian family, consisting of monozygotic twins clinically diagnosed with LS and thereby reprogrammed their peripheral blood mononuclear cells into induced pluripotent stem cells (iPSCs). The LS patient and neurotypical control iPSCs were further patterned into dorsal forebrain neural progenitors, that were terminally differentiated into mature neurons and maintained for 30 days in vitro (DIV).
Results: We found that LS neural cultures maintained for 30 DIV, had increased expression of mature astrocytic marker, glial fibrillary acidic protein (GFAP) relative to the control. This finding is in line with the MRI scans of LS patients that have been reported to exhibit hyperechoic periventricular lesions that are indicative of gliosis. Thus, our iPSC-derived neural model system is able to recapitulate a feature of LS pathology. Further, to understand if there are any defects at functional level, we performed calcium imaging and observed that 30 DIV LS neurons exhibited reduced excitability compared to the control neurons. Lastly, we also verified these phenotypes by generating a protein-truncating mutation in *OCRL* using CRISPR-Cas9 technology in the background of another control iPSC line NCRM5.
Conclusion: Overall, the above findings suggest that *OCRL* is indeed instrumental in regulating neuronal differentiation and spontaneous neuronal activity. Ongoing efforts are focused on understanding the mechanism by which OCRL exerts its functions during early stages of neurogenesis.

New genetically-encodable tools to probe the nuanced regulation of the Extracellular signal-regulated kinase (ERK) pathway

J. Keyes[1,2], K. Slye[1], T. Romania[1], A. Kotau[1], A. Kaib[1], C. Scott[1]; [1]Biology, Pennsylvania State University Erie, Erie, PA, [2]Allied Member, Magee Womens Research Institute, Pittsburgh, PA.

The Extracellular signal-regulated kinase (ERK) signaling axis is activated by a host of divergent signaling molecules which each induce their own specific responses. These cellular responses include fundamental processes such as proliferation, differentiation, migration, and, under certain conditions, even apoptosis. Thus, the ubiquitous utilization of ERK signaling in variable and contrasting cellular processes makes it difficult to inhibit the pathway without causing adverse side effects. Furthermore, dysregulation of the Ras/Raf/MEK/ERK signaling pathway is directly implicated in a variety of disorders ranging from cancer to diabetes. Here, we report new tools to elucidate the nuanced mechanisms of differential regulation of the ERK pathway. First, we report a new genetically-encodable tool to inhibit ERK at specific subcellular locations, allowing us to explore the specific function and mechanisms of regulation of ERK with extremely precise subcellular resolution. Additionally, we report a new genetically-encodable fluorescent biosensor based on previous generations of the ERK-kinase activity reporter (EKAR). Our new biosensor, which we have termed reDox-EKAR1, allows us to probe into the spatiotemporal activity of ERK towards a different class of substrates than substrates probed by previous generations of EKAR. Utilizing these new tools, we report how specific pools of ERK regulate particular cellular functions previously underappreciated in the field, and we present our preliminary results detailing how these specific subcellular pools of ERK are differentially regulated.

B479/P2861

Proximity proteomics identifies network of lipid metabolism regulators in JAK2 V617F interactome

M. Petersen, A. Chorzalska, A. Rodriguez, D. Bonal, A. Olszewski, P. Dubielecka; Brown University, Providence, RI.

Background: Janus kinase 2 (JAK2) is a non-receptor tyrosine kinase that activates cell survival/proliferation transcriptional programs in response to growth factors and cytokines, through signal transducers and activators of transcription (STAT) family of transcription factors. JAK/STAT upregulation is commonly seen in myeloproliferative neoplasms (MPN), and associated JAK2 V617F mutation is seen in a majority of MPN. JAK2-targeted therapeutics improve symptoms but do not alter underlying disease.
Objective: To understand JAK2 V617F signaling patterns in malignant transformation, we measured JAK2 WT and JAK2 V617F cellular interactomes by proximity dependent biotin labeling and mass spectrometry (MS).
Methods: Retroviral (MSCV-IRES-GFP) vectors expressing JAK2 WT or JAK2 V617F fused with biotin ligase (TurboID, PMID: 30125270) were used to transduce murine bone marrow FDC-P1 cells. FDC-P1 cell lines stably expressing TurboID, TurboID-JAK2 WT, or TurboID-JAK2 V617F were stimulated with 50 μM biotin for 3 hours. Cells were lysed and biotinylated proteins enriched using streptavidin-conjugated beads. On-bead trypsin digestion followed by MS determined a pool of biotinylated proteins representing proximal interactors of TurboID, TurboID-JAK2 WT, or TurboID-JAK2 V617F. Significantly enriched TurboID-JAK2 V617F or TurboID-JAK2 WT proximal interacting proteins were designated as 1.5-fold more enrichment (FDR ≤ 0.05) over TurboID, and 1.5-fold difference in enrichment (FDR ≤ 0.05) between TurboID-JAK2 V617F and TurboID-JAK2 WT.
Results: 441 proteins were significantly enriched in TurboID-JAK2 WT over TurboID control and TurboID-JAK2 V617F. 330 proteins were significantly enriched in TurboID-JAK2 V617F over TurboID control and TurboID-JAK2 WT. Top 10 Gene Ontology biological process (GO BP) terms enriched exclusively in TurboID-JAK2 WT included “Positive regulation of establishment of protein localization to telomere”, and “Glucose catabolic process”. GO BP terms exclusively enriched in TurboID-JAK2 V617F included “Cellular response to interleukin-3”, “Fatty acid beta-oxidation”, and “Mitochondrial gene expression”.
Conclusions: Our data indicate that JAK2 V617F is associated with changes in cellular energy metabolism, characterized by increased association with proteins involved in fatty acid beta-oxidation, and decreased association with proteins involved in glucose metabolism. These data are consistent with the report of Skoda group showing that expression of JAK2 V617F resulted in systemic metabolic changes including hypoglycemia, adipose tissue atrophy, and early mortality (PMID: 31511238). Further studies are warranted to determine druggable interactors to revert JAK2 V617F-dependent pathologies.

B480/P2862

Prolonged inhibition of Androgen Receptor Signaling induces expression of Nuclear ErbB3 which renders Prostate Cancer cells susceptible to targeted inhibitors

M. Jathal[1], P. M. Ghosh[2], M. M. Mudryj[1]; [1]Medical Microbiology and Immunology, University of California - Davis, Davis, CA, [2]Urologic Surgery, University of California - Davis, Davis, CA.

Objective: Nuclear expression of the receptor tyrosine kinase (RTK) ErbB3/HER3 increases inhighly aggressive prostate cancer cells, but its nuclear transport mechanism is currently unknown.Prostate tumors rely on the androgen receptor (AR), whose activation transcriptionally controlsErbB3 expression,

but its role in ErbB3 nuclear localization had not previously been reported.Here, we investigated the mechanism by which subcellular localization of ErbB3 was altered inprostate cancer.Methods: ErbB3 localization was investigated in the human prostate cancer tumor progressionmodel LNCaP, C4, C4-2 and C4-2B. ErbB3 was stimulated with heregulin-1β (HRG). Nucleartranslocation was tested with a nucleocytoplasmic transport inhibitor panel (chlorpromazine,filipin III, amiloride and Leptomycin B) LNCaP and C4 cells were continuously cultured with theAR activation inhibitor abiraterone acetate (AbiAc) or ethanol (VEH) or treated with the ARinhibitors enzalutamide, darolutamide and apalutamide. ErbB3 activity and subcellularlocalization were analyzed using confocal microscopy/subcellular fractionation/immunoblot. Cellviability was determined by MTT assay. Proliferation and apoptosis were determined by flowcytometry. Invasive potential was investigated by crystal violet staining of cell colonies. ErbB3expression was reduced by siRNA technology.Results: The ratio of nuclear to cytoplasmic ErbB3 increased in untreated cells from LNCaP<C4-2<C4<C4-2B. In all four lines, nuclear localization of ErbB3 peaked at 30 minutes after HRGtreatment, with a rapid return to the cytoplasm in LNCaP cells (at 1 hour), slower in C4 cells (at 4hours), and continued accumulation in the nucleus in C4-2 and C4-2B 8 hours following HRGtreatment. Treatment with the transport inhibitor panel showed that nuclear accumulation of ErbB3was prevented by the clathrin-dependent endocytosis inhibitor Chlorpromazine (CPZ) but not bythe others. In LN-VEH and C4-VEH cells, HRG induced nuclear translocation of ErbB3 but notin LN-AbiAc or C4-AbiAc cells. Accordingly, HRG increased ErbB3 phosphorylation at Y1328and nuclear Akt phosphorylation at S473 in VEH but not AbiAc cells. C4 cells, which had highbaseline nuclear ErbB3, were more sensitive to the AR inhibitors and showed decreased viabilityand invasive potential compared to LNCaP cells.Conclusions: These results indicate that (1) ErbB3 nuclear localization required clathrin-dependentendocytosis (2) ligand binding of ErbB3 as well as the presence of an active AR is necessary forErbB3 nuclear localization and (3) the presence of nuclear ErbB3 increases sensitivity to ARinhibitors.

Role of ras in regulating nuclear dynamics

H. Baek, S. Arur; University of Texas/MD Anderson Cancer Ctr-52168088, Houston, TX.

Role of RAS in regulating nuclear dynamics

Han Bit Baek and Swathi Arur

Genetics and Epigenetics Program, Department of Genetics, The University of Texas MD Anderson Cancer Center UTHealth Houston Graduate School of Biomedical Sciences, Houston, TX

The Rat Sarcoma protein (RAS) is a small GTPase that transmits extracellular growth factor signals through a downstream kinase cascade to regulate genes that promote proliferation, differentiation, and survival. Thus, mutations in RAS that render it constitutively active lead to oncogenesis and promote tumor onset and metastasis. In addition to somatic mutations in RAS that lead to cancer onset, germline mutations in RAS have been implicated to cause birth defects in humans, known as RASopathies. Whether the mechanisms through which activating mutations in RAS drive cancer progression and cause birth defects are convergent, remain unknown. To determine these mechanisms, I use the *C. elegans* model system to track the impact of activating mutations in RAS on embryonic development. The L19F oncogenic mutation in the GTPase domain of RAS is found in human cancers, yet how it leads to cancer onset remains unknown. Using a *C. elegans* mutant line with the L19F mutation, I discovered for the first time that an oncogenic RAS mutation leads to defects in nuclear dynamics and the formation of two nuclei per cell in the developing embryo. Specifically, I observed that the two nuclei arise during the

transition from the one to two cell stage of the embryo. This is a critical period in early embryo development because the maternal and paternal nucleus, contributed by the oocyte and sperm, must fuse to create the zygotic nucleus prior to the first cell division event. I hypothesize that the failure to fuse the maternal and paternal nucleus, followed by cell division leads to the dual nuclei phenotype in RAS L19F embryos. To test this hypothesis, I used live imaging to investigate a critical step in nuclear fusion: the ability for existing nuclear envelopes between the two nuclei to break down, a process known as nuclear envelope breakdown (NEBD). Thus, I assayed for nuclear dynamics during the first cell division and observed that there was a significant delay in NEBD in the RAS L19F embryos. In the most extreme cases, NEBD failed to occur between the maternal and paternal nucleus leading to the dual nuclei phenotype in the activated RAS mutant embryos. This is the first observation that oncogenic mutations in RAS may lead to a delay in NEBD during mitosis, setting the stage to uncover a novel role of RAS during cell division.

Phosphorylation of Tyrosine 841 Play a Significant Role in JAK3 Kinase's Functions.

S. Sun[1], L. Li[2]; [1]THE UNIVERSITY OF TEXAS AT EL PASO, El Paso, TX, [2]THE UNIVERSITY OF TEXAS AT EL PASO, El paso, TX.

Phosphorylation of Tyrosine 841 Play a Significant Role in JAK3 Kinase's Functions.

AbstractJanus Kinase 3 (JAK3) plays a key role in the development, proliferation, and differentiation of various cells. It regulates gene expression by phosphorylation of Signal Transducer and Activators of Transcriptions (STATs). Recently, we found a new JAK3 kinase domain phosphorylation site, tyrosine-841 (Y841). The effects of phosphorylated tyrosine-841 (pY841) on ATP/ADP binding affinities of the JAK3 kinase domain were systematically studied and reported here. The results show that pY841 reduces the size of the cleft between the N-lobe and C-lobe of the JAK3 kinase domain. However, pY841 was found to enlarge the cleft when an ATP/ADP is bound to the kinase. For unphosphorylated JAK3 (JAK3-Y841), the binding forces between the kinase domain and ATP or ADP are similar. After phosphorylation of Y841, JAK3-pY841 exhibits more salt bridges and hydrogen bonds between ATP and kinase than ADP and kinase. Consequently, the electrostatic binding force between ATP and kinase is higher than that between ADP and kinase. The result is that compared to ADP, ATP is more attractive to JAK3 when Y841 is phosphorylated. Therefore, JAK3-pY841 tends to bind ATP rather than ADP.

B483/P2865

Characterizing the relationship of LGL1 and AKT in neural stem cells

A. Sprowles[1], N. Pedicino[1], S. Yang[1], J. Trzeciak[1], M. King[1], B. Light[1], Y. Hirata[2], L. Colegrove[1], S. Otis[1], M. Lacourse[1], H. Collins[1], C. Petritsch[2]; [1]Biological Sciences, Cal Poly Humboldt, Arcata, CA, [2]Neurosurgery, Stanford University, Palo Alto, CA.

Asymmetric cell division and migration are critical for neural stem cell differentiation and brain development. When these processes are dysregulated in neural progenitor cells (NPCs), developmental defects and diseases like glioblastoma multiforme (GBM) can result. *Lgl1* is a tumor suppressor gene first characterized in *Drosophila* neuroblasts that is best known for its regulation of apical-basal cellular polarity through its association with the Par complex. The PI3K/AKT signaling cascade is also regulated by Par signaling and involved in cellular migration. To investigate the role of LGL1 on the regulation of NPC migration, NPCs were cultured from genetically matched $Lgl1^{-/-}$ and $Lgl1^{+/+}$ primary cell lines

isolated from the subventricular zone (SVZ) and corpus collosum (CC) of P30 mice. Spheroid and scratch test migration assays revealed that loss of *Lgl1* increased migration rates by up to two-fold, demonstrating that LGL1 regulates NPC migration. To see if loss of *Lgl1* could be influencing migration through PI3K/AKT signaling, we used targeted drugs to inhibit mTOR and PI3K in the same cellular migration assays and evaluated the phosphorylation states of AKT in the same genetically matched cell lines and in the subventricular zone of GFAP CRE Lgl1 knock out vs. wild type mice. Our findings suggest that changes in Akt phosphorylation through PDK/PI3K sites are a key link between LGL1 and the migratory defects we observed. Our results are also consistent with findings that loss of *Lgl1* increases rates of cellular migration. Our results contribute to the understanding how loss of cell polarity affects neural cell differentiation, cancer cell properties, and GBM progression.

Cip1 tunes cell cycle arrest duration upon calcineurin activation

M. J. Flynn, J. A. Benanti; University of Massachusetts Chan Medical School, Worcester, MA.

Cells exposed to environmental stress arrest the cell cycle until they have adapted to their new environment. Cells adjust the length of the arrest for each unique stressor, but how they do this is not known. Here, we investigate the role of the stress-activated phosphatase calcineurin (CN) in controlling cell cycle arrest in *Saccharomyces cerevisiae*. We find that CN controls arrest duration through activation of the G1 cyclin-dependent kinase inhibitor Cip1. Our results demonstrate that multiple stressors trigger a G1/S arrest through Hog1-dependent downregulation of G1 cyclin transcription. When a stressor also activates CN, this arrest is lengthened as CN prolongs Hog1-dependent multisite phosphorylation of Cip1. Cip1 plays no role in response to stressors that activate Hog1 but not CN. These findings illustrate how stress response pathways cooperate to tailor the stress response and suggest that Cip1 functions to prolong cell cycle arrest when a cell requires additional time for adaptation.

B485/P2867

A Subset of Lowe Syndrome-Causative Mutations Lead to a Conformational Disease Scenario Counteracted by Allosteric Activator Candidate Drugs

J. J. Lee[1], S. Ramadesikan[2], S. Mundre[1], A. F. Pacheco[1], L. E. Skiba[1], R. C. Aguilar[1]; [1]Biological Sciences, Purdue University, West Lafayette, IN, [2]The Steve and Cindy Rasmussen Institute for Genomic Medicine, Nationwide Children's Hospital, Columbus, OH.

Lowe syndrome (LS) is a lethal, X-linked, multisystem lethal disease with no available cure. LS is caused by mutations in the *OCRL1* gene that result in an altered inositol 5-phosphatase, Ocrl1. Many patient missense mutations have been identified in the catalytic domain of this enzyme, but half of these changes do not affect residues essential for lipid binding or catalysis. We hypothesize that this subset of mutated proteins present an altered conformational equilibrium dominated by a conformer lacking biological function. Therefore, we speculate that allosteric activators able to stabilize the active conformer could restore the function of several variants. In this study, we aimed to characterize the functional consequences of six mutants and evaluate the rescue of these abnormalities by four candidate drugs. We purified recombinant, bacterially produced wildtype ($Ocrl1^{WT}$) and mutated variants of Ocrl1 ($Ocrl1^{MUT}$) for *in vitro* testing of their enzymatic activity. These studies indicated that that $Ocrl1^{MUT}$ could be segregated in 3 different groups with respect to $Ocrl1^{WT}$ activity: comparable (S256N, D431N), altered (M299I), and no (I393F, D451G, V508D) activity. We also observed a similar

trend in Ocrl1^{MUT}-expressing, *OCRL1*-null HK2 cells for previously described Golgi complex fragmentation LS phenotype and phosphatidylinositol 4,5-bisphosphate (PI(4,5)P_2) accumulation, where inactive variants showed more severe abnormalities compared to those with measurable catalytic ability. From several large-scale biochemical drug screens, we identified potential activators of Ocrl1 exhibiting partial rescue of otherwise absent D451G activity. As these tests were carried out with the isolated phosphatase domain, changes seen with drug treatment can be correlated to direct interaction with the catalytic domain. Follow up studies confirmed this rescue for other Ocrl1^{MUT}, with candidate LC9 increasing activity for all tested Ocrl1^{MUT}, even those with unaltered catalysis. Our study sheds light on the pathogenicity and heterogeneity of protein dysfunction seen in various LS causing mutations; in fact, it indicates that some patients exhibit characteristics of a conformational disease. Additionally, candidate drugs tested here present novel therapeutics for LS mediating allosteric activation of patient's Ocrl1^{MUT} *i.e.,* the disease causative as opposed to treatments aimed to alleviate downstream consequences of *OCRL1* mutations.

Dsk1 and Kic1 kinases regulate cellular localization and protein expression of poly(A)-binding protein Pabp

A. Vyas[1], A. Freitas[2], M. Nurimba[3], C. Ylagan[3], A. Sugarman[3], Z. Tang[1]; [1]Claremont McKenna College, Claremont, CA, [2]Pitzer College, Claremont, CA, [3]Scripps College, Claremont, CA.

Dsk1 and Kic1/Lkh1 are orthologs of human SRPK1 and mammalian Clk/Sty kinases, respectively, in the fission yeast *Schizosaccharomyces pombe*. These two proteins belong to a superfamily of LAMMER-related kinases that have crucial roles in diverse cellular processes such as control of cellular viability, differentiation, as well as development. Dsk1 and Kic1 serve as model molecules to decipher the mechanisms by which the LAMMER-related kinases may exert on various cellular processes comment to eukaryotes. We previously discovered the effects of these kinases on pre-mRNA splicing, reported a temperature-sensitive (*ts*) phenotype of partial retention of poly(A)$^+$ RNA in the absence of Dsk1 and Kic1, and illustrated a biochemical association in a complex between Dsk1 and a poly(A)-binding protein, Pabp. These results led us to propose a role of these two kinases in nuclear export of mRNA in addition to their functions in pre-mRNA splicing, possibly through their modulation of the Pabp protein activity. Consistent with this model, using the "Green RNA" system we observed that transcripts of the intron-less *lid1*$^+$/*apc4*$^+$ gene (mRNA) are retained in the nucleus in *Δdsk1* or *Δkic1* mutants. This result excludes improper mRNA splicing as the cause of the defective mRNA export observed in the absence of these kinases and supports their distinct roles in both mRNA export and pre-mRNA splicing. To test this model further, we tagged the *pabp* gene with GFP at its genomic locus for characterizing the cytological and biochemical influence of the kinases on Pabp. Using fluorescence microscopy, we have shown that the cellular localization of Pabp is altered from a diffuse pattern throughout *wild-type* cells to a pattern of partial nuclear retention in the kinase deletion mutants. Based on our preliminary results from FISH assays, the changes in Pabp cellular localization also overlaps to a certain degree with the nuclear retention of poly(A)$^+$ RNA phenotype in the kinase-deletion mutants. Additionally, preliminary results from untreated and cycloheximide treated cultures, indicate reduced levels of full-length Pabp protein in the *dsk1*- and *kic1*- deletion strains when compared to *wild-type* strains. Our findings indicate Dsk1 and Kic1 may regulate Pabp function, thereby affecting multiple steps of gene expression including mRNA processing.

Activating the cAMP pathway promotes NF-κB and TNF-α expression in LPS-treated Schwann Cells

C. Henry, P. Kimmel, M. Wilcox, A. Asirvatham; Misericordia University, Dallas, PA.

Schwann cells have been found to play a critical role in neuron repair following peripheral nerve injury. During nerve injury, the myelin sheath becomes damaged, stimulating Schwann cells to secrete cytokines and initiate an inflammatory response. This recruits immune cells to the site of injury so that the myelin debris can be cleared. Neuronal growth is then facilitated by heregulin and an unknown growth factor that stimulates the cAMP pathway. Although it is clear Schwann cells play a role in nerve repair, there is still yet to be known regarding the exact mechanisms by which they do so. One potential mechanism is via the nuclear factor kappa B (NF-κB) pathway. Lipopolysaccharide (LPS), a cell wall immunostimulatory component of Gram-negative bacteria, can be used to activate the NF-κB pathway and stimulate the production of inflammatory mediators, like tumor necrosis factor alpha (TNF-α). Preliminary studies on Schwann cells treated with different concentrations of LPS at various time points revealed that lower doses promoted cell growth compared to higher concentrations. To further explore the effects of LPS on cell proliferation, the role of NF-κB and TNF-α secretion were examined. It was hypothesized that cells treated with LPS and growth factors will express less NF-κB and TNF-α than cells treated with LPS only. Cells from the immortalized S16 cell line were treated with or without 1 μg/mL of LPS for 3 hours without growth factors (control media, N_2), 12.5 ng/mL heregulin (H), 2 μM forskolin (F), or H+F. Using immunoblotting, NF-κB expression, as measured by densitometry analysis and expressed as a percent control, was higher in LPS-treated cells than in unstimulated cells. Surprisingly, NF-κB expression was higher in LPS-treated cells with H, F, or H+F (1500%, 1243%, and 1557%, respectively) than without growth factors (526%). The increase in NF-κB expression for the LPS-treated cells was accompanied by an increase in TNF-α expression. As expected, TNF-α expression was highest in LPS-treated cells without growth factors (444%) and lowest in untreated cells with F or H+F (34% and 70%, respectively). In summary, it appears as though 1 ug/mL of LPS and growth factors may act synergistically to upregulate NF-κB while downregulating TNF-α expression. These findings suggest that, during nerve injury, there may be some crosstalk between the cAMP and NF-κB pathways in Schwann cells. Therefore, a better understanding of these pathways may reveal a therapeutic target for the treatment of nerve injury and inflammation.

The critical role of Smad H2 helix region in BMP signaling

D. Sinha, T. H. Nguyen, M. Serpe; NIH/NICHD, Bethesda, MD

The critical role of Smad H2 helix region in BMP signaling

Debabrata Sinha, Tho Huu Nguyen and Mihaela Serpe
Section on Cellular Communication, *Eunice Kennedy Shiver* National Institutes of Child Health and Human Development, NIH, Bethesda, MD, 20892, USA.

The highly conserved BMPs control many aspects of neural development, including synapse development and plasticity. The *Drosophila* NMJ, a powerful system to study synapse development, relies on BMP signals for NMJ growth and for synapse maturation and function. BMPs trigger signaling by binding to hetero-tetrameric complexes of type I and type II receptors, BMPRIs and BMPRIIs; activated BMPRIs bind and phosphorylate the intracellular transducers, Smads (Mad in *Drosophila*). In flies, phosphorylated Mad (pMad) accumulates at two locations: (1) in the motoneuron nuclei (nuclear

pMad), where it modulates gene expression in response to canonical BMP signaling, and (2) at the NMJ synapses (synaptic/local pMad), where it shapes synapse composition as a function of synaptic activity. Genetic studies indicate that local pMad remains associated with its own kinase, the BMPRI, and that the conserved H2 helix (within the MH2 domain of Mad) may modulate the Mad-BMPRI interaction. Here we examine how Mad H2 helix influences the Mad-receptor interface.
Using Alpha fold, we modeled the BMPRI and the MH2 domain of Mad with and without the H2 helix and found that H2 removal changes the Mad-BMPRI interface without disrupting the overall MH2 organization. Several human genetic variants map to the H2 helix, including Smad1 $Y^{362}C$ mutation, identified in a patient with colonic atresia, and Smad5 $N^{361}D$ substitution and N^{361}-G^{365} deletion, found in patients with malformation of the heart and epileptic encephalopathy respectively. We generated the equivalent *Drosophila* Mad variants and found that the N^{361}-G^{365} deletion, but not the single point mutations, destroyed the H2 helix. However, none of these mutations affect the overall conformation of the MH2 domain. We expressed these Mad variants in S2 insect cells and noted they have mildly reduced protein stability compared to control Mad. Using an *in vitro* signaling assay, we found that Mad mutants induce significantly reduced levels of pMad in response to BMP signaling (Mad-$N^{361}D$<Mad-(N^{361}-G^{365})<Mad-$Y^{362}C$ < Mad wt). Our current efforts are focused on testing how Mad variants associate with the activated BMPRI at cell membranes. We are also using CRISPR/Cas9 methodologies to edit the *Mad* locus and examine the impact on H2 human variants on BMP signaling *in vivo*, in the context of a whole animal. Specifically, we will employ the powerful *Drosophila* NMJ system to examine the impact of these mutations on canonical and local BMP signaling *in vivo*.

Live-cell Analysis of Akt Activity Using a Genetically Encoded, Fluorescent Kinase Translocation Reporter

S. Foltin[1], J. Rauch[1], L. Oupicka[1], M. Dilsaver[1], G. Filonov[1], G. Lovell[2], J. Trigg[2], C. Schramm[1]; [1]Sartorius, Ann Arbor, MI, [2]Sartorius, Royston, United Kingdom

The PI3K/Akt signaling pathway has been extensively investigated as a therapeutic target due to its mechanistic association with several hallmarks of cancer. Studying kinase activity in live cells over time can be challenging, as standard approaches are limited to end point assays. By using the Incucyte® Kinase Akt Lentivirus Reagent, we were able to monitor dynamic changes in Akt activity in live cells maintained in a physiologically relevant environment throughout the experiment. The reagent encodes a kinase translocation reporter based on a green fluorescent protein-tagged Akt substrate whose subcellular localization is phosphorylation-dependent. In addition, a red fluorescent nuclear marker is utilized to denote the nuclear/cytoplasmic boundary. When Akt is active, the fluorescent reporter is driven to the cytoplasm, while fluorescence remains localized in the nucleus when Akt is inactive. Responses to compounds targeting the PI3K/Akt kinase pathway, including allosteric Akt inhibitors MK2206 and API-1, competitive Akt inhibitors AZD5363 and Ipatasertib, and upstream PI3K kinase inhibitors LY294002 and PI-103 were evaluated. Quantification of treatment effects using the Incucyte® Live Cell Analysis System showed concentration-dependent inhibition of Akt activity for all compounds with varying kinetic profiles over 24 hours. To study activation of Akt, HeLa cells were cultured in the absence of serum to reduce Akt activity prior to stimulation with either epidermal growth factor (EGF) or recombinant insulin-like growth factor (R3-IGF-1). An increase in Akt activity was observed for both treatments, but kinetic measurements demonstrated a more sustained response to R3-IGF-1. Cell lines with mutations in the tumor suppressor PTEN showed no response to serum starvation or activation

with EGF or R3-IGF-1. Differential sensitivity to Akt inhibition between cell lines was also demonstrated. MK2206 decreased Akt activity in a similar concentration-dependent manner in T-47D and MDA-MB-231 cell lines. In contrast, measurements of red object count from the same cells revealed concentration-dependent inhibition of T-47D cell growth but little effect on MDA-MB-231 proliferation. Overall, these data highlight the utility of the Incucyte® Kinase Akt Lentivirus Reagent to provide valuable kinetic measurements of Akt activity using live cells.

B490/P2872

Luteinizing hormone stimulation of meiotic resumption in ovarian follicles by protein kinase A and a PPP-family phosphatase

J. R. Egbert[1], I. Silbern[2,3], K. M. Lowther[1], T. F. Uliasz[1], S.-P. Yee[1], H. Urlaub[2,3], L. A. Jaffe[1]; [1]UConn Health, Farmington, CT, [2]Max Planck Institute for Multidisciplinary Sciences, Göttingen, Germany, [3]University Medical Center Göttingen, Göttingen, Germany

In mammalian preovulatory ovarian follicles, meiotic arrest of fully-grown oocytes is maintained by cyclic guanosine monophosphate (cGMP) that is produced by the membrane guanylyl cyclase natriuretic peptide receptor 2 (NPR2) in the follicle's somatic cells and diffuses through gap junctions into the oocyte. Phosphorylation of several juxtamembrane serines and threonines is essential for full NPR2 activity. The cyclic surge of luteinizing hormone (LH) acts on receptors in the outermost somatic cell layers to rapidly dephosphorylate and inactivate NPR2, lowering cGMP levels in the follicle and oocyte to trigger meiotic resumption. Our goals are to determine whether protein kinase A (PKA) signaling mediates this process, and which LH-activated PPP-family phosphatase dephosphorylates NPR2. Application of the specific PKA inhibitor Rp-8-CPT-cAMPS (Rp) to isolated mouse follicles prior to LH treatment (30 min) prevented NPR2 dephosphorylation, showing that phosphatase activation is mediated by PKA. To identify PPP-family regulatory subunits that undergo a rapid LH-stimulated increase in phosphorylation, lysates of rat follicles treated with or without LH were enriched for phosphorylated peptides and analyzed by liquid chromatography-tandem mass spectrometry (LC-MS/MS) utilizing chemical labeling with tandem mass tags (TMT) for quantification. PPP1R12A and PPP2R5D emerged as two primary candidates. In PPP1R12A, peptides containing phosphorylated S507 residue had ~5-fold higher intensity in LH-treated follicles. PPP2R5D had four sites with elevated intensity with LH: S53 and S566 (10-fold and 4-fold, respectively), and S81/S82 (~2-fold). Quantitative western blotting confirmed these results and showed that inhibition of PKA activity with Rp prevented the LH-induced phosphorylation changes. To determine whether phosphorylation of one or both proteins mediates NPR2 dephosphorylation after LH, we have made mice in which S507 of PPP1R12A or S53/S81/S82/S566 of PPP2R5D are replaced with alanines, and are testing their role in this process. Thus, we have identified two PPP-family regulatory subunits that are rapidly phosphorylated in response to LH-PKA signaling as candidates for effecting NPR2 dephosphorylation, an event required for timely oocyte meiotic resumption.

B491/P2873

Investigating the role of Phosphoinositide-3 Kinases PikF, PikG, and PikH in multicellular development in *Dictyostelium Discoideum.*

H. Drebin, S. Farinas, D. Ali, J. Shen, **M. Edwards**; Amherst College, Amherst, MA

Phosphoinositide-3-kinases (PI3Ks) play crucial roles in multiple signaling networks and are strongly conserved across eukaryotes. Seven PI3Ks have been identified in the genome of the slime mold model *Dictyostelium discoideum*. However, none have been classified as homologs to human Class II PI3Ks . This work suggests that as many as three *Dictyostelium* PI3Ks-PikF, PikG, and PikH-may be functionally analogous to human Class II PI3Ks based on apparent substrate specificity. Furthermore, we demonstrate that two of these three PI3Ks are physiologically vital for *Dictyostelium* to proceed properly through multicellular development.Multiple sequence alignments of human and *Dictyostelium* PI3Ks reveal nearly identical homology in the PI3K catalytic domain region that, in humans, has been biochemically determined to confer substrate specificity. PikF, PikG, and PikH have uncharged residues in place of one of the two basic residues that is necessary for Human Class I PI3Ks to synthesize $PI(3,4,5)P_3$. Class II PI3Ks possess an identical apparent substrate specificity to that of PikF, PikG, and PikH, and suggests that, like human Class II PI3Ks, these *Dictyostelium* PI3Ks may synthesize PI(3)P and $PI(3,4)P_2$ in vivo. Alphafold structural predictions of the catalytic domain further substantiate the conserved homology between human and *Dictyostelium* PI3Ks. In addition, we present evidence for a prominent role for PikF, PikG in multicellular development in *Dictyostelium*. *pikf-* cells display a profound defect in streaming and aggregation during development and additional defects in stalk development. Similarly, *pikg- fail to initiate development altogether.* Our results demonstrate previously undescribed roles for putative Class II PI3K homologs and strengthen our understanding of the conserved homology between PI3Ks in Humans and *Dictyostelium*.

Calcium modulates Rho-kinase activity during collective cell migration

A. E. Mancini, D. P. Isaacs, M. A. Rizzo; University of Maryland, Baltimore, Baltimore, MD

Collective cell migration (CCM) drives physiological processes such as embryogenesis, vascular sprouting, and wound healing, but also drives cancer metastasis. Ras homolog family member A (RhoA) drives CCM through modulation of the actomyosin cytoskeleton. Because of the tight spatiotemporal control of RhoA during CCM, we decided to investigate the role of RhoA's downstream effector, Rho-associated kinase (ROCK), in collectively migrating fibroblasts. We have observed calcium-dependent activation of ROCK with a new FRET-based ROCK sensor. Using a modified scratch assay, we have quantitated ROCK activity in parallel with CCM. Scratch wounding caused an increase in ROCK activity. We have also observed blunting of CCM in response to pharmacological inhibition of ROCK or depletion of intracellular calcium with 100 µM EGTA. To study the role of calcium from different sources in driving ROCK activity during CCM, carbenoxolone, a gap junction blocker, was applied to collectively migrating fibroblasts. Carbenoxolone decreased ROCK activity and intracellular calcium at corresponding time points and slowed CCM. Following treatment with PQ7, a gap junction activator, modest increases in CCM were observed. These results indicate that gap junction intercellular calcium signaling drives ROCK activity during collective cell migration.

The role of Shank3 and zinc in CaMKII translocation by NMDA receptor stimulation

A. D. Nayak, L. E. Guzmán Clavel, G. A. Crescencio, S. A. Kulik, S. A. Kim; Amherst College, Amherst, MA

Synaptic transmission is transduced by postsynaptic proteins that coordinate activity-dependent changes in synaptic structure. It has been previously shown that glutamate binding to NMDA receptors triggers the translocation of Ca2+/calmodulin kinase II alpha (CaMKIIα) to dendritic spines where it acts to decode synaptic Ca2+ oscillations. Although this translocation is critical for synaptic plasticity, the molecular mechanisms underlying recruitment of CaMKIIα to the postsynaptic density (PSD) remain unknown. Recently found to bind directly to CaMKIIα, Shank3 is a zinc-dependent, postsynaptic protein that anchors many key functional molecules in the PSD. Here we show that both Shank3 and zinc play a role in the recruitment of CaMKIIα to dendritic spines. CaMKIIα levels at the spine were found to be dependent on Shank3 concentrations. Similarly, glutamate-induced translocation of CaMKIIα increased with Shank3 concentration. Since Shank3 activation and function requires zinc, we next examined whether zinc also regulates CaMKIIα translocation. Zinc was shown to enhance glutamate-induced recruitment of CaMKIIα, whereas zinc chelation decreased CaMKIIα concentration in spines. Even with Shank3 overexpression, zinc chelation prior to glutamate application led to decreased CaMKIIα translocation. Interestingly, zinc supplementation in Shank3 knockdown neurons rescued the diminished levels of CaMKIIα translocation. Thus, this role of Shank3 in recruiting CaMKIIα to the PSD points to a concerted mechanism between Shank3 and zinc in regulating CaMKIIα. Given that CaMKIIα is known to transduce calcium signaling, this novel interplay of zinc and CaMKIIα suggests that this enzyme may integrate both calcium and zinc signaling to coordinate structural postsynaptic changes.

Post Translational Modification in Signaling

Flagellar cAMP signaling in the eukaryotic pathogen *Trypanosoma brucei*, lessons from phosphoproteomics and fluorescence spectroscopy

D. Velez-Ramirez, M. Shimogawa, A. Wijono, P. Limsuwannarot, A. Leung, K. Hill; University of California, Los Angeles, Los Angeles, CA.

Trypanosoma brucei is a flagellated protozoan parasite and causative agent of sleeping sickness. *T. brucei* flagellum plays critical roles in transmission and pathogenesis. It is surrounded by a phospholipidic bilayer and is laterally connected to the cell body along almost its entire length. We implemented, for the first time in this organism, APEX2-proximity proteomics to examine protein composition of *T. brucei* flagellum, using Dynein Regulatory Complex subunit 1 (DRC1) as bait. The resulting DRC1-proximity proteome gave good overlap with known flagellum proteomes, validating the APEX2 system in trypanosomes. In addition to its canonical role in cell motility, the flagellum is also a signaling platform. Adenylate cyclases located at specific flagellum domains produce cAMP that controls motility and parasite transmission, then cAMP is removed by the flagellar-restricted phosphodiesterase B1 (PDEB1). To investigate the flagellar cAMP cell signaling pathway, we sought to identify cAMP-dependent protein phosphorylation in the flagellum and assess its role in cell motility. By performing APEX2-proximity labeling in tandem with TiO_2-mediated phosphoenrichment, we have been able to define the flagellum phosphoproteome. We next obtained the flagellum phosphoproteome of a PDEB1-knockout, to identify cAMP-dependent phosphorylation. Principal component analysis of control and

PDEB1-knockout samples revealed that the flagellum phosphoproteomes are indeed different, with several proteins differentially phosphorylated in the PDEB1-knockout. Gene ontology analysis of the biological process of this group of proteins, retrieved terms of cell division, mRNA catabolic process and microtubule-based movement, among others. We are now working on obtaining the cAMP-dependent flagellar phosphoproteome of a PDEB1 inducible knockdown. These results will complement our previously obtained steady state cAMP-dependent flagellar phosphoproteome. We are also interested in visualizing cAMP fluctuations inside the flagellum and the cell body. Our working hypothesis is that on PDEB1 mutants, cAMP locally produced at the flagellum tip, freely diffuses along the flagellum and inside the cell body. To test this hypothesis we are implementing a FRET-based cAMP sensor. Altogether, our findings provide evidence on the ways eukaryotic pathogens sense and respond to their environment.

Sheddase-dependent release of membrane-anchored FGF at the cytoneme contact sites

Y. Li, L. Du, A. Sohr, M. Rao, S. Roy; University of Maryland, College Park, MD.

During tissue morphogenesis, cells can precisely coordinate their functions over distance by communicating with secreted paracrine signaling proteins such as fibroblast growth factors (FGFs). The spatiotemporal regulations of FGF signaling have been shown to be critical for development and homeostasis, but the mechanisms that control the target-specific FGF communication over distance are not well-understood. In *Drosophila*, FGF produced in a small group of wing-disc cells is known to regulate the development of the disc-associated air-sac-primordium/ASP, which is functionally analogous to a growing vertebrate lung bud. Although FGF is known to be a secreted signal, previous work has shown that the inter-organ dispersion of FGF from the source to the ASP is highly polarized, target-specific, and is mediated over distance via long polarized actin-based filopodia, named cytonemes. The contact-dependent long-distance FGF exchange via cytonemes is programmed by the post-translational modifications of FGF, which is modified to be glycosylphosphatidylinositol (GPI)-anchored to the outer leaflet of the source cell membrane. The GPI anchor inhibits free/random secretion of FGF but also facilitates the release of FGF only at the source-recipient cytoneme contact sites. This work explores the molecular mechanisms that can control the contact-dependent FGF release at the cytoneme contact sites. By using cell biological, biochemical, and genetic analyses, we found that FGF is shed from the source cell membrane by proteolytic cleavage. We identified a specific region in the FGF backbone required for the cleavage. Phenotypic analyses of deletion FGF mutants, generated by genome editing, suggest that the proteolytic FGF release is essential for signaling and morphogenesis. We identified multiple cell surface proteases that can specifically shed GPI-anchored FGF from the producing cell surface. These sheddases are membrane-tethered and, except for one, are expressed only in the recipient ASP. Despite the lack of expression in the source, these sheddases can be delivered to the source-recipient contact sites and cleave FGF in trans to facilitate contact-dependent FGF release. These results, for the first time, provide new insights into how contact-mediated signal dispersion via cytonemes can be modulated by cell surface sheddases. This work is funded by NIH R35GM124878 to S.Roy.

Understanding Hsp70 phosphorylation using the Hsp70 Chaperone Code array

A. Rysbayeva, S. Omkar, A. Truman; Department of Biological Sciences, University of North Carolina At Charlotte, Charlotte, NC.

Hsp70 (Heat Shock Protein 70) is a well-conserved molecular chaperone involved in the folding and stabilization of a large proportion of the proteome. Global mass spectrometry studies have identified over 80 post-translational modifications (PTMs) on Hsp70 which regulate its activity and which we collectively term the "Chaperone Code". Despite the complexity of the chaperone code, less than 20 PTMs have been fully explored in terms of regulation and function. To study the impact of phosphorylation on Hsp70 we mutated all 73 known phosphorylation sites on budding yeast Hsp70 (Ssa1) to either alanine (phospho-mutant) or aspartate/glutamate (phospho-mimic) and then expressed these 146 single mutants in a *ssa1-4Δ* background. Although nine mutations did not support cell viability, the remaining 137 mutants (Hsp70 Chaperone Code Array) were screened against a variety of stressors allowing us to generate a phenotypic fingerprint for each mutant. We are currently examining the impact of these chaperone code mutants on the toxicity of neurodegenerative proteins that cause ALS and Huntington's disease in humans. Taken together, we hope that the array will be a useful tool for the chaperone field to probe the intricacies of the chaperone code. We are creating equivalent arrays for other kinds of PTMs and the other major chaperones and co-chaperones in an effort to "crack the Chaperone Code". **Keywords: Hsp70, PTMs, Chaperone Code, phosphorylation, yeast**

Betaglycan Glycosaminoglycan Chain Modifications impact Ectodomain Shedding and Endothelial Cell Function in Ovarian Cancer

A. Choi[1], L. Jenkins[2], Y. Liu[3], A. Nixon[3], N. Hempel[4], R. Arend[5], M. Karthikeyan[6]; [1]UNIVERSITY OF ALABAMA AT BIRMINGHAM - Birmingham, AL, Birmingham, AL, [2]University of South Carolina, Columbia, SC, [3]Department of Medicine and Duke Cancer Institute,, Duke University Medical Center, Durham, NC, [4]Department of Medicine, Division of Hematology/Oncology, University of Pittsburgh, Pittsburgh, PA, [5]Gynecologic Oncology, Obstetrics and Gynecology, UNIVERSITY OF ALABAMA AT BIRMINGHAM - Birmingham, AL, Birmingham, AL, [6]Department of Pathology, Molecular Cellular, UNIVERSITY OF ALABAMA AT BIRMINGHAM - Birmingham, AL, Birmingham, AL.

Betaglycan (BG) is a ubiquitously expressed transmembrane PG containing a core protein domain with glycosaminoglycan (GAG) attachments sites at S534/S545 residues on its extracellular domain, to which heparan sulfate (HS) and chondroitin sulfate (CS) chains are covalently attached. BG is commonly referred to as a "part-time proteoglycan" since BG can be expressed on the cell surface with or without GAG chain modifications. BG's ectodomain can also be shed (shed-BG) from the cell surface to release a soluble form. BG is an established co-receptor for the TGF-β superfamily that modulates signaling of TGF-β members both at the cell surface and via the shed form as has been previously reported in breast cancer. Although majority of the prior work has focused on BG's core protein interactions and functions, a thorough understanding of the effects of the BG GAG chains remains lacking. Upon, analysis of the GAG chains of shed-BG in OVCA patient ascites fluid, we find that majority of shed-BG is heavily glycosylated. We thus hypothesize that the GAG chains of BG may impact BG ectodomain shedding and impart autocrine and paracrine responses. To examine the effect of GAG modifications on BG ectodomain shedding, we constructed point mutations at S534/S545 to abrogate GAG chain attachment

sites on BG and expressed them in a panel of cancer cell lines . Cellular expression of BG constructs confirmed the alterations in BG GAG chains. We find that using autoradiography and ELISA a significant reduction in BG shedding in cells expressing unmodified BG (BG-ΔGAG) compared to cells expressing wild type BG (BG-FL), despite no change in cell surface expression. Next, we evaluated autocrine signaling effects of BG GAG mutant expression. We find that BG-ΔGAG mutant shows increased invasion and activation of the TGF-β signaling pathway compared to glycosylated BG mutant (BG-FL). Paracrine effects of Soluble-BG was tested on other cell types found in tumors particularly endothelial cells. Soluble-BG was able to abrogate the effects of growth factors on endothelial cell invasion. Lastly, RNA-SEQ of the BG-GAG mutants identified tissue inhibitor of metallopeptidase-3 (TIMP-3) as a possible regulator of BG ectodomain shedding. Knockdown of TIMP-3 expression through siRNA increased shedding of BG in BG-ΔGAG mutants. Through these findings, we report novel roles and mechanism of ectodomain shedding of the GAG modified and unmodified forms of BG, impacting cell biology, signaling, and endothelial cell functions in ovarian cancer cell systems.

Regulation of Nucleotide-Sugar Levels is Required for Mammalian Glycoconjugate Biosynthesis *in vivo*

N. Linhart[1], A. Florwick[2], A. Tata[3], L. Macadlo[3], P. Tata[3], M. Boyce[1]; [1]Biochemistry, Duke University, Durham, NC, [2]Duke University, Durham, NC, [3]Cell Biology, Duke University, Durham, NC.

Mammalian nucleotide-sugar biosynthetic pathways are well-characterized biochemically, but how cells regulate flux through these pathways in response to normal biological processes or stresses remains poorly understood. To begin to understand how and why nucleotide-sugar levels are regulated, we chose galactose-4-epimerase (GALE) as a model enzyme. GALE directly balances four nucleotide-sugar pools and is implicated in human genetic diseases, such as subtypes of galactosemia and thrombocytopenia. We previously discovered that GALE is essential for the regulation of nucleotide-sugar metabolism and for downstream glycoconjugate biosynthesis in cultured human cell lines. In particular, mucin-type O-glycans, which are commonly found on mucins, rely on GALE for their production. Mucins are highly O-glycosylated and are a main component of mucus, an essential hydrogel that coats a variety of epithelial tissues. In current work, we are determining the role of GALE in mucin biosynthesis and function *in vivo*. mRNA and immunofluorescence data indicate that mucin-secreting club cells of the epithelium and mucous cells of the submucosal glands (SMGs) express high levels of GALE in the human airway. Immunofluorescence (IF) staining on human airway tissue revealed high levels of GALE expression in discrete cell types of the airway epithelium. GALE expression colocalizes with the club cell marker club cell secretory protein (CC10) on the epithelium and the SMG mucous cell marker mucin 5B (MUC5B). These results suggest that GALE may be required in specific mucin-secreting airway cell populations. Ongoing experiments are also defining GALE expression differences in the airways of healthy and muco-obstructive disorder patients (e.g., chronic obstructive pulmonary disease, cystic fibrosis). To assess the functional significance of GALE and nucleotide-sugar regulation in tissue physiology, we have created conditional knockout models in the total epithelial and mucin-secreting cell populations of the murine airway. Tissue characterization to deduce the effects of GALE loss is underway. In addition, we have established GALE$^{-/-}$ *in vitro* airway epithelial culture systems to determine GALE's role in the biosynthesis of airway mucin glycoproteins. Our work supports the hypothesis that GALE is important in the mammalian airway, especially in cell populations known to secret mucins.

Exploring the molecular mechanisms to connect metabolism, DNA damage response and aging

J. Park, H. Lee, Y. Lee, **I. LEE**; Ewha Womans University, SEOUL, KOREA, REPUBLIC OF.

Exploring the molecular mechanisms to connect metabolism, DNA damage response, and Aging

Jingyeong Park*, Haein Lee*, Yelin Lee* and In Hye Lee
Department of Life Science, EWHA Womans University, Seoul, South Korea * These authors equally contributed.

Growing evidence indicates that metabolic signaling pathways are interconnected to DNA damage response (DDR). However, factors that link metabolism to DDR remain incompletely understood. SIRT1, an NAD+-dependent deacetylase that regulates metabolism and aging, has been shown to protect cells from DDR. Here we demonstrate that SIRT1 protects cells from oxidative stress-dependent DDR by binding and deacetylating Checkpoint Kinase 2 (CHK2). We first showed that essential proteins in DDR were hyper-acetylated in Sirt1-deficient cells and that among them the level of acetylated CHK2 was highly increased. We found that Sirt1 formed molecular complexes with BRCA1/BRCA2-associated helicase 1 (BACH1), H2AX, Tumor suppressor p53-binding protein 1 (53BP1), and CHK2, which are key factors of DDR. We then demonstrated that CHK2 was normally inhibited by SIRT1 via deacetylation but dissociated with SIRT1 under oxidative stress conditions. This led to acetylation and activation of CHK2, which increased cell death under oxidative stress conditions. Our data also indicated that SIRT1 deacetylated K235 and K249 residues of CHK2, whose acetylation increased cell death in response to oxidative stress. Thus, SIRT1, a metabolic sensor, protects cells from oxidative stress-dependent DDR by deacetylation of CHK2. Our finding suggests a crucial function of SIRT1 that inhibits CHK2 as a potential therapeutic target for cancer treatment.

The role of docking site modulation of Extracellular Signal-Regulated Kinase on cell migration

T. Romania[1], A. Kaib[1], A. Kotau[1], J. D. Keyes[2]; [1]Pennsylvania State University Erie, Erie, PA, [2]Penn State University Erie, Erie, PA.

Extracellular signal-regulated kinase (ERK) is part of a vital kinase cascade that facilitates cellular communication. ERK has been heavily studied due to its hyperactivity in 90% of cancers but, not much is known above the basic knowledge that ERK is turned on and off in response to a variety of extracellular signals. Preliminary data suggests that ERK oxidation increases ERK activity towards migration-related substrates and decreases activity toward proliferation-related substrates. Initial results between transfected WT and C159S ERK2 in established NIH-3T3 cells provided evidence that ERK2 oxidation on C159 modulated ERK activity influences cell responses to extracellular stimuli. This project continues to explore the complexities of ERK regulation by investigating the oxidation of ERK on C159 substrate selectively.

Impaired phosphorylation of CBP disturbed intestinal homeostasis to lead to colitis

C. Chen, Y. Lin; DEPARTMENT OF Pharmacology, College of Medicine, NTU, Taipei, TAIWAN.

Inflammatory bowel diseases (IBDs), including Crohn's disease (CD) and ulcerative colitis (UC), are multifactorial disorders characterized by chronic inflammation of intestine. CBP is a transcriptional coactivator modulating DNA accessibility to transcription factors. We previously revealed that phosphorylation of CBP at Ser1382/1386 by IKKα plays a critical role in regulating cell fate by suppressing p53-mediated gene expression. CBP-AA-knockin mice were generated by replacing CBP Ser1383/1387 with alanines (AA), and CBP-AA mouse models are found to exhibit a specifically spontaneous colitis phenotype. Bone marrow chimera experiments reveal that the spontaneous colitis is driven by impaired phosphorylation of CBP in non-hematopoietic cells. We explored that a genetic defect of CBP phosphorylation in colonic IECs orchestrated by intestinal stem cells (ISCs) contributed to the spontaneous colitis in a CBP/p53-dependent manner. CBP phosphorylation at Ser1383/1387 (human: Ser1382/1386) plays a critical role in maintaining intestinal homeostasis *in vivo*. A molecularly basic mechanism translating into a clinically important human disease was demonstrated, and more light on the management of bowel disorders was shed.

The Interaction of Gam1 and SAE1/SAE2 Through Structural and Functional Studies

K. Silva, R. Dong, B. Moreno, G. Avila, Y. Xian, C. Xiao; University of Texas At El Paso, El Paso, TX.

Gam1 is an early gene product of the chicken embryo lethal orphan virus. Up to today, it is the only viral protein that globally inhibits host cell SUMOylation. SUMOylation is a post-translational modification system that is essential for various cell functions including against viral infections. Gam1 achieves its function by the elimination of key enzymes SAE1/ SAE2 in the SUMOylation pathway. Understanding the molecular mechanism of the inhibition necessitates the structural studies of the Gam1/SAE1/SAE2 complex. Gam1 will be purified using published protocols. In addition, a recombinant SAE1/SAE2 plasmid was transformed into Rosetta 2 (DE3)pLysS cells to express these eukaryotic genes in bacteria cells. The cells were grown to a certain optical density prior to the induction with Isopropyl ß-D-1-thiogalactopyranoside. After expressing for an optimal length of time, the cells were harvested using centrifugations. SAE1/SAE2 will undergo various chromatographic techniques to isolate the complex that allows for in-vitro analyses of its interactions with Gam1. Purified Gam1/SAE1/SAE2 complexes will be analyzed by structural techniques such as cryogenic electron microscopy. These structural investigations will deepen our understanding of how Gam1 interacts with SAE1/SAE2 to inhibit host cell SUMOylation favoring viral replications. Results from the project will facilitate future development of antiviral strategies.

Prediction and characterization of putative UBA domains in human NEK10.

I. Semchenkov Pastukhov[1], A. Silva Dos Santos[1,2], S. Singh[1,2,3]; [1]Biology, Brooklyn College, CUNY, Brooklyn, NY, [2]The Biochemistry PhD Program, The Graduate Center of the City University of New York, New York, NY, [3]The Biology PhD program, The Graduate Center of the City University of New York, New York, NY.

Ubiquitination is a form of post-translational modification of a protein by attachment of a ubiquitin protein (UBC) to it, varying in the number of chains attached e.g., monoubiquitylation, polyubiquitination, and multiple monoubiquitylation. Depending on the type of ubiquitination, different functions may be carried out by the modified protein ranging from tagging for degradation and recycling by the proteasome pathway to cell signaling, DNA repair, apoptosis, immune response, and protein processing. Ubiquitin forms an isopeptide bond between its terminal glycine and a lysine residue within a ubiquitin associated domain **(**UBA) on the surface of the target protein. Although there is no established motif for UBA domain as of now, researchers have suggested a few common key features present in the areas of interaction that have been experimentally established and analyzed. Using protein structure prediction software and predicted model assessment and analysis, we have identified two potential unreported sites of interaction of ubiquitin within a full length model of NEK10. Of two found sites, one fits the structural and biophysical criteria described in the literature well, while the second site meets the criteria less optimally, especially the net charge around the target lysine. Prediction of the NEK10 UBA-UBC interaction using docking software identifies six possible scenarios that put NEK10's lysine and UBC's glycine within a desirable distance that would allow interaction to happen. The identification of these putative UBA domains within NEK10 opens a complete new aspect of NEK10 biology and will allow new investigations of the role and function of ubiquitination in NEK10 signaling.

Investigating Protein-Protein Interactions In The Purinosome

J. He[1], L. Zou[2], S. Benkovic[1]; [1]Department of Chemistry, Pennsylvania State University, University Park, PA, [2]Huck Institutes of the Life Sciences, Pennsylvania State University, University Park, PA.

There is compelling evidence that the enzymes in the de novo purine biosynthesis (DNPB) pathway form a multienzyme complex — the purinosome — to facilitate substrate channeling and enhance pathway flux. However, biochemical evidence of protein-protein interactions (PPIs) between DNPB enzymes has been limited. Here, we employ two orthogonal approaches, bimolecular fluorescence complementation (BiFC) and co-immunoprecipitation (co-IP), to investigate PPIs of the human bifunctional phosphoribosylaminoimidazole carboxylase/succinocarboxamide synthetase (PAICS), a central member of the DNPB pathway. We found evidence for PAICS interaction with all the other DNPB enzymes, with the single exception of amidophosphoribosyltransferase (PPAT), the first enzyme of the pathway. We also found PAICS interacts with methylenetetrahydrofolate dehydrogenase/cyclohydrolase/formyltetrahydrofolate synthetase 1 (MTHFD1), which produces folate co-factors essential for DNPB. These interactions were observed in cells cultured in both purine-rich conditions, where DNPB activity is low, and in purine-depleted conditions, where DNPB activity is high. This suggests a partial purinosome complex can exist inside the cell regardless of the cell's DNPB activity. We also found that the tagging of PAICS on its carboxyl-terminus disrupts its heteromeric interactions,

but not its homo-oligomerization. To further investigate the structure and composition of the purinosome, we are now using the split-TurboID biotin ligase proximity labeling system to probe higher order PPIs in this multienzyme complex. We found distinct DNPB enzymes, when fused to complementary TurboID fragments, and co-expressed in live cells, can reconstitute functional biotin ligase activity, thereby re-confirming PPIs between DNPB enzymes in vivo. We are now in the process of proteomic analysis of novel split-TurboID labelled products, with the aim of uncovering higher-order interactors within the purinosome. This knowledge will facilitate a better understanding of the composition and the regulation of this important metabolon.

Obesity Increases Stress Granules-Associated Proteins in the First Trimester Placenta

J. Bandres-Meriz; Medical Universiversity of Graz, Graz, Austria

Background: Obesity, a strong inducer of cellular stress, is associated with reduced insulin sensitivity (IS_{HOMA}) and elevated C-peptide (a proxy of insulin serum concentration) in the first trimester of pregnancy. In this period, the human placenta is especially sensitive to changes in the intrauterine environment. We hypothesized that increased C-peptide alters placental proteome and function and, specifically, aimed to identify pathways differently regulated in placentas from obese pregnant women. **Methods:** Placental tissue (gestational age 5^{+0} - 6^{+6} weeks, n=19) from women with high- and low-insulin sensitivity (based on above/below median; median IS_{HOMA}= 0.61) were used for untargeted proteomics (LC-MS/MS). Signal intensities (LFQ values) of G3BP1 and FUS/TLS were correlated with maternal C-peptide and IS_{HOMA}. Immunohistochemistry was performed on placenta sections (3.5µm; n=19) and formation of G3BP1 foci assessed with a scan microscope (Olympus VS200). ACH-3P cells (first trimester trophoblast cell line) were challenged with 10nM insulin for 1h at physiological oxygen tension (6.5% O_2; hypoxia bench) and formation of G3BP1 foci assessed by immunohistochemistry (Zeiss Axio Z1 microscope). Sodium arsenite (500µM) was used as positive control. **Results:** Proteins that localize to stress granules (EIF4B, RPL7A, RPL23, RPS7, RPL10, DNR, HNRNPK, HNRNPD, HNRNPAB, HNRNPA2B1, SF3A1, TRA2B, YBX1, KHSRP, NPM1) were enriched ($p<0.05$) in placentas from low IS_{HOMA} mothers. Protein level of G3BP1, the key structural component of stress granules, correlated with maternal serum C-peptide ($r=0.495$, $p<0.05$), but not with IS_{HOMA}. The protein level of FUS/TLS, a marker of chronic stress granules, also correlated with C-peptide ($r=502$, $p<0.05$). In placenta sections, G3BP1 localized to the villous and extravillous cytotrophoblast. G3BP1 foci were mainly located on the villous cytotrophoblast. *In vitro*, challenging ACH-3P cells with insulin resulted in the formation of G3BP1 foci. **Conclusion:** G3BP1 foci are visible in the cytotrophoblast of the first trimester placenta, the main proliferative cell type early in pregnancy. Increased G3BP1 and FUS protein level suggest increased assembly of stress granules in placentas chronically exposed to hyperinsulinemia. Assembly of G3BP1 foci in ACH-3P cells after insulin treatment suggests that high insulin concentrations activate stress-response pathways in the placenta. In the first trimester placenta, chronic stress, as in obesity, is associated with increased level of proteins characteristics of stress granules.

Investigation into prolific small GTPase ubiquitination by *Legionella pneumophila*

V. Bhadkamkar[1], A. Steinbach[1], D. Jimenez-Morales[2], E. Stevenson[1], G. Jang[1], N. Krogan[1], D. Swaney[1], S. Mukherjee[1]; [1]University of California, San Francisco, San Francisco, CA, [2]Stanford University, Palo Alto, CA

The intracellular bacterial pathogen *Legionella pneumophila* (*L.p.*) usurps eukaryotic host ubiquitination machinery in order to form its replicative vacuole. Among its arsenal of ~330 secreted bacterial proteins (effectors), a growing number have been biochemically characterized as ubiquitin ligases or deubiquitinases, although the targets of these effectors remain elusive. To better understand how *L.p.* hijacks host cell ubiquitination machinery and the targets of these effectors, we performed a global proteomics analysis that measured changes in protein abundance and ubiquitination during *L.p.* infection. Strikingly, we discovered that 79 of 163 mammalian small GTPases of the Ras superfamily are ubiquitinated, but not degraded, during infection in a process dependent upon bacterial effector secretion. Ubiquitinated GTPases include critical regulators of cell proliferation (e.g., Ras), intracellular membrane traffic (e.g., Rab, Arf), and cytoskeletal structure (e.g., Rho, Rac). Since a growing body of work has shown that ubiquitination is a potent regulator of small GTPase activity, we decided to better characterize pan-Ras family small GTPase ubiquitination during infection. Using the small GTPases Rab1, Rab5, and Rab10 as a test cases, we have determined that robust recruitment and retention of these GTPases into the *Legionella*-containing vacuole (LCV) membrane is a requirement for their ubiquitination. In conjunction with an analysis showing strong overlap between LCV-recruited small GTPases and small GTPases ubiquitinated in our mass spectrometry, our data suggest a model in which all LCV-recruited small GTPases are ubiquitinated during infection. Our data also show that two paralogous effectors, SidC and SdcA, promote, but are not required for small GTPase ubiquitination. SidC and SdcA are linked to timely LCV formation and recruitment of ER-membranes to the LCV, suggesting a link between ER-membrane recruitment and pan-small GTPase ubiquitination. Altogether, our data suggest that *L.p.* hijacks small GTPase activity during infection with prolific, pan-family ubiquitinations, and position *L.p.* as a tool to better understand how small GTPases can be regulated by ubiquitination in uninfected contexts.

B507/P2889

Progranulin processing in the epigenetically distinct SW13 cell subtypes

P. Biparva[1], A. S. Pascual[1], K. J. Leyva[1], M. R. Montgomery[2], **E. E. Hull**[1]; [1]Midwestern University, Glendale, AZ, [2]Oklahoma State University, Stillwater, OK

Progranulin (PGRN) is a pleiotropic signaling molecule composed of 7.5 granulin repeats, regulating many diverse biological processes including cellular proliferation, inflammation, tumorigenesis, and lysosome function. A variety of intracellular and extracellular proteases differentially process PGRN and their combined actions determine the biological activity of the processed PGRN products. Utilizing the two epigenetically distinct subtypes of the SW13 human adrenal carcinoma cell line, we focus on the extracellular and intracellular proteases involved in PGRN processing and characterize the resulting PGRN cleavage products. Results suggest that differential processing of PGRN occurring within each SW13 subtype is correlated to both differential growth and lysosomal pH. Specifically, the slow-growing, metastatic subtype produces higher levels of PGRN, increased levels of matrix metalloproteinases (MMP) 2/9, and has a higher lysosomal pH than the more proliferative subtype. Interestingly, when

PGRN is exogenously added to the culture medium, the proteases expressed by each subtype influences whether PGRN will be processed into a product(s) promoting growth or a product(s) promoting inflammation. We also show that the pH of lysosomes in each subtype differs, with the slowly growing, metastatic subtype having a significantly higher pH than the proliferative subtype. This result suggests that lysosomal proteases, which are more functional at a lower pH, may be responsible for producing a PGRN product(s) that promotes growth in the proliferative subtype, while the higher lysosomal pH of the slowly growing subtype does not. Ongoing experiments address the possibility that decreasing lysosomal pH may shift the processing of PGRN, influencing the biological activities associated with this versatile signaling molecule. As mutations in the PGRN gene are implicated both in dysfunctional lysosomal pH and a variety of neurodegenerative diseases, these results may provide a novel approach to regulating inflammation and growth by intracellular mechanisms.

The polySUMOylation-dependent pathway promotes nucleolar release of Tof2 for mitotic exit

E. Gutierrez-Morton[1], L. Collins[1], S. Vanga[2], Y. Wang[1]; [1]Florida State University, Tallahassee, FL, [2]Lincoln High School, Tallahassee, FL.

SUMOylation involves the covalent attachment of SUMO (small ubiquitin-like modifier) to target proteins. This posttranslational modification is essential and impacts numerous cellular processes by altering protein localization and abundance. SUMOylation is a highly dynamic and reversible process. In *Saccharomyces cerevisiae*, SUMO proteases Ulp1 and Ulp2 readily reverse SUMOylation to prevent polySUMOylation. Perturbations to SUMO homeostasis are linked with aberrant cell cycle progression and tumor proliferation such as breast cancer. Recent work has shown that several yeast nucleolar proteins, including Tof2 and Net1, are SUMOylated. Tof2 and Net1 are required for nucleolar sequestration of Cdc14, a phosphatase that plays an essential role in mitotic exit by dephosphorylating the substrates of cyclin-dependent kinases. However, it is currently unknown if Tof2/Net1 SUMOylation regulates Cdc14 release and mitotic exit. We found that the protein level and the nucleolar localization of Tof2, but not Net1, were cell cycle regulated. Depletion of SUMO protease Ulp2 caused Tof2 polySUMOylation, nucleolar delocalization, and degradation.Interestingly, Tof2 delocalization and degradation depend on polySUMO-triggered ubiquitination by SUMO-targeted ubiquitin ligase and the subsequent extraction by Cdc48 segregase. In addition, the absence of Tof2 or induction of polySUMOylation leads to nucleolar release and activation of Cdc14 phosphatase. Overall, these results demonstrate a polySUMO-dependent mechanism for Tof2 delocalization from the nucleolus during anaphase, which frees Cdc14 to promote mitotic exit.

Signaling Networks Governing Cell Migration

B510/P2891

Phosphorylation of Arl4A/D promotes their binding by the HYPK chaperone for their stable recruitment to the plasma membrane

M. Lin[1], C. Yu[2,3], F. S. Lee[1,4,5]; [1]Institute of Molecular Medicine, National Taiwan University, Taipei, TAIWAN, [2]Department of Cell and Molecular Biology, Chang Gung University, Taoyuan, TAIWAN, [3]Department of Thoracic Medicine, Chang Gung Memorial Hospital, Taoyuan, TAIWAN, [4]Center of Precision Medicine, National Taiwan University, Taipei, TAIWAN, [5]Department of Medical Research, National Taiwan University Hospital, Taipei, TAIWAN.

The Arl4 small GTPases participate in a variety of cellular events, including cytoskeleton remodeling, vesicle trafficking, cell migration, and neuronal development. Whereas small GTPases are typically regulated by their GTPase cycle, Arl4 proteins have been found to act independent of this canonical regulatory mechanism. Here, we show that Arl4A and Arl4D (Arl4A/D) are unstable due to proteasomal degradation, but stimulation of cells by fibronectin (FN) inhibits this degradation to promote Arl4A/D stability. Proteomic analysis reveals that FN stimulation induces phosphorylation at S143 of Arl4A and at S144 of Arl4D. We identify Pak1 as the responsible kinase for these phosphorylations. Moreover, these phosphorylations promote the chaperone protein HYPK to bind Arl4A/D, which stabilizes their recruitment to the plasma membrane to promote cell migration. These findings not only advance a major mechanistic understanding of how Arl4 proteins act in cell migration, but also achieve a fundamental understanding of how these small GTPases are modulated by revealing that protein stability rather than the GTPase cycle acts as a key regulatory mechanism.

B511/P2892

Oligomerization of Arl4 small GTPases promotes their function in cell migration

Y. Lai[1,2], S. Wu[1,2], F. S. Lee[1,2,3]; [1]Institute of Molecular Medicine, College of Medicine, National Taiwan University, Taipei, TAIWAN, [2]Department of Medical Research, National Taiwan University Hospital, Taipei, TAIWAN, [3]Center of Precision Medicine, College of Medicine, National Taiwan University, Taipei, TAIWAN.

Protein dimerization or oligomerization participates in regulating various of cellular signaling transduction. Oligomerization of Ras small G proteins has been reported to regulate effectors binding and downstream pathway, which is important for their oncogenic activity and merits further research. Three isoforms Arl4 (Arl4A, Arl4C and Arl4D) small G proteins belong to the Arf family of Ras superfamily and each of them has been reported to promote cell migration via specific downstream effectors. Here, we identified Arl4A and Arl4D could form homo- and hetero-oligomerization through its C-terminal tail. By co-immunoprecipitation, *in vitro* binding assay, and size exclusion gel filtration, we showed that Arl4A and Arl4D formed homo- or hetero-dimerization and/or oligomerization. By immunofluorescence image analysis, we observed that Arl4A and Arl4D were cooperatively recruited to the plasma membrane. Moreover, the oligomerization of Arl4A and Arl4D contributes to their plasma membrane localization and promotes cell migration. Thus, we infer that homo- and/or hetero-oligomerization Arl4A and Arl4D play pivotal roles in regulating plasma membrane localization and their downstream functions.

B512/P2893

A Local Ca^{2+} and RhoA Signaling Crosstalk Facilitates Cell Migration by Reinforcing Actin Network in the Lamellipodia

E. Iu[1], A. Bogatch[1], W. Deng[2], J. Humphries[3], M. Humphries[4], G. Tanentzapf[2], S. Plotnikov[1]; [1]University of Toronto, Toronto, ON, Canada, [2]University of British Columbia, Vancouver, BC, Canada, [3]Manchester Metropolitan University, Manchester, United Kingdom, [4]University of Manchester, Manchester, United Kingdom

Cell migration underlies a wide range of physiological processes from embryonic development to tissue regeneration. The process of cell migration begins by the extension of membrane protrusions, such as lamellipodia. Such protrusive structure is driven by actin polymerization, which is tightly regulated by a complex of signaling pathways, including Rho GTPases and Ca^{2+}-dependent signaling. While the key role of Ca^{2+} signaling in lamellipodia protrusions has been demonstrated, the molecular mechanisms by which Ca^{2+} facilitates lamellipodia assembly is largely unknown. We first identified a mechanosensitive Ca^{2+}-permeant channel, TRPV4, as a positive regulator of lamellipodia protrusion by screening a panel of siRNAs targeting ion channels. Suppression of TRPV4 reduces the Ca^{2+} influx in protruding lamellipodia, and subsequently, decreases the density of F-actin in lamellipodia. To understand how the TRPV4-mediated Ca^{2+} influx facilitates lamellipodia protrusion, we interrogated the involvement of small GTPases by using FRET biosensors. To our surprise, we found that RhoA activity peaks in protruding lamellipodia, which coincides spatially with the Ca^{2+} influx. Furthermore, we showed that local upregulation of RhoA activity in lamellipodia requires TRPV4 activity. Suppressing RhoA or its downstream effector, formins, also decreased F-actin density, suggesting that TRPV4-mediated Ca^{2+} signaling promotes actin assembly by maintaining a high RhoA activity. By immunostaining, we showed that suppression of TPRV4 decreased the amount of active Ca^{2+}-calmodulin-dependent protein kinase II (CaMKII), a key Ca^{2+} signaling hub, in lamellipodia. Furthermore, we showed that local inhibition of CaMKII halted cell protrusions, suppressed RhoA activity and decreased F-actin density in lamellipodia, suggesting that CaMKII transduces local Ca^{2+} signals from TRPV4 to RhoA. To identify the RhoA regulator downstream of TRPV4 and CaMKII, we compared the phospho-proteome of isolated lamellipodia fractions purified from TRPV4- and CaMKII-inhibited cells. Using FRET and cell spreading assays, we functionally tested 14 potential RhoGEFs/GAPs, whose phosphorylation depends on TRPV4 and CaMKII. We found that depleting RhoGEF TEM4 decreased density of F-actin and RhoA activity independent of TRPV4 or CaMKII activation, suggesting that TEM4 is a Ca^{2+}-regulated RhoGEF that regulates lamellipodia protrusions. Finally, we showed that suppression of this signaling axis suppresses the protrusive activity and migration of melanoblasts in mouse skin explant. Together these data elucidate a novel Ca^{2+} signaling axis composed of TRPV4/CaMKII/RhoA that reinforces lamellipodial actin network, facilitates lamellipodial protrusions, and promotes cell migration.

B513/P2894

Exploring the Functional Roles of PI5K in Regulation of PI(4,5)P2 during Cell Migration

Y. Deng[1], P. N. Devreotes[2]; [1]Johns Hopkins University, Baltimore, MD, [2]Johns Hopkins University School of Medicine, Baltimore, MD.

Cell migration is involved in a lot of important physiological activities during development, such as wound healing and cancer metastasis. It is emerging that the amoeboid migration is organized by a coupled excitable network whose minimal topology consists of an autocatalytic positive feedback loop

and a delayed negative feedback loop. This gives rise to a defined threshold of activation either by stochastic noise or external input, causing a firing of signaling and cytoskeletal networks which is manifested by a protrusion or macropinosome formation. *Dictyostelium* cells display such excitability through signal transduction (STEN) and cytoskeletal (CEN) networks, but the mechanisms of regulation of some signaling components are still poorly studied. We are studying how PI(4,5)P2 is regulated and the relations between PI(4,5)P2 and Ras. Here we proposed that PI(4,5)P2 is primarily regulated by PI5K, an enzyme that converts PI4P to PI(4,5)P2. The piki- cells which have a significant PI(4,5)P2 level decrease, indicate that there is a strong correction between PI5K and PI(4,5)P2. We showed that PI5K colocalizes with PI(4,5)P2 at the rear of cells and shares complementary wave patterns with Ras and other front proteins. We identified the membrane binding region within PI5K using truncation studies. We found that deleting this membrane binding region will make PI5K fall to cytosol and potentially lower PI(4,5)P2 levels on plasma membrane. We recruited cytosolic PI5K to the membrane using iLiD optogenetic approach to determine if PI5K function and PI(4,5)P2 level can be restored upon recruitment. We performed co-immunoprecipitation assay and proved that PI5K can be pulled down from plasma membrane. Our hypothesis is Ras inhibits PI5K directly or relocates PI5K to further achieve the goal of inhibiting PIP2 levels and this forms a rapid autocatalytic loop. PKB slowly phosphorylates PI5K to form a delayed negative feedback loop. To test this hypothesis, we made PI5K point mutation T262A (nonphosphorylatable) and T262E (phosphomimetic) to study how PKB phosphorylation will restore PI5K and further inhibit Ras. We did cAMP global simulation assay on PI5K WT/T262A/T262E cells using PHcrac-RFP as the marker to look at the time difference for PKB phosphorylation. Taken these results together, we hope to find a new mechanism to explain Ras-PI5K-PI(4,5)P2 relations.

Diffusion-limited Dynamic Partitioning Can Define Cortical Asymmetry and Control Wave-like Spatiotemporal Patterning of Multiple Membrane Proteins

T. Banerjee[1,2], S. Matsuoka[3,4], Y. Miao[1], Y. Kamimura[4], D. Biswas[5], D. S. Pal[1], M. Ueda[3,4], P. A. Iglesias[5], P. N. Devreotes[1]; [1]Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, [2]Deaprtment of Chemical and Biomolecular Engineeering, Johns Hopkins University, Baltimore, MD, [3]Graduate School of Frontier Biosciences, Osaka University, Osaka, JAPAN, [4]Laboratory for Cell Signaling Dynamics, RIKEN Center for Biosystems Dynamics Research, Osaka, JAPAN, [5]Department of Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD.

Dynamic cortical patterning of different signal transduction and cytoskeletal components has recently emerged as an underlying phenomenon that organizes the spatial and temporal scale of pseudopodia formation, macropinocytosis, cytokinesis, and cell polarity. These propagating waves and flashes have been theoretically modeled using different biomechanochemical excitable or oscillatory networks consisting of multiple interacting autocatalytic and feedback loops. All these patterns, that orchestrate information flow between membrane and cytoplasm, are conventionally considered to propagate via a “trigger wave” or “stadium wave” mechanism. Typically, network activating proteins, such as PI3K, Akt, and SCAR/WAVE are thought to be transiently and asymmetrically recruited from cytosol to membrane, whereas deactivating components such as PTEN and myosin II dissociates from the membrane in those particular domains. The recruitment and release process is spatially coordinated and repeated multiple times to maintain asymmetric patterns. However, this model excludes the possibly of symmetry breaking of any integral or lipid-anchored membrane proteins which remain associated with the membrane. Here, we report that, multiple lipid-anchored membrane proteins, such as PKBR1, Gβγ, R-

Pre, and RasG, in contrary to various previous reports, exhibits highly asymmetric dynamics in the plasma membrane during cortical patterning and protrusion formation in migrating *Dictyostelium* cells. We found that the symmetry breaking processes of these membrane proteins could be successfully organized in absence of actin polymerization. Combining receptor activation and photoconvertible-protein based translocation assays, we demonstrated that these patterns are generated by dynamic partitioning or phase separation of different lipid-anchored proteins to specific membrane compartments. Using single-molecule imaging based measurement of membrane-dissociation and diffusion kinetics, we discovered that, instead of commonly accepted recurrent recruitment-release mediated "trigger wave" or "stadium wave" machinery, differential diffusion coefficient of these lipid-anchored proteins in different domains of the membrane drive this symmetry breaking and wave propagation processes. Computational simulation of excitable network involving stochastic reaction-diffusion master equation established that, while there are characteristic differences, either periodic shuttling or dynamic partitioning based self-organization can yield similar cortical wave patterns with the same length and time scale, as observed experimentally.

Front rear polarity establishment during bleb based migration under confinement

A. Jha[1], A. Chandra[2], J. Haugh[3], C. Waterman[1]; [1]National Institutes of Health, Bethesda, MD, [2]North Carolina State University, Raleigh, MD, [3]North Carolina State University, Raleigh, NC.

Cancer cells with high contractility are prone to blebbing and when confined in the absence of integrin based cell-substrate adhesion, exhibit "leader bleb-based" migration characterized by a highly polarized morphology with a long, stable leader bleb leading the direction of migration especially during metastasis. However, the mechanisms mediating the establishment and maintenance of the extreme cell polarization are not known. We sought to test the hypothesis, that polarization is mediated by the segregation of signaling components on the plasma membrane especially growth factor receptors. To test this, I performed time-lapse imaging of highly metastatic melanoma cells under 3µm vertical confinement. In the absence of integrin signaling, Epidermal Growth Factor Receptor (EGFR) signaling is required for bleb stability and hence polarity during bleb-based migration. EGFR exhibited a strong gradient with accumulation at the base of the bleb compared to the bleb tip. Other transmembrane proteins (TM) also exhibit strong gradient however proteins on the outer and inner leaflet of the PM are distributed uniformly showing lack of any membrane flow from tip to the base of the bleb. With super resolution live imaging of actin and manipulations, we show TM gradients are established in the blebs due to strong corralling by membrane proximal actin, accumulation of large picket proteins like CD44 and rapid protein turnover on the back of the bleb compared to the tip of the bleb not by advection due to fast actin retrograde flow. The back of the bleb has stronger membrane-cortex link that enhances the actin corralling. With fluorescence anisotropy measurement we show that EGFR activity is high in the back of the bleb. This asymmetry results surprisingly in a reverse front-rear Rho-GTPase and phosphoinositide lipid polarity signature compared to adhesion based cell migration with RhoA/PIP2 in the front and Rac/PIP3 in the back of the bleb. With this work, I elucidate novel mechanisms of protrusion formation and front-rear polarity establishment during less understood bleb-based migration and front-rear polarity establishment.

Mapping variation in the morphological landscape of human U2OS cells with optical pooled CRISPRi screening

R. D. Labitigan[1,2], A. L. Sanborn[3,4], C. V. Hao[4], C. K. Chan[5], N. M. Belliveau[2], E. M. Brown[5], M. Mehrotra[2], J. A. Theriot[1,6]; [1]Department of Biochemistry, Stanford University, Stanford, CA, [2]Department of Biology, University of Washington, Seattle, WA, [3]Department of Computer Science, Stanford University, Stanford, CA, [4]Department of Structural Biology, Stanford University, Stanford, CA, [5]Allen Institute for Cell Science, Seattle, WA, [6]Howard Hughes Medical Institute, University of Washington, Seattle, WA.

Image-based screening is a powerful platform to identify genetic regulators of spatial and organizational cell phenotypes. However, in the case of phenotypes relating to cell-scale cytoskeletal organization and morphology, the contributions of individual gene products are challenging to define due to the complexity present in natural phenotypic variation. While image-based screens are typically arrayed (i.e. perturbations are kept in separate wells), recent technologies have enabled a pooled format that promises to increase scalability and reduce technical variability, thus allowing for more precise phenotypic encoding and greater potential for biological discovery.

We leveraged the controlled nature of image-based pooled screening to assess the impact of CRISPRi knockdown of 366 genes that had been shown or proposed to alter cell morphology or actin filament architecture in human U2OS osteosarcoma cells. The large, widely varied shapes and intricate internal organization of U2OS cells provide an ideal system to study genetic determinants of complex morphological states. To determine the identity of the guide RNA in each cell, we optimized in situ sequencing technologies to maximize the efficiency and confidence of DNA barcode readout from fixed cells. We captured the phenotype and genotype of 1.5 million cells by imaging the actin cytoskeleton, nucleus, and DNA barcodes, and successfully assigned guide RNAs to 85% of cells.

A persistent challenge in image-based screens is how to rigorously describe high-dimensional phenotypes. Using a deep learning algorithm, the β-variational autoencoder, we generated a phenotypic space that quantitatively maps the range of single-cell phenotypes across the most important modes of variation in the full dataset. This phenotypic mapping was distinct from a mapping generated via a more conventional approach employing morphological profiling-based dimensionality reduction, but still detected similar gene hits while requiring minimal design decisions. We also developed a constrained sampling method to generate interpretable visualizations of morphological variation within this high-dimensional phenotypic space, enabling us to define the effects of specific gene knockdowns even in the presence of substantial underlying phenotypic variability. By relating these phenotypic shifts to each other, we construct a quantitative and interpretable landscape of monogenically tunable modes of variation in U2OS morphological structure. The approach we develop for mapping and visualizing phenotypic variation in a high-dimensional space is generalizable and can be applied to diverse biological image datasets.

Investigating Intrinsic and Extrinsic Mechanisms of GBM Invasion

M. J. Barraza[1], A. Banisadr[1], F. B. Furnari[2], A. J. Engler[3,4]; [1]Biomedical Sciences Graduate Program, University of California, San Diego, La Jolla, CA, [2]Department of Pathology, University of California, San Diego, La Jolla, CA, [3]Department of Bioengineering, University of California, San Diego, La Jolla, CA, [4]Sanford Consortium for Regenerative Medicine, La Jolla, CA.

Glioblastoma Multiforme (GBM) is the most lethal and common primary brain tumor in adults, with a median patient survival of 12-15 months following current standard of care. This poor prognosis is largely due to highly invasive tumor cells that evade surgical resection and develop multiple mechanisms of therapeutic resistance, leading to patient relapse with recurrent GBM. Adding to this aggressive character, GBM is heterogeneous, with 25% of cases containing cells expressing a constitutively active epidermal growth factor receptor (EGFR) truncation of exons 2-7 known as variant III, i.e., EGFRvIII. These cells have enhanced oncogenic properties and can activate neighboring glioma cells overexpressing wtEGFR through an extrinsic mechanism, leading to cooperative invasion. It remains unclear how different EGFR mutation combinations, in conjunction with hallmark GBM mutations (i.e., *PTEN* deletion), impact tumor aggressiveness. Thus, we hypothesize that intrinsic signaling initiates invasion mechanisms, while extrinsic signaling in genotypically diverse tumor populations enhance glioma cell migration into brain parenchyma. To model GBM heterogeneity, we utilized an isogenic mouse astrocyte model of high-grade glioma (mHGG) containing combinations of common GBM mutations (i.e., *Ink4a/Arf* deletion, *PTEN* deletion, and wtEGFR or EGFRvIII overexpression). A spinning disc assay, which applies shear stress to cells seeded on an ECM-coated coverslip by spinning at defined angular velocities in a PBS buffer, was used to measure average adhesion strength of these cell populations. 2D and 3D migration assays were used to measure both intrinsic and extrinsic migratory properties to further characterize invasion phenotypes. We found that cells expressing EGFRvIII have intrinsically lower adhesion strength compared to wtEGFR and parental cells. Correspondingly, EGFRvIII cells traveled a greater distance and at a faster speed than wtEGFR and parental cells in the 2D migration assay. Interestingly, wtEGFR cells exposed to *Ink*$^{-/-}$EGFRvIII conditioned media (CM) for 24 hours had reduced adhesion strength and enhanced migration; however, wtEGFR cells exposed to *Ink*$^{-/-}$ *Pten*$^{-/-}$EGFRvIII CM remained unchanged in terms of adhesion and migration, suggesting a role for PTEN in regulating EGFRvIII extrinsic signaling. Furthermore, tumor spheroids composed of varying ratios of two cell populations (i.e., wtEGFR and EGFRvIII) exhibited a spectrum of migratory patterns when embedded in a collagen matrix, ranging from independent to collective migration. Overall, these studies provide insight into the role intratumoral heterogeneity plays in glioma cell migration and possibly suggest new targets for therapeutic intervention.

Extracellular Matrix Composition Tunes Macrophage Morphology, Motility, and Adhesion through Distinct Integrin-Mediated Signaling Pathways

M. Stinson, J. D. Rotty, A. Laurenson; Uniformed Services University of the Health Sciences, Bethesda, MD.

The microenvironment of tissue-resident macrophages is complex and mutable, containing a variety of signaling molecules, glycoproteins, and fibrous proteins that are tissue and context dependent. Macrophages must be capable of rapidly navigating and responding to these 3D environments in order

to maximize their functions as first responders to pathogens, wounds, and sites of inflammation. Some of the most well characterized fibrous glycoproteins constituting the extracellular matrix (ECM) are collagen, fibronectin, and laminin. Substantial work has been done to understand the interactions between macrophages and fibronectin, a substrate that induces spreading and persistent migration. However, often-cited studies suggest that macrophages do not adhere to laminin. Our work has demonstrated that ECM components differentially elicit morphological and migratory phenotypes that depend on distinct integrin binding and activation of downstream cytoskeleton-regulating pathways. The same population of bone marrow derived macrophages (BMDM) plated on equal concentrations of fibronectin and laminin 111 demonstrate distinct morphological features and migration characteristics. Laminin 111 elicits faster, less persistent myosin II-dependent migration, lower adhesion, and smaller spread cell area. Conversely, BMDMs plated on fibronectin are slower, more persistent, adhere strongly and have a large spread cell area. We next demonstrate that each of these ECM sensing pathways are distinct. Lower concentrations of laminin 111 cause cells to slow down and spread out, and less fibronectin causes cells to speed up. Additionally, with a series of inhibitor experiments, we determined that laminin 111 appears to increase migration velocity and dynamic shape changes during motility by increasing myosin II activity, while decreasing persistence and inducing a smaller cell shape through ROCK activity. Furthermore, αvβ3 and αvβ5 inhibition was shown to increase macrophage velocity on fibronectin, while α6 inhibition blocked binding to laminin 111 completely. To summarize, α6 binds to laminin 111 and increases ROCK and Myosin II activity to a higher degree than the RGD-binding integrins that recognize fibronectin. The resulting laminin 111 phenotype overrides cell spreading, causing macrophages to ball-up, migrate less persistently and at a higher velocity. These data suggest that macrophages sense ECM differences through differential integrin binding, leading to altered adhesion, activation of specific cytoskeletal regulators, and altered dynamic macrophage behaviors. It is also possible that ECM sensing may be a critical modulator of additional innate immune functions beyond motility.

Quantifying Correlation of Cell Migration, Membrane Remodeling, and Cortical Localization of Actomyosin Cytoskeletal Components in Live Animals

D. Chen[1], N. Melis[1], W. Losert[2], R. Weigert[1]; [1]National Institutes of Health, Bethesda, MD, [2]University of Maryland, College Park, MD.

Cell migration requires local membrane remodeling at the leading edge and the rear of the cell (e.g., uropod), a process which involves dynamic protrusions and retractions driven by cytoskeletal rearrangements. State of the art 2-photon intravital subcellular microscopy (ISMic) enables the acquisition of 4-D movies of interstitial cell migration *in vivo* with a resolution of a few hundred nanometers and a frame rate of 6 seconds. Here, we describe a quantitative tool to investigate how local levels of non-muscle myosin IIA (NMIIA) and cell membrane remodeling dynamics coordinate to drive the cell migration. The proposed method is customized with MATLAB. The cell shape is quantified through snake algorithm. The cell boundary at each frame is defined with consecutive boundary points at subpixel precision for local boundary curvature calculation. The local boundary motion is identified by tracking the boundary points with minimum displacement criterion. The onset, dynamics, and lifetime of each local membrane protrusion at the cell leading edge are monitored, as well. For each boundary point, a cortical box of a selected depth is defined, and the local average fluorescence intensity of cell voxels in that box is measured for the NMIIA-GFP, expressed in the migrating neutrophils. NMIIA

distribution in the leading edge and uropod of each migrating cell are defined as the fraction of time that a cell maintains a defined level (low, medium, high) of NMIIA during migration. At the subcellular level, this method provides the correlation between the cortical NMIIA and local cell membrane remodeling. At the cell level, it provides the correlation between persistence of cell migration direction, NMIIA distribution, and local membrane protrusions at the leading edge (or the uropod). Neutrophil migration *in vivo* and in 3-D collagen gel mimicking the *in vivo* ECM were quantified using this tool. We found that NMIIA was recruited not only to the retracting rear of migrating neutrophils but also at the leading edge, where it positively correlated with the local cell boundary curvature. Notably, this quantitatively defined phenotype was not observed in 2-D under agarose in vitro assays where NMIIA is mostly concentrated at the retracting uropod. Finally, NMIIA recruited at the leading edge of the cell facilitated the persistence of cell migration direction, possibly through stabilization of the lifetime of the local protrusions at the leading edge.

Defining the role of CD56/NCAM in human natural killer cell polarization and migration

A. L. Martinez, M. J. Shannon, E. M. Mace; Columbia University Irving Medical Center, New York, NY.

CD56/neural cell adhesion molecule (NCAM) is a glycoprotein that plays a poorly defined role in lymphocyte functions including cell migration and natural killer (NK) cell cytotoxic function. While we have previously described localization of CD56 to the uropod of migrating NK cells, the role that it plays in cell migration and cell polarization remains undefined. The intracellular domain of the 140 kDa isoform of NCAM can play a role in mediating signaling interactions through the Src kinase Fyn and focal adhesion kinase in neurons, however the mechanism of CD56/NCAM function in immune cells has not been described.

To investigate the role of CD56 in NK cell migration, we deleted CD56/NCAM from human NK cell lines. We found that CD56-knockout (CD56-KO) NK cells had impaired spontaneous cell migration on the LFA-1 integrin ligand ICAM-1 compared to wild-type (WT). Automated detection of cell tracks and morphology from confocal microscopy data identified specific features of CD56 deficient cells, namely abnormal cell eccentricity and decreased speed, persistence, and track length. Live cell confocal imaging of LifeAct mScarlet WT and CD56-KO NK cells demonstrated that actin ruffling was intact in CD56-KO but cells formed multidirectional lamellipodia-like structures, suggesting that a lack of cell polarity contributed to the cell migration defect. Actin flow speed and percent immobile (non-flowing) actin was unchanged, suggesting that actin polymerization is unaffected by the absence of CD56. This imaging further identified the presence of unusual actin structures in CD56-KO NK cells, specifically large actin foci on the basal surface of migrating cells. Structured illumination microscopy (SIM) confirmed the presence of these structures, which were also enriched for vinculin and Pyk2, in migrating cells. Additional SIM imaging identified an increased frequency, but decreased area, of activated integrin foci in CD56-KO NK cells, further suggesting that CD56 plays a role in promoting integrin turnover and actin homeostasis. Reconstitution of CD56-KO cells with full-length CD56/NCAM, but not CD56/NCAM missing the intracellular domain, restored the actin phenotype, demonstrating that the intracellular domain of CD56/NCAM plays a role in integrin-mediated signaling in human NK cells. Together, our data identify a novel role for CD56/NCAM in NK cell adhesion and migration.

Rap1 coordinates cell-cell adhesion and cytoskeletal reorganization to drive collective cell migration during rapid wound healing

K. E. Rothenberg, R. Fernandez-Gonzalez; University of Toronto, Toronto, ON, Canada

Coordinated cell movements contribute to tissue development and repair and to the spread of metastatic disease. We investigate collective cell migration during wound healing in the *Drosophila* embryonic epidermis. Upon wounding, the cells immediately adjacent to the wound become polarized: cell-cell adhesion molecules are internalized from the wound edge, and actin and the molecular motor non-muscle myosin II accumulate at the interface with the wounded cells, forming a supracellular cable around the wound that coordinates cell movements. The cable is thought to assemble from and anchor at former tricellular junctions (TCJs) along the wound edge, which are reinforced during wound closure through the accumulation of adherens junction components. However, the mechanisms that coordinate the adhesive and cytoskeletal rearrangements required for rapid wound closure are unclear. We found that reducing the activity of the small GTPase Rap1 using a dominant-negative form of the protein (Rap1DN) slowed wound repair by 45%. The slower wound closure was accompanied by defective actomyosin polarization to the wound edge and a loss of E-cadherin at TCJs. Embryos expressing a mutant form of the Rap1 effector Canoe/Afadin that cannot bind Rap1 displayed a defect in E-cadherin accumulation at TCJs similar to the effects of Rap1DN, but with normal myosin polarization. This suggests that Rap1 signals through Canoe to drive TCJ reinforcement, but not to assemble the supracellular cable. To understand how Rap1 may be affecting actomyosin cable assembly, we measured Rho1/RhoA activity in Rap1DN embryos and showed that Rho1 activity was reduced by 72% in Rap1DN embryos, which was accompanied by a 54% reduction in tension at the wound edge. We found that the RhoGEF Ephexin, which can be activated by Rap1, was necessary for myosin polarization to the wound edge and rapid wound repair, with no significant effects on E-cadherin redistribution. Our data support a model in which Rap1 simultaneously drives actomyosin cable assembly via activation of Rho1 through Ephexin and reinforces adhesion at TCJs via Canoe to enable rapid migration to heal embryonic wounds.

Investigating Mechanisms of FGF Dispersal and Spatial Organization of Downstream Signaling in Migrating Cells

T. V. Gibney, L. Latifi, A. M. Pani; Biology, University of Virginia, Charlottesville, VA.

Cell signaling dynamics are tightly regulated in space and time to orchestrate cellular activities such as migration, proliferation, and differentiation. We are using *C. elegans* postembryonic muscle progenitors as a tractable model to dissect signaling mechanisms *in vivo*. One muscle progenitor type, sex myoblasts (SMs) migrate from near the tail of the worm to the center during larval development. Fibroblast Growth Factor (FGF) signaling is required for SM migration, and FGF has been hypothesized to act as a chemoattractant for migrating cells. FGFs are often thought of as soluble signaling proteins that can diffuse to form gradients. However, extracellular diffusion has not been observed with endogenous FGFs, and in several contexts FGFs are membrane anchored proteins that signal at cell contacts. To investigate how FGFs guide SM migration, we tagged the endogenous FGF (EGL-17) involved in SM migration and imaged its dynamics along with membranes of FGF-expressing cells and migrating SMs. Unexpectedly, we did not observe an extracellular FGF gradient from the center of the worm, but

instead observed FGF expressed by ventral cells along the route taken by migrating SMs. However, live imaging of FGF along with ligand and receptor expressing cells, in their natural context and in misexpression experiments, demonstrated that FGF/EGL-17 is diffusible *in vivo* and spreads between cells that are not in contact. We then anchored the endogenous FGF to source cell membranes, which disrupted SM migration and confirmed that free FGF dispersal is required despite the absence of a visible extracellular gradient. Misexpression experiments are also consistent with diffusible FGF acting as a directional cue for SMs. To investigate how extracellular FGF is translated into directed cell migration, we characterized and manipulated localization of downstream components that link activated FGF receptors to cytoskeletal regulators and/or Ras-MEK-ERK signaling. We found that the Ras GEF SOS-1 localizes to the leading and ventral edges of migrating SMs. Redistributing a SOS catalytic domain around the entire cell disrupted SM migration similar to SOS-1 degradation. This work provides direct evidence that an endogenous FGF acts as a diffusible signaling protein and provides new insights into mechanisms that translate extracellular signals into directed cell behaviors.

CED-12/ELMO/ELMOD can switch from promoting to inhibiting F-actin formation in the same tissue

M. Soto, T. Venkatachalam, L. Cordova Burgos; Rutgers - Robert Wood Johnson Medical Sch, Piscataway, NJ.

ELMO (engulfment and cell migration) proteins were first discovered in *C. elegans*, and are conserved from humans to plants, fungi and amoebae. Comparisons in other species have identified two families within the ancient ELMO family. Shorter ELMOD proteins, primarily composed of an ELMO domain, typically encode a GAP with hydrolysis activity towards Arf and Arl GTPases. Longer ELMO family proteins, with additional domains, support the GEF function of partner CED-5/DOCK-180 proteins, to activate Rac/Rho family GTPases. The original ELMO, CED-12, is longer, includes a PH membrane binding domain, and was thought to act, together with CED-5/DOCK180, to activate CED-10/Rac1 during engulfment and cell migrations. We therefore expected CED-12/CED-5 to behave as a GEF for CED-10/Rac1, and activate F-actin during a cell migration essential for *C. elegans* embryogenesis, ventral enclosure. During ventral enclosure, a sheet of epidermal cells migrates to enclose all other tissues. Instead, we discovered that loss of CED-12, CED-5 or their partner protein CED-2/CRKII, all lead to embryonic lethality due to excess F-actin formation, increased dynamics in the migrating cells, and faster migrations. However, corpses that are engulfed by these same migrating epidermal cells show lower F-actin and slower corpse disappearance, as would be expected for loss of a CED-10/Rac1 GEF. To address how loss of CED-12/CED-5 can have two opposing effects in the same cells as they undergo corpse engulfment and cell migration, we investigated if CED-12 harbors both ELMOD and ELMO functions. Aligning CED-12 to other *C. elegans* GAP proteins and to ELMODs identified a GAP region in CED-12. Mutating a candidate catalytic Arginine in this region (R537A) altered the epidermal cell migration function, and not the corpse engulfment function. Thus, a single ELMO/ELMOD protein can use distinct domains to carry out two opposite functions. Additional studies, including those to identify the signals that activate the GEF or GAP functions of CED-12, and to identify the GTPase targets of the GAP function, will further our understanding for how GEF and GAP functions can be coordinated, even within the same cells.

B524/P2905

Glioblastoma cell migration requires membrane tension and endocytosis regulated by Plexin-B2

C. Junqueira Alves[1], T. Hannah[1], R. Wiener[1], M. Tipping[2], R. Alves Dias[3], J. Rodrigues Furtado de Mendonça[3], H. Zou[1], R. Friedel[1]; [1]Icahn School of Medicine At Mount Sinai, New York City, NY, [2]Memorial Sloan Kettering Cancer Center, New York City, NY, [3]Federal University of Juiz de Fora, Juiz de Fora, Brazil

Background: Infiltrative growth is a major cause of high lethality for the malignant brain tumor glioblastoma (GBM). To initiate invasion, GBM cells face the challenge of negotiating through tight interstitial space inside the brain. The mechanisms of how GBM cells regulate invasiveness are unclear. As tumor cells frequently usurp developmental pathways, we suggest that the Plexin axon guidance receptors may regulate GBM invasiveness.**Method:** We have established a novel *in vitro* paradigm that utilizes a 3D-printed microchannel device to investigate the capability of GBM cells to migrate through constrictions of different sizes. We speculated that the GBM cell migration may be through endocytosis, which is a major regulator of signaling events and has been shown to be regulated by membrane tension. We interfered with GBM cell migration using drugs known to inhibit endocytosis. Next, we deleted Plexin-B2 in GBM cells by lentiviral CRISPR-Cas9. We probed membrane tension using live fluorescent membrane tension probe and optical tweezers. We also investigated the endocytosis dynamics using fluorescent labeled dextran, plasma membrane-targeting dyes, and membrane-attached intracellular fluorescent proteins in live GBM cells. **Results:** Wild-type GBM cells showed active locomotion, high velocity, and forward motility through the constrictions. In contrast, Plexin-B2 knockout cells extend long cellular processes, displayed plasma membrane rupture, and failed to 'infiltrate' through narrow constrictions. It was associated with low uptake of cytoplasmic dextran, reduced endocytosis of membrane-attached intracellular proteins, and low membrane tension. Similar phenotypes were observed after treating WT GBM cells with endocytosis inhibitors. **Conclusion:** Plexin-B2 regulation of membrane tension and endocytosis provides biomechanical plasticity for GBMs facing the challenge of negotiating through tight spaces during cancer invasiveness.

B525/P2906

The molecular basis for rational targeting of FGFR-driven proliferation and motility

J. Migliavacca[1], K. Santhana Kumar[1], L. L. Kopp[1], A. Gries[1], S. Yan[1], C. Brunner[2], M. Schuster[3], O. Zerbe[3], G. Schneider[2,4], M. A. Grotzer[1], **M. Baumgartner**[1]; [1]University Children's Hospital Zurich, Zurich, Switzerland, [2]ETH Zurich, Zurich, Switzerland, [3]University of Zurich, Zurich, Switzerland, [4]ETH Singapore SEC Ltd, Singapore, Singapore

Objective: Receptor tyrosine kinases (RTK) promote growth and dissemination in pediatric tumors including medulloblastoma (MB). We hypothesized that repression of protein-protein interactions downstream of activated RTKs could constitute a novel means to inhibit oncogenic signal transmission. Therefore, we delineated molecular interactions downstream of fibroblast growth factor receptor (FGFR) signaling in MB and identified and validated small bioactive molecules that repress FGFR-driven growth and invasiveness.

Methods: Using 3D in vitro, in vivo and cerebellar slice culture models, we identified the FGFR signaling pathway as a driver of growth and invasiveness in MB. Using proteomics and functional assays, we determined key molecular components of oncogenic FGFR signaling in MB. By computational screening combined with functional, biophysical, and structural binding analyses, we discovered and validated novel small molecule compound inhibitors of FGFR-driven growth and invasiveness.

Results and discussion: We identified the FRS2 protein as an essential immediate downstream transmitter of FGFR signaling in MB and demonstrate a central role for STRN3 to further integrate these signals toward growth and invasiveness. Mechanistically, STRN3 interacts with the kinase MAP4K4, couples it to the protein phosphatase 2A and thereby inactivates growth repressing activities of MAP4K4. In parallel, STRN3 enables MAP4K4-mediated phosphorylation of PKC delta and VASP, which combined are necessary to promote tissue invasion. To selectively repress pro-invasive FGFR functions, we identified and functionally validated small molecule ligands of FRS2 that prevent FRS2 activation and downstream signaling. We demonstrate efficacy of these ligands in inhibiting invasion and growth promoting activities, confirmed on-target activity and identified potential off-targets.
Conclusion: The cooperation of STRN3 and MAP4K4 represses tumor suppressive hippo signaling and promotes invasiveness through PKC delta and VASP. These tumor promoting functions of the activated FGFR can be blocked by a small molecule ligand of the FRS2 adaptor protein. Thus, the here identified FRS2 ligand bears promise for further pre-clinical evaluation as an anti-growth promoting and anti-metastatic therapeutic applicable to FGFR-driven tumors.

B526/P2907

Lamellipodin drives stiffness-dependent cell cycling through YAP

J. A. Brazzo, Y. Heo, Y. Bae; Jacobs School of Medicine and Biomedical Sciences, Buffalo, NY

The stiffness of the extracellular matrix (ECM) regulates cell proliferation via mechanotransduction. In this process, the fibrous ECM directly engages integrins in the cell membrane that activate FAK (focal adhesion kinase), p130Cas, and Rac GTPase. This signaling cascade triggers cyclin D1 for progression to S phase of the cell cycle and cell proliferation. We recently showed that lamellipodin is critical for this progression, and that lamellipodin itself is regulated by ECM stiffness through the FAK-p130Cas-Rac signaling axis. How stiffness-sensitive lamellipodin mechanistically drives cell cycling inside the nucleus is unclear. YAP (Yes-associated protein) is a proto-oncogene that translocates to the nucleus and induces cyclin D1 and cell cycle progression and also is critical for the mechanotransduction of ECM stiffness into proliferative gene expression. We hypothesize that lamellipodin controls stiffness-dependent cell cycle progression via YAP nuclear translocation. To test this, we cultured serum-starved wild-type and lamellipodin-overexpressing ($Lpd^{o/x}$) mouse embryonic fibroblasts (MEFs) on low-stiffness (physiologically relevant, 2-4 kPa) bis-polyacrylamide hydrogels functionalized with fibronectin in the presence of 10% serum for 24 h. The expression, phosphorylation, and nuclear translocation of YAP were assessed via immunoblotting and epifluorescence microscopy. The percentage of YAP in the nuclei of $Lpd^{o/x}$ cells was nearly 2-fold that in wild-type cells, but the total protein and S127 phosphorylation levels were not different. We then treated $Lpd^{o/x}$ cells on low-stiffness hydrogels with verteporfin, an inhibitor of YAP nuclear translocation, and assessed cyclin induction via immunoblotting and S phase entry via EdU incorporation. Treatment with verteporfin drastically reduced cyclin A and B induction and S phase entry. Our findings show that (i) mechanosensitive regulation of lamellipodin increases nuclear accumulation of YAP, (ii) nuclear YAP is critical for lamellipodin-mediated stiffness-dependent cell cycling, and (iii) the regulation of YAP by lamellipodin is independent of the phosphorylation of YAP and activation of MST1/2, which are mediators of the canonical Hippo signaling pathway that regulates YAP nuclear translocation. Further research will explore how lamellipodin directly regulates the nuclear translocation of YAP.

B527/P2908

Emergent actin flows explain distinct modes of gliding motility

C. L. Hueschen[1], L.-a. Segev Zarko[1], J.-H. Chen[2], M. A. LeGros[2], C. A. Larabell[2], J. C. Boothroyd[1], R. Phillips[3], A. R. Dunn[1]; [1]Stanford University, Stanford, CA, [2]Lawrence Berkeley National Laboratory, Berkeley, CA, [3]Caltech, Pasadena, CA

During host infection, single-celled apicomplexan parasites like *Plasmodium* and *Toxoplasma* use a motility mechanism called gliding, which differs fundamentally from other known mechanisms of eukaryotic cell motility. Gliding is thought to be powered by a thin layer of flowing filamentous (F)-actin sandwiched between the plasma membrane and a myosin-coated inner membrane complex. How this surface actin layer drives the diverse apicomplexan gliding modes observed experimentally - helical, circular, and twirling, and patch, pendulum, or rolling - presents a rich biophysical puzzle. Here, we use single-molecule imaging to track individual actin filaments and myosin complexes in live *Toxoplasma gondii.* Based on these data, we hypothesize that F-actin flows arise by self-organization, rather than following a microtubule-based template as previously believed. We develop a continuum model of emergent F-actin flow within the unusual confines provided by parasite geometry. In the presence of F-actin turnover, our model predicts the emergence of a steady-state mode in which actin transport is largely rearward. Removing actin turnover leads to actin patches that recirculate up and down the cell, a "cyclosis" that we observe experimentally for drug-stabilized actin bundles in live parasites. These findings provide a mechanism by which actin turnover governs a transition between distinct self-organized F-actin states, whose properties can account for the diverse gliding modes known to occur. More broadly, we illustrate how different forms of gliding motility can emerge as an intrinsic consequence of the self-organizing properties of F-actin flow in a confined geometry.

Single Cell Chemotaxis and Directed Migration

B528/P2909

Cortical actomyosin suppresses directed migration signaling networks

J. Kuhn, P. Devreotes; Johns Hopkins University, Baltimore, MD.

Many modes of eukaryotic migration require cells to separate the newly polymerizing actin meshwork at the cell front from actomyosin-based contraction at the cell back. The location and configuration of cytoskeletal molecules are controlled by upstream signal transduction events. The terms, Signal Transduction and Cytoskeletal Excitable Networks, STEN and CEN, reflect the biochemically excitable properties displayed by molecules in each of these systems. Much is understood about how the STEN regulates the CEN in random and directed migration. To examine how changes in cytoskeletal mechanics and organization might feedback to influence STEN, we developed methods to rapidly and locally alter myosin activity and cortical actin organization in migrating vegetative and developed cells. First, we show that *reducing* myosin assembly leads to an *increase* in activated Ras and an increased sensitivity to chemotactic stimulus. Second, *activation* of cortical actin regulator RacE *decreases* STEN activation. Surprisingly, Dictyostelium Rho homolog RacE activation leads to elevated actin polymerization, but this formation is relatively resistant to Arp 2/3 inhibition. Concomitantly, RacE activation causes a reduction in Ras activation and PtdIns(3,4,5)P3 levels. Taken together, our data suggest that cortical actomyosin suppresses cell front signaling molecules and suggests a novel mechanism for how cells can maintain front-back segregation during migration.

PD-LI promotes rear retraction during persistent cell migration by altering integrin β4 dynamics

M. Wang, C. Xiong, A. Mercurio; University of Massachusetts Chan Medical School, Worcester, MA.

Although the immune checkpoint function of PD-L1 has dominated its study, we report that PD-L1 has an unanticipated intrinsic function in promoting the dynamics of persistent cell migration. PD-L1 concentrates at the rear of migrating carcinoma cells where it facilitates retraction, resulting in the formation of PD-L1-containing retraction fibers and migrasomes. PD-L1 promotes retraction by interacting with and localizing the β4 integrin to the rear enabling this integrin to stimulate contractility. This mechanism involves the ability of PD-L1 to maintain cell polarity and lower membrane tension at the cell rear compared with the leading edge that promotes the localized interaction of PD-L1 and the β4 integrin. This interaction enables the β4 integrin to engage the actin cytoskeleton and promote RhoA-mediated contractility. The implications of these findings with respect to cell-autonomous functions of PD-L1 and cancer biology are significant.

B530/P2911

An external, long-lived memory in cell migration based on retroactions with the substrate.

J. D'Alessandro[1], A. Barbier-Chebbah[2], V. Cellerin[1], O. Benichou[2], R. Mège[1], R. Voituriez[3,2], B. Ladoux[1]; [1]Université Paris Cité, CNRS, Institut Jacques Monod, Paris, FRANCE, [2]Sorbonne Université, CNRS, LPTMC, Paris, FRANCE, [3]Sorbonne Université, CNRS, Laboratoire Jean Perrin, Paris, FRANCE.

Cell migration is controlled by the integration of intracellular dynamics and extracellular cues. Meanwhile, it is known that cells do not leave their substrate virgin but instead they can modify its properties on their tracks. Although this bidirectional flow of information between the cell and its environment is well accepted, whether the two retroact onto each other had not been investigated so far. By studying the migration of isolated cells, either confined on 1d-tracks or moving freely in 2d, we evidenced such a crosstalk effect: cells leave a footprint on their path and they show a strong tendency to retrace their steps. This relies on modifications of the substrate by the cells, which in turn change the cell-substrate interaction when cells reach the edge of their footprint and eventually push them to repolarise backwards. To analyse the consequences of this self-attraction on the properties of cell motion, we designed a model of persistent self-attracting walk. We demonstrated that this entails ageing of the cell trajectories, but also changes dramatically the way cells explore their environment. Finally, our findings suggest that this “stigmergy” effect may also affect cell migration in situations where it was not suspected before.

Piezo1 and ROCK2 Promote Fast Amoeboid Migration in Confined Environments

A. Caruso, N. Kar, J. Logue; Albany Medical College, Albany, NY

Cell migration through confined environments may induce a phenotypic transition to fast amoeboid (leader bleb-based) migration. However, the molecular mechanism(s) controlling this phenotypic transition remain poorly understood. Here, we show that regulation of intracellular calcium levels by the plasma membrane tension sensor, Piezo1, promotes the Leader Bleb-Based Migration (LBBM) of melanoma cells. Using a ratiometric assay, intracellular calcium is shown to rise with increasing levels of

confinement. Chelation of extracellular and intracellular calcium by BAPTA and BAPTA-AM, respectively, inhibits LBBM. Moreover, in highly motile cells, we found intracellular calcium levels to be dramatically increased at the cell rear. Using the Piezo1 inhibitor, GsMTx4, and RNAi, we can inhibit the phenotypic transition to fast amoeboid (leader bleb-based) migration. Therefore, we wondered if Piezo1 through calcium/calmodulin activates Myosin Light Chain Kinase (MLCK) to promote actomyosin contractility and amoeboid migration. Using a microchannel based assay, we find that ROCK2 and not MLCK, promotes amoeboid migration. Altogether, our work reveals an unanticipated collaboration between Piezo1 and ROCK2 in amoeboid migrating melanoma cells.

Cortical turnover required for adhesion-independent pressure-driven migration

C. Copos[1], W. Strychalski[2]; [1]Northeastern University, Boston, MA, [2]Case Western Reserve University, Cleveland, OH.

Directed cell migration accompanies us from conception to death. Experiments have highlighted the diversity in migration strategies employed by cells in physiologically relevant environments. In three-dimensional fibrous matrices and confinement between two surfaces, some cells migrate using pressure-driven round membrane protrusions. In this form of migration, the role of substrate adhesion is thought to be minimal, and it remains unknown if and how a cell can migrate without any adhesion complexes. We build a biomechanical computational model of a cell moving in a channel using pressure-driven adhesion-independent motility mechanism. Simulations show that the cell cannot effectively migrate when the actin cortex is modeled as a purely elastic material, even with asymmetric channel geometry. Cells do migrate effectively if actin turnover is included with a viscoelastic description for the cortex. We report that locomotion occurs even when cells are placed in suspension, and locomotion displacement is enhanced with physical confinement and importantly, cortical turnover.

B533/P2914

An AMPK phosphoregulated RhoGEF feedback loop drives shape invariant amoeboid migration *in vivo*

B. Lin[1,2], J. Luo[1,2], R. Lehmann[1,2,3]; [1]Skirball Institute and Department of Cell Biology, New York University School of Medicine, New York, NY, [2]Whitehead Institute for Biomedical Research, Cambridge, MA, [3]Department of Biology, Massachusetts Institute of Technology, Cambridge, MA.

The 'textbook' image of a migrating cell features a dynamic, actin-filled protrusion at its leading edge that orients and propels movement. However, cells can migrate in 3D/confined environments through alternative, shape invariant amoeboid modes powered by cell-scale, retrograde cortical actin flow. It remains unclear whether these amoeboid migration modes are natively employed *in vivo.* Moreover, how upstream signaling networks control such forms of motility without a defined leading edge remains undefined. Here, we develop cell type-specific imaging and perturbation techniques to show that inherently spherical *Drosophila* primordial germ cells (PGCs) employ global, retrograde cortical actin flows for orientation and propulsion during guided developmental homing. Extracted PGCs maintain constant cortical actin flows in the absence of confinement or contractile stimuli, suggesting this flow-based engine runs cell autonomously. These cortical actin flows are largely dependent on formin mediated actin polymerization rather than canonical branched actin polymerization associated with mesenchymal motility. PGCs use RhoGEF2, a RhoA-specific RGS-RhoGEF, as a dose dependent regulator of cortical flow through a feedback loop requiring its conserved PDZ and PH domains for membrane

anchoring and local RhoA activation. This feedback loop is regulated by RhoGEF2 availability and surprisingly requires AMPK rather than canonical $G\alpha_{12/13}$ signaling. AMPK multisite phosphorylation of RhoGEF2 near a conserved EB1 microtubule-binding SxIP motif releases RhoGEF2 from microtubule-dependent inhibition, providing a novel steering mechanism for shape invariant amoeboid motility. Thus, we establish the mechanism by which global cortical flow and polarized RhoA activation can be dynamically adapted during natural cell navigation in a changing environment.

Neuronal growth cone turning evoked by chemotropic 5-HT gradients

X. Zhang, A. W. Schaefer, J. L. Burton, P. Forscher; MCDB, Yale University, New Haven, CT.

Bath application of serotonin (5-HT) increases rates of growth cone advance via a mechanism involving: 1) a Ca^{2+}-calcineurin-cofilin dependent increase in peripheral domain (P-domain) retrograde F-actin flow and 2) a parallel increase in PKC dependent nonmuscle myosin II activity. Here we report on how 5-HT chemical gradients affect the above behaviors. We used flash photolysis of caged 5-HT to generate soluble gradients and analyzed growth cone responses. Exposure to 5-HT gradients first triggered central domain (C-domain) reorientation and advance towards the source, and subsequently the peripheral domain (P-domain) turned and extended to the source. After calcineurin inhibition: C-domain advance was observed but significantly delayed while P-domain protrusion towards the source was inhibited. In contrast, Myosin II inhibition completely abolished both C-domain advance and P-domain protrusion. Quantitative analysis of actin filament dynamics during 5-HT evoked turning responses revealed that C-domain advance was guided by contractile actin arcs in the transition zone (T-zone) while P-domain retrograde F-actin flow rates remained constant. With calcineurin inhibition, actin arcs still formed in spite of the delayed C-domain advance. With non-muscle myosin II inhibition, actin arc activity and growth cone turning were both inhibited. A possible role for microtubule (MT) dynamics during chemotropic responses was also investigated. Preliminary results suggest MT growth trajectories preferentially aligned with actin arcs towards 5-HT sources. In summary, our results suggest a key role for contractile actin arc structures in coordinating these chemotropic growth cone turning responses. Our results also continue to cast the role of P-domain retrograde F-actin flow and the classical molecular clutch model of growth cone turning in a new light.

Exploring the effect of extracellular matrix composition on the leading edge dynamics of dendritic cells migrating under confinement

N. M. Badillo, A. Gasilina, J. A. Hammer; National Institutes of Health, Bethesda, MD.

Dendritic cells play a critical role in initiating the adaptive immune response. Their function depends on their ability to take up antigens and migrate to lymph nodes, where they then present the antigens to naive T lymphocytes. During migration to lymph nodes, dendritic cells are guided by a gradient of the chemokine CCL19/CCL21 and must navigate environments of varying extracellular matrix composition. Efficient navigation through these microenvironments involves coordinated movements of the cell's nucleus, actin-rich extensions, and microtubule cytoskeleton, which together regulate space exploration, cell edge coordination and path finding. Like other leukocytes, dendritic cells can switch between non-adhesive and integrin adhesion-based modes of cell migration. Although the parameters required for leading edge coordination in the absence of adhesive substrates are well defined, much less

is known about leading edge coordination in dendritic cells migrating on adhesive substrates under confinement. To investigate this, we differentiated dendritic cells from murine bone marrow, stimulated them with lipopolysaccharide, and imaged their directed migration towards a CCL19 gradient on surfaces coated with BSA (blocked), collagen I, fibronectin, or laminin in an under-agarose assay. The resulting movies were analyzed for total distance traveled, velocity, directionality, space exploration, and leading edge formation using manual tracking. The organization of the actin and microtubule cytoskeletons was also determined by immunofluorescence staining for filamentous actin and α-tubulin. We observed that, unlike dendritic cells migrating on BSA-blocked surfaces or surfaces coated with collagen I or fibronectin, cells migrating on laminin-coated surfaces exhibited multiple, continuously protruding and retracting leading edges. Surprisingly, dendritic cells exhibited similar velocities, directionality and persistence regardless of matrix composition. Current efforts are directed at identifying the mechanisms by which dendritic cells maintain their migratory capacity while responding to varying extracellular matrix compositions.

B536/P2917

Understanding 3D Neutrophil Migration using PCA-based cell morphological analysis

A. van Loon[1], N. Belliveau[1,2], J. Theriot[1,2]; [1]University of Washington, Seattle, WA, [2]Howard Hughes Medical Institute, Chevy Chase, MD

Neutrophils are fast-moving innate immune cells that play a variety of important roles in the response to infection and inflammation. Although the ability of neutrophils to migrate in 3D is essential to mediate their immunological activity, relatively little is known about the mechanics of this process. Neutrophils rapidly deform and contort themselves to navigate the fibrous extracellular matrix, resulting in complex and dynamic morphology. Cellular morphology encodes information about the cell intrinsic mechanisms and environmental factors that define it. Recent analytical advances using spherical harmonic transformation and principal component analysis (PCA) have improved our ability to quantitate 3D cellular morphology. This new 3D shape analysis allows us to identify and visualize the primary ways in which 3D cell shape varies by reconstructing the shapes of average cells that represent each mode of variation. I probed the limitations of this new methodology by performing simulations using simple shapes with known dimensions of shape variation and determined that the method is highly sensitive to object alignment and resolution. To capture the shapes of migrating neutrophils, I fluorescently labeled the membranes and nuclei of dHL-60 neutrophil-like cells and imaged both labels at high resolution during 3D cell migration in collagen gels with instant structured illumination microscopy. In this data, I found that basic metrics of cell and nuclear shape, including surface area, volume, and elongation, are highly correlated with one another. To determine the primary modes in which dHL-60 shape varies, I performed PCA-based 3D shape analysis using dHL-60s cells aligned to their trajectories. Migration speed was most correlated with the top PC, which represented cell elongation along the axis of trajectory and alignment of the cell's long axis to the axis of trajectory. Collective shape analysis of CRIPSRi knockdown HL-60 cell lines for two candidate genes from a 3D motility screen, FMNL1 and CORO1A, along with control cells, revealed significant differences in a number of PCs that represented cell elongation as well as cell and nuclear volume. This work demonstrates that 3D shape analysis can be a useful tool in understanding the mechanics of neutrophil migration in 3D, but also has great potential as a platform for phenotypic comparison.

B537/P2918

Model of how septin ring compartmentalization aids T-cell circumnavigation in extracellular matrices

S. Alawadhi[1], D. M. Rutkowski[1], A. S. Zhovmer[2], E. D. Tabdanov[3], D. Vavylonis[1]; [1]Lehigh University, BETHLEHEM, PA, [2]U.S. Food and Drug Administration, Silver Spring, MD, [3]Pennsylvania State University, Hershey-Hummelstown, PA

In order to efficiently migrate through complex environments, T cells adopt a variety of migration modes including amoeboid and mesenchymal motions. Their ability to push the nucleus through narrow passages is critical for their migration through the extracellular matrix. Zhovmer et al. recently discovered that T cells in collagen matrices move with the aid of septin rings, which form around the nucleus at locations where extracellular matrix obstacles create high negative cell curvature. The resulting septin/F-actin rings subdivide the volume of the cell into separate compartments, with potentially different microenvironments. We developed a 2D computational model to test how such compartmentalization aids cell motility. In the model, beads representing the plasma membrane and nucleus move according to forces of bending rigidity, tension, contraction, fluctuating protrusions, and excluded volume interactions from encountered obstacles. Cell and nuclear volume conservation are implemented as area conservation forces. A weak nuclear centering force is implemented to represent cytoskeleton- and organelle-mediated nuclear centering. We assume that septin ring formation leads to compartment boundaries at sites where obstacle enforce proximity between the cell membrane and nucleus. We show that formation of these boundaries leads to a nuclear piston mechanism that enhances motility at high obstacle density.

B538/P2919

The role of acetylated microtubules in directed cell migration.

C. J. Saez Gonzalez, A. Deb Roy, T. Inoue; Johns Hopkins University Sch Med, Baltimore, MD

Cell migration is essential for many physiological processes including embryonic development, wound healing, and immune responses. Cells achieve efficient directional migration through two major steps: front-and-back polarization and re-arrangement of interactions between the cell and extracellular matrix (ECM). Cells adhere to the ECM using actin-based multiprotein complexes called focal adhesions (FAs) with which the cells exert forces to push or pull themselves to migrate, while long-term polarity is maintained by another cytoskeletal components, microtubules (MTs) Therefore, efficient cell polarity and migration are achieved by coordinated regulation of actin, MTs, and FAs. However, it remains unknown if there is a central regulator that orchestrates these seemingly distinct subcellular organizations. Our lab has recently found that cells lacking α-tubulin acetyltransferase 1 (αTAT1), the sole mediator of MT acetylation, display defects in FAs as well as in front-and-back polarity. To further characterize molecular mechanisms of αTAT1 functions as a potential master regulator of cell migration, live-cell, time-lapse fluorescence microscopy combined with pharmacological and genetic perturbations was performed in cell migration assays. As a result, cells with an αTAT1 knockout (KO) generally moved faster in random migration, in addition to interestingly exhibiting poor chemotactic performance with reduced directionality. In addition, while immunostaining of vinculin, a marker for FAs, showed a decreased signal in cells lacking αTAT1, western blot showed a similar expression of other FA proteins between our WT and αTAT1 KO cells, suggesting that it is molecular organization that contributes to FA defects, rather than changes in expression level of molecular constituents. Collectively, our data

illuminate a role of acetylated MTs as a regulator of directed cell migration by concertedly regulating front-and-back polarity and FAs dynamics.

Non-canonical Wnt signaling promotes stem cell migration during regeneration of fly and mouse barrier epithelia

D. J. Hu, J. Simons, H. Jasper; Genentech, Inc., South San Francisco, CA

Somatic stem cells (SCs) are tightly regulated to preserve tissue homeostasis and repair damaged tissue. During regeneration, accurate stem cell positioning is critical for proper integration of newly-generated cells into damaged epithelia. However, the extent in which stem cells can migrate in different adult tissue, and the mechanisms regulating this behavior is poorly understood. We have previously demonstrated that, in the *Drosophila* intestine, intestinal stem cells (ISCs) undergo actin-dependent migration towards sites of injury. ISC migration is regulated by activation of the non-canonical Wnt pathway in ISCs by matrix metalloproteinase-dependent cleavage of Otk, the fly orthologue of the Wnt co-receptor Ptk7, in neighboring enteroendocrine (EE) cells. We have now demonstrated that stem cells in the mouse trachea, known as basal cells (BCs), share a similar capacity to migrate after tissue damage. We observe that BCs undergo actin-dependent migration towards sites of injury after the mouse trachea is damaged by polidocanol or laser ablation. Similar to *Drosophila* ISCs, migration of BCs is regulated by non-canonical Wnt signaling. Genetically knocking out Ptk7 inhibits BC migration, and results in impaired regeneration. Our findings identify a key role of SC migration during mammalian airway repair, and provide insight into the molecular mechanisms governing tissue regeneration.

Cell-cell Junctions

The *Caenorhabditis elegans* ASPP homolog APE-1 is a junctional protein phosphatase 1 modulator

G. M. Beacham[1], **D. T. Wei**[1], E. Beyrent[1], Y. Zhang[2], J. Zheng[1], M. M. K. Camacho[1], L. Florens[2], G. Hollopeter[1]; [1]Molecular Medicine, Cornell University, Ithaca, NY, [2]Stowers Institute for Medical Research, Kansas City, MO.

How serine/threonine phosphatases are spatially and temporally tuned by regulatory subunits is a fundamental question in cell biology. Ankyrin repeat, SH3 domain, proline-rich-region-containing proteins are protein phosphatase 1 catalytic subunit binding partners associated with cardiocutaneous diseases. Ankyrin repeat, SH3 domain, proline-rich-region-containing proteins localize protein phosphatase 1 catalytic subunit to cell-cell junctions, but how ankyrin repeat, SH3 domain, proline-rich-region-containing proteins localize and whether they regulate protein phosphatase 1 catalytic subunit activity in vivo is unclear. Through a *Caenorhabditis elegans* genetic screen, we find that loss of the ankyrin repeat, SH3 domain, proline-rich-region-containing protein homolog, APE-1, suppresses a pathology called “jowls,” providing us with an in vivo assay for APE-1 activity. Using immunoprecipitations and mass spectrometry, we find that APE-1 binds the protein phosphatase 1 catalytic subunit called GSP-2. Through structure-function analysis, we discover that APE-1’s N-terminal half directs the APE-1-GSP-2 complex to intercellular junctions. Additionally, we isolated mutations in highly conserved residues of APE-1’s ankyrin repeats that suppress jowls yet do not preclude GSP-2 binding, implying APE-1 does more than simply localize GSP-2. Indeed, in vivo reconstitution of APE-1

suggests the ankyrin repeats modulate phosphatase output, a function we find to be conserved among vertebrate homologs.

Mechanical Cell Model of Epithelialization

C. Cammarota[1], N. Dawney[2], M. Jüng[3], A. G. Fletcher[4,5], D. T. Bergstralh[1,2]; [1]Physics & Astronomy, University of Rochester, Rochester, NY, [2]Biology, University of Rochester, Rochester, NY, [3]Biomedical Engineering, University of Rochester, Rochester, NY, [4]School of Mathematics and Statistics, University of Sheffield, Sheffield, UNITED KINGDOM, [5]Bateson Centre, University of Sheffield, Sheffield, UNITED KINGDOM.

Monolayered epithelia are sheets of polarized cells that are one-cell thick; this arrangement is vital to tissue functions like filtration, secretion, or absorption. Our work aims to understand how physical constraints, including cell density, cell stiffness, cell-cell, and cell-substrate connections, affect the development of a polarized tissue architecture. While computational modeling can be used to address these problems, existing models generally focus on the arrangement of cells in the tissue plane rather than tissue depth. We therefore developed a new model to explore this axis. We find that a spatial constraint holding the cells in close proximity is required for cells to develop lateral connections. We have validated this in culture; Madin Darby Canine Kidney (MDCK) cells will spread along their substrate rather than grow lateral connections given space. Additionally, the model predicts that cells will form into a polarized architecture even at reduced cell-cell adhesion strength, which we have confirmed in culture using calcium depletion. Together, these results suggest that cell-cell adhesion is subordinate to tissue density in the development of the polarized architecture. We are currently working to model cell division to probe how densification influences development.

B543/P2923

Actin-dependent recruitment of AGO2 to the zonula adherens

M. Bridges, A. Daulagala, A. Risner, C. Kingsley, M. E. Davis, J. Nair-Menon, **A. Kourtidis**; Regenerative Medicine and Cell Biology, Medical University of South Carolina, Charleston, SC.

The adherens junctions (AJs) are cadherin-catenin - based structures that are essential architectural components of epithelial tissues. E-cadherin junctions in mature epithelial cell monolayers tether to an apical actomyosin ring to form the zonula adherens (ZA). In addition to their critical architectural role, epithelial AJs mediate numerous signaling pathways directing cell behavior. Along these lines, we have previously demonstrated that the E-cadherin - p120 catenin partner PLEKHA7 recruits and regulates core RNA interference (RNAi) complexes, such as the microprocessor and RNA-induced silencing complex (RISC), specifically at the ZA. However, the mechanism mediating recruitment of these RNAi components to the ZA remained unexplored. Analysis of the PLEKHA7 proteome reveals that the top group of its interactors are actin-binding proteins. This group includes LIM-domain containing protein family members, some of which have been associated in the past with the key enzymatic component of RISC, namely Argonaute 2 (AGO2), in cytoplasmic p-bodies. We now show that depletion not only of PLEKHA7, but also of either one of three of its interacting LIM-domain containing proteins, namely LMO7, LIMCH1, and PDLIM1, results in loss of AGO2 junctional localization. Depletion of either of PLEKHA7, LMO7, LIMCH1, PDLIM1, also results in defects on actomyosin organization at the ZA, including disruption both of structural integrity and of tension of the apical actin ring. Using

pharmacological disruption of actomyosin and calcium-switch assays, we demonstrate that junctional recruitment of AGO2 indeed depends on both the structural and the tensile integrity of the actomyosin cytoskeleton at the ZA. Taken together with our previous findings, showing that junctional recruitment of AGO2 is critical for regulation of a set of homeostatic miRNAs, our results portray a mechanosensitive RNAi machinery at the ZA, responsive to actomyosin perturbations, with potential implications in tissue remodeling and in disease.

Architecture and dynamics of a novel desmosome-endoplasmic reticulum organelle

N. Bharathan[1], W. Giang[1], J. S. Aaron[2], S. Khuon[2], T. Chew[2], S. Preibisch[2], E. T. Trautman[2], L. Heinrich[2], J. Bogovic[2], D. Bennett[2], D. Ackerman[2], W. Park[2], A. Petruncio[2], A. V. Weigel[2], S. Saalfeld[2], C. Project Team[2], A. W. Vogl[3], S. N. Stahley[1], A. P. Kowalczyk[1]; [1]Dermatology, Pennsylvania State College of Medicine, Hershey, PA, [2]Janelia Research Campus, Howard Hughes Medical Institute, Ashburn, VA, [3]Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, CANADA.

Desmosomes are adhesive intercellular junctions that provide strength and integrity to the epidermis and other epithelia. Dysfunction of the endoplasmic reticulum (ER) resident calcium pump, SERCA2, causes Darier's disease (DD), an epidermal disorder characterized by compromised desmosomal adhesion and abnormal keratinocyte differentiation. However, the mechanism by which ER dysfunction impairs desmosome formation is unclear. Using electron microscopy and live-cell fluorescence imaging, we found that peripheral ER tubules are in close proximity to desmosomes and form mirror image arrangements at desmosomes. Close to 100% of desmosomes made contact with ER tubules within a 2-minute duration. At desmosomal regions, 66% of ER membranes are stable compared to only 39% at non-desmosomal regions, suggesting that desmosomes stabilize ER associations. Focused Ion Beam Scanning Electron Microscopy (FIB-SEM) and 3D reconstructions revealed intricate nanoscale associations of ER tubules with keratin filaments and the desmosome outer dense plaque. Knockout of a key desmosomal cadherin, desmoglein 2, resulted in altered peripheral ER morphology at cell-cell contacts, indicating that desmosomes regulate peripheral ER tubule organization. Keratin intermediate filaments, which anchor to desmosomes, aligned and intertwined with ER tubules on either side of the desmosome plaque. To determine how alterations in keratin filaments influence ER organization, we expressed a keratin 14 mutant that forms aggregates and causes the epidermal blistering disease, epidermolysis bullosa simplex. Virtually all keratin aggregates exhibited persistent ER association and shifted ER morphology from tubular to sheet-like. Finally, we tested associations between ER, keratin, and desmosomes during dynamic cellular processes such as desmosome fusion and formation of nascent cell-cell contacts. We observed that ER tubules maintained contact with desmosome puncta immediately prior to and after fusion. Furthermore, we observed that ER tubules extend to the cell periphery at sites of de novo desmoplakin puncta formation and keratin filament assembly at sites of new cell-cell contact, suggesting that ER tubules pattern regions of the plasma membrane for desmosome formation. Our results reveal a unique tripartite structural complex comprising the ER, desmosomes, and keratin filaments. Furthermore, this architectural arrangement of the ER is altered when desmosomes or keratins are perturbed, thus revealing desmosomes and intermediate filaments as a previously unappreciated modulator of ER tubule morphology and dynamics.

Syncytin-mediated membrane tubular connections facilitate the intercellular transfer of cargos including Cas9 protein

C. Zhang, R. Schekman; HHMI/UC Berkeley, Berkeley, CA.

Intercellular communication is an essential process for continuity of life in diverse organisms. Many modes of communication have been reported including extracellular vesicles (EVs) and tunneling nanotube structures. Here, we set up two delivery systems, Cas9-based dual-luciferase system and tri-fluorescent split-GFP system, to study cargo transfer between cells. We found that the EVs are inefficient to deliver Cas9 protein into reporter cells containing an integrated copy of nano-luciferase behind a site which when edited would allow the expression of nano-luciferase. In contrast, donor and acceptor cells cocultured to near confluence showed a 60-fold increase in luciferase expression. Among our tested donor & acceptor cell pairs, HEK293T & MDA-MB-231 is the best for intercellular transfer. However, Cas9 was not transferred among HEK293T cells. The tri-fluorescent split-GFP based system further confirmed that cargos were transferred through cell-cell contact from HEK293T to MDA-MB-231, but not among HEK293 cells. Next, we found that the intercellular transfer is actin and actin-related protein dependent rather than through the endocytosis pathway. Live-cell imaging results suggest that Cas9 transfer is mediated by open-ended membrane tubular connections with several microns in diameter. The structure of tubular connection between cells was further confirmed by correlative light and electron microscope. The human endogenous fusogen, syncytin, in recipient cells appears to control membrane fusion at the point of cell-cell junction. The depletion of syncytin, especially syncytin 2 in recipient cells significantly reduced the Cas9 transfer and blocked the formation of open-ended membrane tube. Full-length syncytin, but not truncated mutants, rescued the effect of depletion of syncytins on Cas9 transfer. Syncytin overexpression in HEK293T cells partially facilitated Cas9 transfer among HEK293T cells. Additionally, dynamin-mediated transport of plasma membrane proteins including syncytin to cell surface in recipient cells, appeared necessary for membrane tube formation and cargo transfer. These findings uncover a molecular basis for the formation of open-ended membrane tubular connections between cells, which may also facilitate to further understand the cell-cell communication in multicellular organisms and permit the development of an efficient means for targeted delivery of Cas9/gRNA.

The Cell Cycle Modulates Active Stresses in Epithelial Tissue via Regulation of Junctional Mechanics

S. Mukherjee[1], J. Devany[2], M. L. Gardel[1]; [1]James Franck Institute, University of Chicago, Chicago, IL, [2]Physics Department, University of Chicago, Chicago, IL.

Epithelial tissue is comprised of cells which form adhesive, junctional contacts with each other. Epithelia are highly dynamic, with cellular level processes such as cell division, cellular shape changes and junctional remodeling leading to generation of forces that are transmitted across junctions. Tissue level active stresses derived from these cellular level processes underly complex behavior such as morphogenesis, collective migration, and wound healing. While some of the underlying cellular processes contributing to active stresses have been described in some detail, the extent to which active stresses are modulated by the cell cycle in proliferative epithelia is largely unknown. To investigate the effects of the cell cycle on active stresses, we cultured model MDCK monolayers on soft collagen substrates. Under these conditions, focal adhesion area and stress fiber abundance are greatly reduced,

and cellular motion is derived from active stresses transmitted across cellular junctions. We abrogated the cell cycle via pharmacological inhibition of CDK1, or via overexpression of $p27^{kip1}$, a multifunctional cyclin dependent kinase inhibitor. We observed a marked reduction in active stresses, as indicated by a reduction in cellular motion, when the cell cycle was abrogated with either method. We further found that CDK1 inhibition led to a reduction in junctional E-cadherin, and phosphorylated p120-catenin levels, but no change in total p120-catenin levels. Junctional dynamics have been implicated in modulation of active stresses in epithelia, and we found that CDK1 inhibition led to a marked reduction in E-cadherin surface mobility, likely as a result of impaired E-cadherin endocytosis. Taken together, our results support a model where the cell cycle regulates junctional dynamics to modulate active stresses in epithelia. We postulate that active stresses arise from differential regulation of junctional dynamics in cells at different stages of the cell cycle in a proliferative epithelial monolayer, and we are working to test this hypothesis. We are also working to elucidate the mechanism through which the cell cycle regulates junctional composition and dynamics and investigating if the cell cycle regulates cortical Rho-GTPase signaling to modulate active stresses.

Coactosin-Like Protein 1 (COTL1) is a Novel Regulator of the Intestinal Epithelial Barrier Integrity and Repair

S. Lechuga, A. Marino-Melendez, A. I. Ivanov; Inflammation and Immunity, Cleveland Clinic Foundation, Cleveland, OH.

The actin cytoskeleton plays critical roles in regulating integrity and repair of epithelial barriers by mediating assembly of adherens junctions (AJs) and tight junctions (TJs) and controlling epithelial wound healing. Actin filaments associated with epithelial junctions and driving cell migration are highly dynamic and have a turnover that is controlled by numerous actin-binding proteins. The mechanisms underlying actin filament turnover in healthy and injured intestinal epithelium remains poorly understood. Coactosin-like protein 1 (COTL1) is an essential regulator of actin filament assembly, yet its functions in mucosal epithelia have not been previously investigated. In this study, we investigate the roles of COTL1 in regulating the structure and remodeling of AJs and TJs in model human intestinal epithelial cells (IEC). COTL1 was found to be enriched at apical junctions in polarized SK-CO15 IEC monolayers. The knockdown of COTL1 by RNA interference significantly increased paracellular permeability of cell monolayers, altered the recruitment of AJ/TJ proteins to steady-state apical junctions, attenuated junctional reassembly in a calcium-switch model, and inhibited formation of polarized epithelial cysts in 3-D Matrigel. Furthermore, COTL1 depletion attenuated collective IEC migration in a wound healing model. Our findings highlight COTL1 as a novel regulator of the intestinal epithelial barrier integrity and repair.

Oral pathogens regulate epithelial cell behavior though the adherens junction-associated RNAi machinery

C. R. Kingsley, J. Nair-Menon, M. Engevik, A. Kourtidis; Regenerative Medicine and Cell Biology, MUSC, Charleston, SC.

Increasing evidence portrays key roles of host-microbial interactions in the progression of epithelial diseases, including tumorigenesis. A pathogen that has been linked with tumor progression is oral

microbe *Fusobacterium nucleatum* (*F. nucleatum*). However, the mechanisms by which *F. nucleatum* may influence epithelial cell behavior are not fully known. Notably, *F. nucleatum* has been associated with loss of epithelial integrity. The adherens junction (AJ) is an essential, E-cadherin-based, cell-cell adhesion complex that is key for epithelial tissue integrity but has also been implicated in regulation of cell behavior. Further, we have previously shown that epithelial AJs through the E-cadherin-p120 catenin partner PLEKHA7, recruit and regulate core components of the RNA interference (RNAi) machinery, such as DROSHA and AGO2, to suppress oncogene expression and pro-tumorigenic cell transformation. Thus, we sought to interrogate the AJ-associated RNAi machinery as a potential mechanism mediating the effects of *F. nucleatum* in epithelial integrity and pro-tumorigenic transformation. We used a well-differentiated colon epithelial cell line model (Caco2), and assessed effects of *F. nucleatum* on AJs and other pro-tumorigenic markers. Caco2 cells were exposed to either heat-inactivated bacteria, or to bacterial supernatant from *F. nucleatum spp. nucleatum*,*Streptococcus salivarius* and *Escherichia coli spp. Nissile*. Cells were fixed after 8, 16, and 24 hours of incubation, and examined by immunofluorescence and confocal microscopy for changes in the junctional localization of E-cadherin, p120 catenin, PLEKHA7, AGO2, and DROSHA. Results showed that localization of PLEKHA7, AGO2, and DROSHA was disrupted by *F. nucleatum*, but not by *Streptococcus salivarius* or *Escherichia coli.* Also, these changes in localization were accompanied by upregulation of oncogenes such as JUN and SNAIL, as shown by western blot of cells treated with *F. nucleatum* supernatant for 24 hours. Oncogenes JUN and SNAIL were previously found to be suppressed by the junctional RNAi. This data supports that *F. nucleatum* may be promoting pro-tumorigenic transformation through disruption of the AJ-associated RNAi machinery leading to increased expression of oncogenes, and this can help deepen our understanding of the mechanisms mediating host-pathogen interactions in epithelial homeostasis and disease.

The blood-brain barrier responds to inflammation differently in juvenile and adult brains

J. D. Ochrietor, A. Gonzalez, F. Laveus, J. Gelsleichter; Biology, University of North Florida, Jacksonville, FL.

The blood-brain barrier (BBB) is essential for protecting the central nervous system from foreign insults. Because of this barrier, which restricts the free passage of most bacteria, viruses, and other pathogens, the brain maintains a sense of immune priviledge. However, diseases resulting from or contributing to inflammation, especially chronic inflammation, may alter the integrity of the BBB and allow pathogen-containing fluids to leak into the central nervous system. Basigin, a member of the immunoglobulin superfamily, is a cellular marker of blood vessel endothelial cells and hence is a component of the BBB. Reports indicate that Basigin may be responsible for reduced integrity of the BBB in the neural retina in response to chronic inflammation associated with diabetes. Therefore, the purpose of the present study was to evaluate Basigin expression at the BBB in the mouse brain in response to an inflammatory stimulus. Because Basigin serves as a chaperone for plasma membrane expression of monocarboxylate transporters (MCTs), which are expressed in the central nervous system, expression of MCT1 was also evaluated. Mouse brains were isolated from animals at several post-natal ages and incubated in the presence of lipopolysaccharide (LPS) or saline, for various times. Protein expression was measured via quantitative ELISA and immunohistochemistry. In juvenile animals, Basigin expression decreased with increasing LPS treatment time. Conversely, in adult animals, Basigin expression increased with increasing LPS treatment time. The change in expression was observed on blood vessel endothelial cells within the

brain samples. In contrast, MCT1 expression in response to LPS was like that of the saline-treated samples at all ages tested. The data suggest that the integrity of the BBB is influenced differently at different ages. As Basigin increases in response to an inflammatory stimulus in the adult brain, barrier integrity may concomitantly diminish, leading to the potential for neurodegenerative diseases. Young brains appear to prevent this degenerative process via the decreased expression of Basigin in response to chronic inflammation. It is not yet known whether intracellular signaling via TLR4, which is the receptor for LPS, or via subsequent cytokine production accounts for the changes in Basigin expression. Future studies will examine if Basigin expression, and hence BBB integrity, is similarly influenced by SARS-CoV-2 spike protein, for which Basigin is a known receptor.

The RhoG guanine nucleotide exchange factor SGEF controls junctional localization of desmosomal proteins.

H. C. Lee[1], A. Rabino[2], R. Garcia-Mata[2], A. Dubash[1]; [1]Biology, Furman University, Greenville, SC, [2]Biological Sciences, University of Toledo, Toledo, OH.

The desmosome is a cell-cell adhesion complex which facilitates the mechanical stability of tissues. Desmosome function depends upon a tripartite organizational structure wherein transmembrane cadherins (Desmoglein and Desmocollin) link adjacent cells in the extracellular space, armadillo proteins (Plakophilin and Plakoglobin) stabilize the intracellular plaque, and the cytolinker Desmoplakin (DP) connects the plaque to the intermediate filament network. Disruption of the desmosome adhesion complex is predominantly observed in a range of different cutaneous syndromes and several types of cardiomyopathy, as skin and heart tissues undergo continuous mechanical stress. Loss of desmosomal integrity is also observed in cancer, where loss of desmosomal proteins accompany epithelial to mesenchymal transition (EMT). Determining the signaling mechanisms which control desmosome structure is therefore relevant for a wide range of different pathologies. Recent work has uncovered an important role for the protein Src Homology 3 (SH3)-containing GEF (SGEF) in maintaining the structure of both adherens junctions and tight junctions in epithelial cells. SGEF is a guanine nucleotide exchange factor specific for the RhoG GTPase, as it enhances the activity of the GTPase via promotion of GDP-GTP exchange. In our study, we analyzed a potential role for SGEF in regulation of the desmosome adhesion complex. Compared to control MDCKs, SGEF knockdown cells demonstrate a significant reduction in the junctional localization of several different desmosomal proteins, such as Desmoplakin, Desmoglein-2 and Plakoglobin. Importantly, these changes are not due to alteration of gene expression, as total protein levels of desmosomal proteins (assessed by western blot) are not changed upon SGEF knockdown. Interestingly, we observe a similar reduction in localization (but not expression) of desmosomal proteins upon knockdown of RhoG. Taken together, these studies have uncovered an important role for SGEF and RhoG in maintaining the junctional localization of desmosomal proteins. Future work will focus on whether regulation of desmosomal structure by SGEF requires its guanine nucleotide exchange function and whether SGEF-mediated changes in desmosome protein localization affect junctional strength and integrity.

Kinetics study of hydration and skin barriers markers in a novel calcium differentiated normal human keratinocyte model

M. Juan, A. Guillemain, T. Naiken, **E. Leblanc-Noblesse**, K. Pays, C. Nizard; LVMH Recherche, Saint Jean de Braye, FRANCE.

INTRODUCTION

Skin is the largest and outermost organ of the human body, which makes it an important barrier against external aggressions and water loss. Due to its stratified epithelium formed by layers of keratinocytes and the lipophilic film on its surface, skin is impermeable to most molecules and microorganisms. Skin hydration, claimed by cosmetic products, involves many markers such as aquaporins for water transport, proteins of the cornified envelope, adherens and tight junctions as well as transport of lipids or nutrients. This study permits us to study the expression of several markers in a new model of normal human keratinocytes cultured to confluence in the presence of calcium to mimic the different cell layers of epidermal differentiation.

MATERIALS AND METHODS

A cell culture of normal human keratinocytes is carried out in 96 plate systems dedicated to microscopy. When the cells reach the confluent stage, the culture is treated with calcium to promote epidermal differentiation. On day 1, 2,3,4, 6 and 7 cells are fixed, and immunostaining performed. The expression of 12 hydration and skin barrier markers is measured by immunofluorescence in a High Content Screening system (Cellomics). A specific program image analysis to each marker has been specially developed on the Cellomics system.

RESULTS

The expressions of each studied marker are quantified at every time of calcium treatment, taking into account the cellular localization specific to each marker. This has been verified by bibliographical data and immunostaining on normal skin sections. For example, it should be noted that the membrane expression of Aquaporin 3, a protein involved in the epidermal transport of water and glycerol, reaches its maximum expression after 4 days of calcium treatment and then declines. On the contrary, the expression of involucrin, a major protein of the cornified envelope, is optimally expressed after 7 days of Calcium.The results obtained in this study allowed us to better understand the kinetics of appearance of its markers in a model of normal human keratinocytes in culture. The cellular localization specific to each marker, as well as the associated image analysis method, allow us to obtain a very good in vitro model to test the cosmetic efficacy of active ingredients on cutaneous phenomena linked to hydration, nutrition and the barrier function.

Gap junction transendocytosis in glia modifies brain-derived extracellular vesicle formation

L. Udo-Bellner, E. Khodra, S. Khan, **R. Stout**; New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY

Gap junctions are required for normal brain function through their roles in neurons, brain endothelial cells, and very prominent functions in glia. Gap junctions made up of connexin proteins serve several functions in addition to forming direct routes for intercellular communication of metabolites, signaling molecules, and RNA. Among numerous non-channel functions, Cx43 gap junctions regulate autophagy and mediate intercellular transfer of protein and membrane through a process called transendocytosis.

Internalization of gap junctions by endocytosis has long been known to act via transendocytosis of protein, membrane, signaling molecules, RNA, and even organelles such as mitochondria. Other research groups have shown that downstream processing of endocytosed gap junctions (called connexosomes) can take varied paths; one prominent path was shown by electron microscopy to be multivesicular bodies. We hypothesize that brain derived extracellular vesicles (EVs) found in the blood are derived from glia (astrocytes and tanycytes) located in brain areas proximal to fenestrated vessels without blood brain barrier. We broke the investigation into subparts tested them using a variety of super-resolution microscopy tools and custom image analysis methods that we developed for this research. We found: 1) EVs derived from Cx43-expressing astrocyte-condition culture media contain Cx43. 2) EVs derived from serum of mice contain Cx43 and characteristics of EVs are radically altered in a mouse model of neurodevelopmental disease. 3) *In situ,* Cx43 and CD63 (marker for both multivesicular bodies and EVs) colocalized frequently in glial cell bodies and rarely at specialized cell extensions in the brain. It will be critical to understand the steps downstream of gap junction transendocytosis and connexosome processing in the hypothalamus because gap junctions and transcytosis in the glial cells of this brain region have recently been shown to be critical in systemic metabolism regulation and the effects of anti-obesity drugs. We will present our most recent unpublished findings with expected major significance for health conditions ranging from obesity, to metabolic disorder, to neurodegenerative disease.

Regulation of Heterotypic Endothelial-Osteoblast interactions via Connexin-43

S. Alimperti; Georgetown University, Washington, DC

Objectives: Glucocorticoids (GCs) are key treatments of inflammatory and immune disorders. Due to prolong use, most patients are at high risk of developing osteopenia or osteoporosis. Although GCs are closely associated with bone loss, their effect in bone microvasculature is incompletely understood. Here, we engineered a 3D biomimetic vascularized bone platform, named bone on a chip, to investigate molecular mechanisms of osteoblast-endothelial interaction in response to glucocorticoids. **Methods:** This bicellular microfluidic system consists of 3D perusable blood vessels embedded within a mixture of green fluorescent protein (GFP) labelled human osteoblasts (hOBs) and collagen I/fibrinogen/gelatin matrix. By using this platform, we microscopically captured the connexin-43 (labeled with red fluorescent Alexa Fluor® 568) heterotypic endo-bone interaction in presence of GCs, such as hydrocortisone, prednisone, prednisolone, and dexamethasone. Under these conditions, vascular leakiness were measured by the particle/ FITC-dextran assay and osteogenic potential was evaluated by calcium deposition, osteoimage assay, and quantitative RT-PCR analysis. In addition, we knockdown connexin-43 with siRNA compared to scrambled siRNA and assay for angiogenesis and osteogenic potential. We also used on overexpression viral vector with mutant inactive Connexin-43 (Con-43SD, Con-43SA) to rescue the effect of GCs on angiogenesis and osteogenic potential to confirm the role of Connexin-43. **Results:** We engineered and characterized a 3D biomimetic glucocorticoid-induced osteoporosis models to investigate osteoblast-endothelial interaction. Our results showed that the presence of glucocorticoids, 200nM hydrocortisone, 100nM prednisone, 100nM prednisolone, and 100nM dexamethasone, decreased the formation of neovessels and bone compared to the untreated group by 5-fold and 7-fold, respectively. GCs inhibited early, intermediate, and late bone markers, such as RUNX2, COLA1 and OPN and decreased the barrier integrity. We identified that GCs controlled angiogenesis via MAPK signaling pathway by phosphorylating a gap junction molecule, named connexin-

43. To this end, connexin-43 knockout endothelial cells showed inhibition of angiogenesis and loss of their interaction with bone cells, indicating that connexin-43 is necessary for their intracellular communication. **Conclusions:** Collectively, this study permits us to capture dynamic changes in endothelial-bone interactions under inflammatory conditions by dissecting the connexin-43/MAPK mechanism. Our findings may shed light on microvascular barrier function related to inflammatory bone diseases and may utilize it as potential therapeutic target to better maintain bone homeostasis.

Dissecting the roles of claudins and JAM-A in providing tight junction-dependent mechanical resistance

T. Nguyen; School of Life Science, SOKENDAI, Okazaki, Japan

Epithelial cell monolayer is constantly exposed to mechanical stress. Epithelial cells resist mechanical stress to maintain monolayer integrity, which is essential to maintain body homeostasis. Unlike adherens junctions and desmosomes whose functions in withstanding mechanical stress are well established, little has been known about the roles of tight junctions (TJs) in epithelial mechanical resistance. Here we report that claudins and JAMs, the two major classes of membrane proteins of TJs, play essential roles in maintaining epithelial integrity upon mechanical stress. MDCK II cells that lost claudins and JAM-A (Claudin/JAM-A KO cells) showed the local disruption of the apical junctional complex. Time-lapse imaging revealed that junction breakages occur when the cells are exposed to mechanical stress. Intriguingly, these local junction breakages were accompanied by the local disorganization of circumferential actin bundles. Perturbation of F-actin polymerization in Claudin/JAM-A KO cells enhanced the junction breakage phenotype, supporting the idea that the cell junction integrity in Claudin/JAM-A KO cells critically depends on the F-actin arrangement. Taken together, these results reveal a novel function of TJs in the mechanical resistance of epithelial cell junctions.

Terminating Structures of Tunneling Nanotubes

V. Ayres[1], V. Tiryaki[2], I. Ahmed[3], D. Shreiber[4]; [1]Michigan State University, East Lansing, MI, [2]Siirt University, Siirt, Turkey, [3]CUNY Medgar Evers, New York, NY, [4]Rutgers, The State University of New Jersey, Piscataway, NJ

Tunneling nanotubes (TNTs) are a recently recognized mechanism for cell-cell communication involving direct exchange of molecular through organelle materials along microns-long nanoscale-diameter pathways. Reported investigations have elucidated TNT actin, or actin-tubulin, along-length structures, and their associated transporters for molecules and/or organelles. Recent work has demonstrated specialized initiating and terminating structures. While TNTs are demonstrated as triggered by environmental stressors such as hypoxia and/or disease situations such as cancer(s) [1], they are also observed under non-pathological conditions. In this work, morphological and protein investigations of terminating structures triggered by environmental conditions ranging from mild (quiescent-like) to stressful (hypoxic) are presented for purity-enhanced cultures of primary astrocytes. Nanoscale “hand” terminating structures are investigated using gSTED super-resolution microscopy, atomic force microscopy and immunocytochemistry. Actin and intermediate filament components are observed, while tubulin may be secondary, if present. A previously reported actin gap is observed with an upper limit of 50 nm diameter or less. Similarities and differences of terminating structures across mild

through stressful environments are correlated with differing levels of RhoGTPase activity [2,3]. 1. Investigating the Role of Claudins in Epithelial Cell Shape

J. N. Warshaw[1], C. P. Chaney[2], D. K. Marciano[1]; [1]Cell Biology/Internal Medicine, Nephrology, UT Southwestern Medical Center, Dallas, TX, [2]Department of Internal Medicine, UT Southwestern Medical Center, Dallas, TX.

Epithelial cells may have specialized shapes that allow them to execute diverse functions. These include transient plasma membrane protrusions, such as filopodia and lamellipodia, as well as longer-lived protrusions. The mechanisms that underly cell shape specializations and their maintenance are not well understood. Using a novel fluorescent reporter, our lab identified a tubular cell type in the kidney medulla with branched, finger-like cell protrusions. It is unknown how these protrusions form and what function they serve. To better understand how these cells develop protrusions, we conducted a time-course of single nuclei RNA sequencing in the postnatal mouse kidney. Differential gene expression analysis revealed that Claudin-10 transcript is highly enriched in these cells throughout development. Claudins are components of tight junctions that regulate paracellular permeability. Several tight junction proteins, including claudins, have been implicated in "waviness" at the plasma membrane. To interrogate the role of Claudin-10 in cell protrusion formation, we generated a *Cldn10* conditional knockout mouse (*Cldn10* cKO). Our preliminary findings demonstrate that neonatal deletion of *Cldn10* in the kidney abrogates the formation of cell protrusions, which appear truncated and irregular. These changes in cell shape are accompanied by abnormalities in renal function. In summary, our group has identified a novel cell type in the kidney that forms complex, interdigitating cell protrusions whose formation is dependent on Claudin-10. Future studies will continue to characterize the *Cldn10* cKO phenotype and establish a mechanistic link between tight junctions, cell shape, and function.

Contact Stimulation of Collective Migration as a Novel Driver in Tissue Morphogenesis

M. C. Bischoff[1], J. E. Norton[1], S. Bogdan[2], M. Peifer[1]; [1]University of North Carolina At Chapel Hill, Chapel Hill, NC, [2]University of Marburg, Marburg, Germany

Cells migrate collectively to form tissues and organs during morphogenesis and tissue homeostasis, and many metastatic cancer cells adopt similar behaviors. This process requires the directed, coherent movement of cell groups. We developed a new model to explore the underlying mechanisms: *Drosophila* muscle cell precursors migrating to ensheath the testis. They use a new type of collective cell

behavior, lacking lamellipodial protrusions, but instead, using numerous filopodia to move as a cohesive cluster in a formin-dependent manner. During migration, these cells are loosely interconnected via filopodia containing N-Cadherin. Loss of N-Cadherin triggers individualized cell behavior at the expense of overall directionality. Genetic, pharmacological and mechanical perturbation analyses reveal an essential role for the Rho family GTPases, Rac2, Cdc42 and Rho1. They differentially control both protrusion dynamics and focal adhesion formation and stability. Our data uncover a cell contact-dependent asymmetry in matrix adhesion dynamics, as matrix adhesions have a much shorter live time at the cell-cell edge. This appears to allow cells to transduce intracellular force into locomotion towards the free space, and thus enables highly coordinated collective motility without any differentiation into leader and follower cells. We propose a model in which Rho family GTPase mediated contact stimulation of migration drives the directional movement of a cell sheet that behaves like a supracellular unit. Currently, we are addressing which specific signal(s) activate/deactivate Rho family GTPases and thus trigger the cell-cell contact-dependent changes in adhesion dynamics. To identify potential candidates, we are using bulk RNA-seq to compare migratory and post-migratory stages. We are then testing candidate regulators from this list and the curated literature via an RNAi-screen. To determine if candidates regulate Cdc42-activity, we are developing a specific Cdc42-GTP live-sensor.

Focal Adhesions and Invadosomes

B558/P2938

Evolutionary Analysis of Cell-Substrate Adhesion Composition and Dynamics During Migration

J. Fierro Morales, M. Roh-Johnson; University of Utah, Salt Lake City, UT.

In Metazoans, cells use cell-substrate adhesions called focal adhesions (FAs) - a multilayered protein complex physically linking the extracellular matrix to the intracellular actin cytoskeleton - for efficient migration. Though this machinery was believed to be Metazoan-specific, genomic sequencing of organisms across Eukaryotes suggests organisms as evolutionarily distant as Amoebozoa possess putative homologues of core FA components. It is unclear, however, if cell-substrate adhesions in organisms evolutionarily distant from Metazoans are conserved in function and composition to Metazoan FAs. An ideal organism for investigating cell-substrate adhesions across evolutionary time is the Amoebozoan, *Dictyostelium discoideum*. Our evolutionary analyses suggest *Dictyostelium* can form cell-substrate adhesions despite lacking homologues of known core FA components. It is contentious, however, if *Dictyostelium* form cell-substrate adhesions and, if so, what the composition of these adhesions is. Time-lapse fluorescent microscopy of actin and paxillinB (PaxB), the *Dictyostelium* homologue of the core FA component Paxillin, shows the two components co-localize at punctate structures on the cell ventral surface. Inhibition of actin ablates PaxB punctae formation, and the integrin beta-like protein, SibC, also localizes to ventral surface punctate structures. These data suggest that *Dictyostelium* form cell-substrate adhesions at the ventral surface, and quantitative analysis reveals that *Dictyostelium* cell-substrate adhesions are highly dynamic and are smaller in size and shorter in duration than Metazoan FAs. Furthermore, preliminary imaging of cells expressing truncated versions of PaxB indicate conservation of Paxillin domain specific functions. We are currently studying the localization of additional *Dictyostelium* homologues of core FA components to cell-substrate adhesions with the goal of **elucidating how cell-substrate adhesions have evolved. This knowledge will subsequently aid research into the evolution of adhesion-dependent mechanisms such as migration, cytokinesis, and pathogenesis**.

CASK, a Novel Mediator of Adhesion Cytoskeletons

Y. Tseng, Y. Lin, F. Tsai; Department of Pharmacology, National Taiwan University College of Medicine, Taipei, TAIWAN.

Calcium/calmodulin dependent serine protein kinase (CASK) is a scaffolding protein with multiple domains, and its multi-domain property provides the possibilities for CASK to interact with various proteins. Previous studies have shown that CASK plays an important role in the function of certain calcium channels, and that cell migration could be affected by decreased expression of CASK, suggesting that CASK may be critical for cytoskeletal remodeling. Therefore, the aim of this study is to investigate whether and how CASK regulates cytoskeletal remodeling, with specific focus on adhesion cytoskeletons.To investigate the effect of CASK perturbation on adhesion cytoskeleton, short-hairpin RNA (shRNA) lentiviruses were used on cultured human keratinocytes (HaCaT) to knockdown CASK.We first studied CASK-mediated effects on cell-matrix adhesion, using immunofluorescence (IF) to label paxillin, which is the key component of focal adhesion (FA) complexes. Interestingly, FA signals in CASK knockdown (shCASK) HaCaT cells were increased compared with the control group, indicating that CASK reduces FA structures. To further elucidate whether CASK reduces FA by suppressing its formation or enhancing its degradation, a ROCK inhibitor (Y27632) and calpain knockdown (shCalpain) HaCaT cells were used together with CASK knockdown to determine how FA would be influenced. Increased FA can be observed after treating cells with either shCASK or shCalpain. However, double knockdown of CASK and calpain did not lead to further increase in FA signals, indicating that CASK may be involved in calpain-mediated FA degradation. In contrast, under the suppressive effect of Y27632 on FA, shCASK treatment could still enhance focal adhesion signals, suggesting that the ROCK signaling pathway may not contribute to the shCASK-mediated alterations in FA signals. We also studied CASK effects on cell-cell adhesion by labeling E-cadherin. The distribution of E-cadherin was altered in CASK-knockdown HaCaT cells. Compared with the control group, E-cadherin was mostly presented in the membrane of shCASK treated cells, indicating that CASK may regulate the dynamics of cell-cell adhesion structures.We are currently working on the molecular mechanisms of how CASK regulates cell-matrix and cell-cell adhesions, with the hope to elucidate CASK functions on adhesion cytoskeletons.

Signal transducer and activator of transcription 3 (STAT3) and Talin-1 colocalize at focal adhesions

A. E. Temple, A. M. McCarthy, F. Chu, S. Walker; Molecular, Cellular, and Biomedical Sciences, University of New Hampshire, Durham, NH.

STAT3 activation is important for cell proliferation, migration, and angiogenesis, and elevated phosphorylated STAT3 generally correlates with poor prognosis in many human cancers. In addition to its nuclear transcriptional activity, phosphorylated STAT3 has been shown to localize to focal adhesions where it interacts with phosphorylated focal adhesion kinase. However, the role of STAT3 at focal adhesions is still not completely understood. To better understand the interacting partners of STAT3 in the cytoplasm, we used a phosphoserine 727 STAT3 antibody to pulldown STAT3 and interacting proteins from whole cell lysates of breast cancer cells with LIF stimulation to activate STAT3. Samples were subjected to mass spectrometry analysis and Talin-1 was identified with LIF stimulation, indicating a potential interaction. Talin-1 has an important function in cell adhesion and is essential in integrin

activation and focal adhesion assembly. To assess the interaction of STAT3 and Talin-1, we overexpressed fluorescently labeled constitutively active STAT3 and Talin-1 in breast cancer cells and utilized confocal microscopy to demonstrate an overlap between STAT3 and Talin-1 at focal adhesions. This supports our hypothesis that STAT3 and Talin-1 colocalize and interact at focal adhesions. To assess the effects of Talin-1 on STAT3 activity, Talin-1 was overexpressed and STAT3 transcriptional activity was measured using a STAT3-responsive luciferase reporter. We found that STAT3 transcriptional activity was reduced with Talin-1 overexpression, suggesting that Talin-1 may sequester STAT3 at focal adhesions, thereby reducing its transcriptional activity. Our data indicates a potential interaction between STAT3 and Talin-1 at focal adhesions. Additional coimmunoprecipitation experiments and colocalization studies are being completed to further validate the mass spectrometry findings and siRNA studies are being utilized to determine if the interaction of STAT3 and Talin-1 is necessary for STAT3 localization at focal adhesions. This STAT3-Talin-1 interaction could implicate a novel STAT3 function at focal adhesions, thus providing an alternative approach to targeting STAT3 in cancer.

B561/P2941

Regulation of focal adhesions during single cell migration *in vivo*

Q. Xue, S. Varady, T. Waddell, J. Carrington, M. Roh-Johnson; University of Utah, Salt Lake City, UT

The majority of focal adhesion research over the last 40 years has been on 2D substrates. Research using 3D *in vitro* models initially led to controversies regarding whether cells even formed focal adhesions when migrating in a 3D environment. Follow up work has shown that cells do indeed form focal adhesions when in this environment - These focal adhesion structures are difficult to resolve in a more complex 3D environment, and thus, much less is known about their regulation. Currently, it is also entirely unknown what molecules make up a focal adhesion, or how these focal adhesions form and are regulated, during single cell migration in a native *in vivo* environment. To address this critical aspect of cell migration, we developed an *in vivo* zebrafish system in which we can directly visualize the formation of focal adhesion structures of highly migratory cells with high resolution. By comparing focal adhesions between this *in vivo* system and the traditional *in vitro* cell culture model, we find that a key site of phosphoregulation on Paxillin, tyrosine 118 (Y118), exhibits reduced phosphorylation in migrating cells *in vivo* in both zebrafish and mouse melanoma models, contrary to the critical role for this phosphorylation event in cell culture studies. Furthermore, direct modulation of this residue by site-directed mutagenesis leads to opposite cell migration phenotypes *in vivo* versus *in vitro*: Expression of a non-phosphorylatable version of Y118-Paxillin promotes cell migration in both migrating cancer cells and macrophages *in vivo*, despite inhibiting cell migration in the *in vitro* cell culture conditions. To further understand the mechanism of this regulation, we find that the upstream kinase, focal adhesion kinase (FAK), is downregulated in cells *in vivo*, and that cells expressing non-phosphorylatable Y118-Paxillin exhibit increased activation in CRKII-DOCK180-Rac pathway, leading to increased cell migration. This work reveals an altogether new mechanism for how focal adhesions are regulated during single cell migration, and potentially generates alternative therapeutic approaches in the treatment of cancer.

B562/P2942

The Rac-GAP alpha2-Chimaerin interacts with paxillin and regulates invadopodia turnover

G. Kreider-Letterman[1], **R. Garcia-Mata**[2], K. Snyder[1], A. Rabino[1], F. Aftab[1], S. Goicoechea[1]; [1]University of Toledo, Toledo, OH, [2]University of Toledo, TOLEDO, OH.

Metastatic cells escape the tumor and enter the bloodstream by developing actin-rich membrane protrusions called invadopodia that degrade the extracellular matrix to allow invasion of surrounding tissues. Invadopodia formation is regulated by Rho GTPases, a family of proteins that regulates the actin cytoskeleton; however, the molecular mechanisms that control their turnover are still poorly understood. Rho GTPases are regulated by the opposing actions of guanine nucleotide exchange factors or GEFs, which regulate the activation, and GTPase-activating proteins or GAPs, which catalyze the inactivation. Here, we identify the Rac1-specific GAP α2-Chimaerin (α2-CHN), as a key regulator of invadopodia dynamics in human breast cancer cells in a process that involves the binding of α2-CHN to the tyrosine-phosphorylated form of paxillin. Our results show that when the expression of α2-CHN is silenced, invadopodia are more stable and have a longer lifetime than control cells. This phenotype is rescued by re-expressing an shRNA-resistant α2-CHN. Furthermore, overexpression of α2-CHN inhibited the formation of invadopodia. Silencing α2-CHN promoted matrix degradation and invasive behavior, consistent with the increased invadopodia formation. Using a combination of fixed and live cell imaging, and a FRET-based Rac1 sensor, we show that α2-CHN localizes to invadopodia and that silencing α2-CHN promotes Rac1 activation at invadopodia. The molecular mechanisms by which α2-CHN regulates invadopodia dynamics are still under investigation, but we believe that paxillin phosphorylation is playing a role. Paxillin is a key component of invadopodia, and its phosphorylation plays a role in the disassembly of invadopodia. Here we show that α2-CHN knockdown induces an increase of phospho-paxillin at invadopodia compared to control cells. We also demonstrate that phospho-deficient paxillin (Y31-118F) has a lower affinity for α2-CHN than WT and phospho-mimetic (Y31-118E) paxillin. We have previously shown that the Rho GTPase RhoG was important for invadopodia disassembly in a process that involved paxillin phosphorylation. Our new results suggest that RhoG and Rac1 may have opposite roles in the regulation of invadopodia turnover. While RhoG activity needs to be high during invadopodia disassembly, our new data suggests that RhoG-mediated phosphorylation of paxillin may mediate the recruitment and activation of α2-CHN to inactivate Rac1 at invadopodia during disassembly. In summary, we have identified a novel signaling pathway involving α2-CHN, Rac1, and paxillin phosphorylation, which functions in the regulation of invadopodia turnover in human breast cancer cells.

B563/P2943

Focal adhesion kinase phase separation regulates autophosphorylation

N. E. Lea, L. B. Case; Massachusetts Institute of Technology, Cambridge, MA

Focal adhesion kinase (FAK) is a 120 kDa cytosolic tyrosine kinase which localizes to focal adhesions, where it is activated and involved in signaling to promote cell migration, proliferation and anchorage-dependent survival. FAK is often overexpressed or overactive in cancers where it contributes to tumor angiogenesis, metastasis, invasion and anchorage-independent survival. FAK activation is initiated by autophosphorylation of tyrosine 397 *in trans*, however the mechanism of FAK activation is not fully understood. Our lab has recently shown purified FAK can undergo phase separation alone *in vitro.* We are currently investigating how FAK phase separation influences its autophosphorylation on tyrosine

Y397 using biochemical assays with purified FAK. We measured the rate of autophosphorylation using western blot analysis as well as a newly developed fluorescence microscopy assay. We found that phase separation consistently correlates with a significant increase in the rate of autophosphorylation. Conditions or mutations that reduce phase separation result in slower autophosphorylation while conditions that increase phase separation result in faster autophosphorylation. We conclude that phase separation is sufficient to increase the rate of FAK autophosphorylation *in vitro*. Future experiments will determine if FAK phase separation is necessary for normal FAK signaling in cells or if aberrant FAK phase separation contributes to phenotypes of FAK overexpressing cancers.

B564/P2944

Understanding the mechanism behind inhibition of Focal Adhesion Kinase (FAK)

D. E. Akwa, V. Yang, N. Lea, L. B. Case; Massachusetts Institute of Technology, Cambridge, MA

Focal adhesion kinase (FAK) is a 125 kDa cytosolic tyrosine kinase that regulates cellular migration, proliferation, and survival. In cells, it is localized and activated at focal adhesions where it acts as a scaffold and promotes the phosphorylation of several substrates. FAK signaling can be regulated through an alternative promoter in the FAK gene, which results in expression of FAK related non kinase (FRNK). FRNK lacks the N-terminal FERM domain and kinase domain, but contains the C-terminal intrinsically disordered linker and the focal adhesion targeting domain (FAT). FRNK expression in cells is sufficient to inhibit FAK autophosphorylation and downstream signaling, but the mechanism of inhibition is unclear. Our preliminary data shows that FAK undergoes phase separation *in vitro*, but adding FRNK is sufficient to inhibit FAK phase separation. We hypothesize that FRNK could inhibit FAK signaling by disrupting the oligomerization and subsequent phase separation of full length FAK protein. Using our *in vitro* system, we have characterized mutants of FRNK that differentially affect FAK phase separation. We assess phase separation by measuring solution turbidity (which increases as droplets form and scatter light) and by visualizing droplets with DIC or fluorescence microscopy. Changing the intrinsically disordered linker results in FRNK proteins that have different effects on phase separation. We also find that dimerizing or oligomerizing FRNK is sufficient to restore phase separation, likely through restoring the oligomerization of full-length FAK. We conclude that FRNK acts as a monovalent ligand that destabilizes FAK phase separation *in vitro*. Now, we are testing the ability of these FRNK mutants to inhibit FAK signaling in mouse embryonic fibroblasts (MEFs) to determine if FAK phase separation is important for FAK signaling in cells.

Stress Response, Chaperones and Quality Control

Dissecting the synergistic role of the unfolded protein response in wound infections

S. Lee, C. Celik, A. Tan, M. Veleba, K. A. Kline, **G. Thibault**; Nanyang Technological University, Singapore, SINGAPORE.

Infected wounds affect 7-15% of hospitalized patients and significantly increase the duration of hospitalization and treatment cost per day. Biofilm-forming *Enterococcus faecalis*, has been isolated from wounds associated with diabetic foot ulcers, burns and surgical sites. Therapeutic efforts have been concentrated on addressing microbial factors. However, this is inadequate in the presence of biofilm-forming microorganisms which renders antimicrobials sub-effective. The arrest in the

inflammatory phase during wound healing, due to incomplete elimination of pathogens, has been underpinning the basis for wound chronicity. Recent evidence from us and others has shown that the mammalian unfolded protein response (UPR) promotes the development of bacterial skin and soft tissue infection and impairs wound healing. Therefore, we hypothesized that UPR activation serves as a synergistic node to propagate wound infection. To investigate, we use *in vitro* and *in vivo* infection and wound healing models to delineate the relationship between the bacteria, UPR and wound healing. We found that the infection of C57BL/6 mice, NIH 3T3 mouse fibroblasts and HaCaT human keratinocytes with *E. faecalis* infection result in significant UPR activation, specifically through the IRE1 and PERK branches. The UPR activation translated to a reduced rate of wound migration in our *in vitro* cell migration assay. We established and optimized a high-throughput screen pipeline to reveal *E. faecalis* factors that induce UPR activation. In parallel, we are performing single cell RNA-sequencing of infected wound to reveal the stress responses in different cell types. These findings suggest that the UPR may serve as a target for combinational therapy to reduce the recurrence of wound infections, eliminating the bottleneck of wound care.

Regulation of nuclear morphology under stress conditions in *Xenopus laevis* extracts

S. Sengupta, D. Levy; University of Wyoming, Laramie, WY.

Size is critical to function at all levels of biological organization. For example, there is significant variation in cell size between species, cell types, and developmental stages. The size of the nucleus tends to scale with cell size. Normal cells have a nuclear size within a defined range, while aberrations in nuclear morphology are often associated with disease, for instance cancers and laminopathies. The exact mechanisms by which a cell maintains nuclear size, shape, and structure are not well understood, although nuclear lamins have been implicated. We are addressing how nuclear shape and size change in response to various stress conditions, specifically osmotic stress (mannitol), oxidative stress (hydrogen peroxide), and proteotoxic stress (proteasome inhibitor MG132). Because treating cells with stressors can elicit complicated and pleiotropic effects, we chose to use a simplified system, de novo nuclear assembly in *Xenopus* egg extract. The extract is transcriptionally inert, allowing us to investigate transcription-independent stress responses, and the biochemical composition of the extract is easily manipulated, for instance through addition of molecular stressors. We first examined how stress conditions impact nuclear assembly. Nuclei assembled in MG132-treated extracts showed reduced stability with frequent ruptures, while osmotic and oxidative stress had little effect on assembly. Next, we treated pre-assembled nuclei, finding that all stress conditions induced changes in nuclear morphology, typically a reduction in nuclear size and wrinkling of the nuclear envelope. Concomitant with these nuclear morphology changes we observed a delocalization of lamin B3 away from the nuclear envelope and appearance of ring-like structures within the nucleus that stained for Aquaporin 2. Our future work will elucidate the underlying mechanisms responsible for these stress-induced changes in nuclear morphology.

B568/P2947

Cracking the Hsp70 chaperone code

A. Truman; Biological Sciences, University of North Carolina At Charlotte, Charlotte, NC.

The Hsp70 molecular chaperone has been extensively studied for the last 50 years; it is highly conserved and is essential for many cellular processes. Research has primarily focused on how Hsp70 function is regulated via transcription, expression of highly related paralogs and the suite of co-chaperone binding partners. Despite this, we still know very little about the post-translational modifications (PTMs) of Hsp70 and how these modifications may affect its cellular function. Powerful technologies such as affinity purification of proteins coupled with tandem mass spectrometry (AP-MS/MS) have uncovered a substantial number of modified sites on Hsp70. These PTMs can be added and removed rapidly, allowing fine-tuning chaperone function when required. The large number of detected modifications such as phosphorylation, ubiquitination, SUMOylation and acetylation) suggest a “chaperone code” similar in nature to the combinatory PTM code that exists on histones. We are currently examining the role of 73 Hsp70 phosphorylation sites on a range of chaperone-mediated processes that include the heat shock response, glucose utilization, the DNA damage response and human pathologies such as cancer and neurodegenerative disease. We hope that understanding of the reciprocal interplay between chaperones and key signal transductions system will lead to an unprecedented ability to manipulate chaperone function for experimental and translational purposes.

B569/P2948

Rapid heat-induced Hsp70 phosphorylation is critical for proteostasis in yeast

S. Omkar, A. Truman; Department of Biological Sciences, UNCC, Charlotte, NC.

Heat shock protein 70 (Hsp70) is a central component of protein folding and signal transduction pathways. Recent studies have identified roles for post-translational modifications (the Chaperone Code) in fine-tuning chaperone function. The role of post-translational modifications (PTMs) on Hsp70 under heat shock are poorly understood. To understand how heat shock impacts Hsp70 PTMs, we performed quantitative mass spectrometry on yeast Hsp70 isolated from untreated and heat shocked cells. We identified a novel heat-induced Hsp70 phosphorylation site on the substrate binding domain of Hsp70 that was activated rapidly (<5mins) by heat and other agents that challenged cell integrity. Surprisingly, phosphorylation of this site was induced in all the cytosolic paralogs of Hsp70 (Ssa1-4). Using genetic and molecular techniques, we identified key cell integrity proteins necessary for activation of Hsp70 phosphorylation. Mutation of Hsp70 to prevent heat-induced phosphorylation resulted in yeast that were viable but were sensitized to heat stress and cell wall damaging agents. Phospho-mutant yeast were unable to mount a significant transcriptional response to heat shock, suggesting Hsp70 phosphorylation is needed for correct formation of core heat shock transcriptional complexes. Taken together we believe that rapid heat-induced phosphorylation of Hsp70 is an initiating event in the heat shock response, a process which may be universally conserved in all organisms. **Key words: Hsp70, phosphorylation, heat shock, yeast, chaperone code**

Tardigrade small heat shock proteins can limit desiccation-induced protein aggregation

J. D. Hibshman[1], S. Carra[2], B. Goldstein[1]; [1]Biology Department, The University of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Department of Biomedical, Metabolic, and Neural Sciences, University of Modena and Reggio Emilia, Modena, ITALY.

Small heat shock proteins (sHSPs) are chaperones known for their response to heat stress. While sHSPs have well-characterized roles in heat tolerance, potential roles for sHSPs in desiccation tolerance have not been as thoroughly explored. We identified nine sHSPs from the genome of the tardigrade *Hypsibius exemplaris,* each containing a conserved alpha-crystallin domain flanked by disordered regions. Many of these sHSPs are highly expressed and in some cases are upregulated during desiccation. We found that tardigrade sHSPs were sufficient to improve desiccation tolerance when expressed in *E. coli*. Purification and subsequent analysis of two sHSPs, HSP21 and HSP24.6, revealed that these proteins can form large complexes *in vitro*, similar to oligomeric assemblies documented for other sHSPs. These proteins limited heat-induced aggregation of the model enzyme citrate synthase. Heterologous expression of HSP24.6 improved bacterial heat shock survival, and the protein significantly reduced heat-induced aggregation of soluble bacterial protein. Thus, HSP24.6 likely chaperones against protein aggregation to promote survival of heat stress. Furthermore, HSP21 and HSP24.6 also limited desiccation-induced aggregation and loss of function of citrate synthase. This suggests a mechanism by which tardigrade sHSPs promote desiccation tolerance: by limiting desiccation-induced protein aggregation, thereby maintaining proteostasis and supporting survival. These results suggest that sHSPs, classical chaperones, provide a mechanism of general stress resistance that can also be deployed to support survival during anhydrobiosis.

Novel stress granule proteins identified by Microscoop, a microscope-guided hypothesis-free subcellular protein discovery platform

C. H. Y. Cheung, W. Chong, H. Chang, C. Chung, C. Huang, Y. Chen, C. Chang, **J. Liao**; Syncell Inc., Taipei, TAIWAN.

Stress granules (SGs) are dynamic, non-membrane-bound assemblies of protein and RNA formed in response to cellular stress. Their pathological implications in cancer and neurodegenerative disease render it crucial to study SG composition for therapeutic applications. Previous SG proteomic studies have been achieved by biochemical fractionation or proximity labeling prior to mass spectrometric (LC-MS/MS) analysis; however, the procedures are usually labor intensive and technically challenging due to the small-sized and membrane-less nature of SGs. Moreover, the essence that SG markers mostly have multiple sub-cellular localizations, further complicates the studies. In this work, we took advantage of Microscoop, an automatic microscope system integrated with a machine learning-based algorithm, to explore the SG proteome. Microscoop enables site-specific protein identification by inducing photo-labeling precisely at the selected region-of-interest. SGs were first induced in U2-OS cells by arsenite and stained for G3BP1, a common SG marker. Immunofluorescence images of G3BP1 were applied to generate a computer vision (CV) based algorithm to differentiate G3BP1 in stress granules from that in the cytoplasm. A sequential process of fluorescence imaging, CV-driven pattern generation, and photochemical labeling was automatically implemented to achieve SG protein-specific biotinylation until sufficient cells was labeled for subsequent protein enrichment and LC-MS/MS analysis. In total, 2,614

proteins were found in three biological replicates. 77% of the triplicate-overlapped proteins were identified as SG proteins, showing a high specificity of the enrichment. STRING analysis of the proteins with a stringent threshold further disclosed 8 highly confident proteins as the core interactors in the SG interaction network. More importantly, these 8 proteins have no prior annotation as SGs. Immunofluorescence staining confirmed that 6 of them, i.e. EIF3CL, DDX17, PPIA, RPSA, YWHAE, and RPLP0 showed SG pattern and co-localized with G3BP1 in stressed cells but not in normal cells, confirming the discovery capability of our method. Collectively, our study unravels novel SG proteins, which possibly serve as core SG components, and demonstrates the capability of the Microscoop technology to achieve subcellular in situ protein discovery.

RRM of eIF4B affects stress granule assembly and disassembly

J. Bolivar, N. Decuzzi, E. Kofke, K. Beglinger, J. Albeck, C. Fraser; UC Davis, Davis, CA.

Cells must respond to environmental stress to ensure survival and recovery. One stress response mechanism involves forming cytoplasmic structures called stress granules (SGs). SGs are non-membrane bound organelles composed of mRNA transcripts, RNA binding proteins, and 40S ribosomal subunits bound by eukaryotic initiation factors (eIFs). Rapid formation of SGs (within ~30 minutes of oxidative stress) serves to protect mRNAs and the translation initiation machinery during survival and recovery. However, the precise mechanism by which SGs assemble during stress and disassemble after stress is poorly defined. Specifically, we do not understand how interactions between the translation machinery and other SG components regulate the kinetics of SG assembly and disassembly. To overcome this barrier and move the field forward, I have generated a real-time single-cell kinetic assay to monitor stress granule assembly and disassembly. I found that the RNA recognition motif (RRM) domain of eIF4B protein can change the rate at which stress granules assemble and disassemble. Our findings could provide insight to other applications such as the effect of chemotherapeutic drugs on SG assembly and disassembly, or to determine if changes in the translation initiation machinery could speed up SG disassembly in a neurodegenerative model.

A new role for the p24 family in antitrypsin Z clearance from the endoplasmic reticulum

B. Roberts, D. Mitra, **P. Satpute-Krishnan**; Biochemistry and Molecular BIology, Uniformed Services University, Bethesda, MD.

We report a novel role forp24-family proteins as protein quality control (PQC) factors that associatewith and facilitate the clearance of the misfolding alpha1-antitrypsin Z mutant(ATZ) from the endoplasmic reticulum (ER). ATZ has been well established to becleared from the ER to ER-derived vesicles for direct delivery to lysosomes viaone or more ER-to-lysosome-associated degradation (ERLAD) pathways that requirethe involvement of lipidated LC3 (LC3-II) molecules and are inhibited withautophagy inhibitor, 3-methyladenine. We discovered that ATZco-immunoprecipitated with p24-family members including Tmp21 and TMED9, inaddition to the ERLAD components calnexin and FAM134B that were previouslyreported by the Molinari lab (Fregno et al. 2018). This contrasts with wildtype alpha1-antitrypsin (AAT), which did not co-immunoprecipitate with FAM134B,calnexin or the p24-family members. Live cell imaging experiments revealed thatATZ and the p24-family members trafficked together from the ER to lysosomes butwere trapped together at the ER-exit sites marked by Sec24C

upon treatment withbrefeldin A and nocodazole. Similarly, ATZ and p24-family members were trappedtogether in ER-derived compartments upon treatment with 3-methyladenine.Importantly, depletion of Tmp21 or TMED9 significantly increased theintracellular levels of ATZ and prevented the trafficking of ATZ to lysosomes.Conversely, overexpression of these p24-family members promoted the degradationof ATZ. These and additional preliminary co-immunoprecipitation andcolocalization data and p24-family depletion experiments suggest a model inwhich the p24-family plays a key role in ATZ-clearance by bridging ATZ togetherwith ERLAD machinery and COPII coat proteins for the formation of ER-derivedERLAD vesicles. Taken together, our work reveals a new role for thep24-family in clearing misfolded proteins by-way-of the ERLAD pathway.

B574/P2953

Elucidating CHCHD10 Phenotypes Using Inducible Cellular Models

C. I. Lantz; NINDS, Bethesda, MD.

Mutations in the mitochondrial protein CHCHD10 cause autosomal dominant neuromuscular disorders including frontotemporal dementia (FTD)/ALS, mitochondrial myopathy, and lower motor neuronopathy (SMAJ, spinal muscular atrophy Jokela type). Most of these CHCHD10 disease phenotypes result from mutations in a conserved hydrophobic α-helical region in the middle of the protein and have a strict genotype-phenotype relationship, with the G58R mutation causing a pure myopathy and the G66V mutation causing a pure lower motor neuronopathy. The molecular basis for this genotype-phenotype relationship is not well understood. The current model of pathogenicity is toxic gain-of-function, as CHCHD10 knock-in mice but not CHCHD10 KO mice recapitulate the myopathy phenotype seen in patients with the G58R or S59L variants, as demonstrated by our lab and others. Work from our laboratory also identifies OMA1-dependent mitochondrial fragmentation and activation of the integrated stress response, as adaptive responses to mutant CHCHD10 misfolding. Preliminary evidence from our lab demonstrates that the G66V variant but not the myopathy-causing G58R variant decreases the solubility of the protein. We hypothesize that differences in misfolding of the G58R and G66V variants underlie their selective toxicity on myocytes and lower motor neurons, respectively. Using iPS cells, we have developed cellular models of both neuropathy and motor neuron disease causing mutations. We are comparing their phenotypes when differentiated into both induced myocytes and induced motor neurons. As a reference, we have also compared transcriptional responses of induced myocytes and induced motor neurons to mitochondrial toxins. We anticipate study of these cells will provide insight into the genotype-phenotype combinations observed in patients.

Possible involvement of a heat-dependent myokine CCL5 on adipogenesis in mice

K. Murata, Y. Sato-Ishiuchi, T. Nedachi; Toyo University, Gunma, JAPAN.

Recently, skeletal muscle is recognized as an endocrine organ, producing proteins and peptides, defined as myokines. It has been established that contraction of skeletal muscle and/or nutritional states regulate the secretion of some of these myokines. Although the temperature of skeletal muscles can be changed during exercise and/or by changes in ambient temperature, its impact on myokine regulation has not been completely understood. In this study, we focused on skeletal muscle-derived C-C chemokine ligand 5 (CCL5), which we recently identified as a heat-dependent myokine and investigated its precise regulation by heat stress. In addition, we also investigated the potential involvement of the

heat-dependent myokines on adipogenesis.First, comprehensive analysis of myokines secreted from mouse C2C12 myotube revealed that CCL5 secretion is significantly reduced by heat stimulus. This heat-dependent CCL5 reduction was further confirmed by ELISA, western blotting, and quantitative PCR analysis. We next examined whether the acute heat stress in mice affects serum CCL5 concentration, as well as CCL5 gene expression in skeletal muscle. Male C57B6/J mice, maintained at 23 C, were exposed to 45 C for 1 hour, followed by back to 23 C chamber (the recovering time). CCL5 gene expression in skeletal muscle was significantly reduced by approximately 0.1- to 0.5-folds after 3 hours of the recovering time. Serum CCL5 concentration was acutely elevated by 1 hour of the heat exposure; however, importantly, was significantly reduced by approximately 0.5-fold after 23 hours of the recovering time. Moreover, we explored the physiological significance of the heat-dependent reduction of the myokine CCL5. We found that the addition of heat-stimulated C2C12 myotube cell culture supernatant to 3T3-L1 adipocytes causes an increase in cell size and large lipid droplet, whereas this change is abolished by the addition of recombinant CCL5.Overall, these suggest that heat stimulus decreases secretion of CCL5 from skeletal muscle both in vivo and invitro, and this CCL5 reduction by heat stimulus potentially altered the adipocyte metabolism. Although further studies are required to elucidate the physiological significance of the heat-dependent decreases in CCL5, it can be hypothesized that these heat-dependent myokines regulate lipid homeostasis which was disrupted by heat stimulus.

Characterization of the unfolded protein response in normal human skin fibroblasts

L. Sobilo, L. Maclart Marsal, K. Lazou, M. Moreau, P. Schaeffer, M. Juan, E. Leblanc-Noblesse, A. Bulteau, K. Pays, C. Nizard; LVMH Recherche, Saint Jean de Braye, FRANCE.

Introduction: By ensuring protein synthesis and folding, endoplasmic reticulum (ER) is essential for the maintenance of proteostasis. Numerous perturbations (inflammation, oxidative stress) can lead to an accumulation of misfolded proteins in the ER leading to its engorgement and thus to an ER stress. Response to this stressful situation, the cell has developed an adaptive mechanism to repair the misfolded proteins: the UPR (Unfolded Protein Response). This response is induced by the recruitment of chaperon protein GRP78/BiP which leads an activation of three distinct signaling pathways coming from the ER transmembrane proteins: IRE1, PERK ATF6. Dermal matrix which is essential for skin elasticity and thickness is composed of protein such as collagens with unique and specific structure which function rely on their folding. Therefore, ER is essential for the maintenance of the biological functions of the skin, so the purpose of this study was, first to study le ER Stress in dermal Fibroblasts et then characterize the expression of aims targets of the UPR. **Materials and Methods:** Firstly, NHF were cultured with a specific pharmacological ER stressor, thapsigargin (a SERCA2 Ca^{2+} pump inhibitor that depletes ER Ca^{2+}) and the cells were collected at different times to study the gene expression (RT-qPCR by TLDA Technology) and the proteins expression (Western Blot). Afterward, the targets of UPR were observed in NHF stressed by immunostaining with confocal microscopy. Finally, the impact of stress induced by thapsigargin on NHF were studied on activity of proteasome by spectrophotometry. **Results:** Our results showed that the Ca^{2+} depletion in ER with thapsigargin causes a strong cytotoxicity on skin fibroblasts. The ER stress were detected with the significative increase of le GRP78/BiP target which leads to the activation of certain UPR pathway. In fact, we constated that the three UPR pathways didn't responded of the same manner in the time and with different concentrations of the thapsigargin. ATF6 pathway seems to be more sensitive then IRE1a pathway and that PERK which require a strong ER stress to be activate. The different response of three UPR pathways describe that dermal fibroblasts cells can

activate some defense strategies to rebalance the right conformed proteins production to maintain homeostasis and avoid cell death.

Aspirin metabolite sodium salicylate downregulates the unfolded protein response and cell migration in colorectal cancer cells

N. Rauth, D. Bhandari; Chemistry and Biochemistry, California State University Long Beach, Long Beach, CA.

A daily regimen of low dose aspirin has been epidemiologically linked to reduced occurrence of many cancers particularly colorectal cancer. However, the cellular mechanism(s) for this protection is not well understood. Cancer cells have altered metabolic demands and rapid proliferation rate that can induce endoplasmic reticulum (ER) stress. During ER stress, cells activate an evolutionarily conserved signaling pathway known as unfolded protein response (UPR). The adaptive UPR signaling has been correlated to acquisition of malignancy and chemoresistance in cancer cells. Therefore, we investigated if aspirin affects the ability of cancer cells to activate UPR upon induction of ER stress. We treated colorectal cancer cell line DLD1 with sodium salicylate (NaSal), a metabolic derivative of aspirin and induced ER stress with tunicamycin, which halts N-linked glycosylation - an importance posttranslational modification of secretory proteins in the ER. We then analyzed the expression of various proteins involved in UPR signaling via western blotting. Our data indicate that NaSal treatment downregulates UPR signaling. Specifically, we observed significantly reduced levels of ER chaperone glucose-regulated protein of 78kDa (GRP78) whose overexpression has been implicated in chemoresistance. Using flow cytometry based annexin V assay, we observed a greater percentage of apoptosis in cells treated with NaSal-tunicamycin as compared to the control sets. Finally, using a wound healing assay, we also observed reduced cell migration upon NaSal treatment. Together, this work sheds light on a potential mechanistic basis for the chemopreventive action of aspirin. Our current and future experiments are directed toward understanding the molecular mechanism by which NaSal regulates UPR and cell migration.

B578/P2957

The G protein-coupled receptor (GPCR) FSHR-1 and the SPHK-1 lipid kinase regulate *C. elegans* life- and healthspans via a common pathway

R. Adkins, J. R. Kowalski; Biological Sciences, Butler University, Indianapolis, IN.

Later years of life are often characterized by reduced cognitive function and mobility. One contributor is the cellular accumulation of reactive oxygen species (ROS), but our understanding of how cells respond to ROS to promote health and survival is incomplete. Follicle stimulating hormone receptor-1 (FSHR-1) and sphingosine kinase-1 (SPHK-1) mediate responses to oxidative stress and regulate life history traits in the roundworm *Caenorhabditis elegans*. The genes encoding both proteins are conserved in humans where they are implicated in stress responses, cell survival and neuronal function. *fshr-1* and *sphk-1* work together to mediate responses to intestinal oxidative stress in *C. elegans*. Whether these genes work in a common pathway to control lifespan or healthspan is unknown. Previous studies indicated potential phenotypic differences in life history traits based on the worms' bacterial food source. The typical source, OP50 *E. coli,* is pathogenic compared to the HB101 strain. We hypothesized differences in pathogenicity between the two strains cause decreased lifespan and locomotion through oxidative

stress effects that may differentially affect the mutants. Here we show *sphk-1* and *fshr-1* are required for normal life- and healthspan in *C. elegans*. We found significant reductions in mutant lifespans on both lawns versus wild type worms, but no differences within genotype across food. *fshr-1, sphk-1* and double mutants had decreased swimming rates compared to wild type worms on HB101 at all timepoints, but no significant difference in motor decline over time between the genotypes. This suggests the genes may not act in a timed manner to regulate accumulation of oxidative stress. We also saw non-additive effects for the genes on both lifespan and healthspan, as double mutants showed phenotypes equal to single mutants, indicating *fshr-1* and *sphk-1* work in a single pathway to mediate life- and healthspan. Lawn pathogenicity levels do not affect lifespan in the mutants, suggesting the potential decrease in innate immunity does not make the worms susceptible to increased OP50 pathogenicity. These data provide evidence of a common genetic pathway between *sphk-1* and *fshr-1* during aging, consistent with their known roles in oxidative stress mediation. Future studies will explore details of this relationship via tissue-specific *fshr-1* rescue and depletion experiments.

B579/P2958

Unveiling 'musica universalis' of the cell: central dogma riding the 12-h tides

B. Zhu; University of Pittsburgh, Pittsburgh, PA.

Biological oscillations often cycle at the harmonic frequencies of the 24h circadian rhythm, a phenomenon coined "Musica Universalis". Like the circadian rhythm, the 12h ultradian rhythms are also evolutionarily conserved, prevalent and robust. Originally thought to be regulated by the circadian clock and/or environmental cues, recent new evidence support the notion that the majority of 12h rhythms are regulated by a distinct and cell-autonomous oscillator that is separate from both the 24-h circadian clock and the cell cycle oscillator. Mechanistically, 12h oscillator is transcriptionally regulated at multiple steps. 12h rhythmic chromatin occupancy of Spliced form of XBP1 (XBP1s) and histone methyl transferase complex together shape the 12h epigenome and drive 12h nascent transcription of genes at dawn and dusk, which are enriched for basal transcription regulation, mRNA processing and export, ribosome biogenesis, translation initiation, and protein processing/sorting in the Endoplasmic Reticulum (ER)-Golgi in a temporal order consistent with the progressive molecular processing sequence described by the central dogma. In addition to tight control at the transcription initiation step, 12h rhythm of nuclear speckle liquid-liquid phase separation dynamics further regulates the 12h oscillator at the mRNA processing and transcription elongation step. Physiologically, liver-specific deletion of the 12h oscillator resulted in accelerated liver aging and steatosis, manifested with mitochondrial dysfunction, and dysregulated proteostasis, lipid and mRNA metabolism. Evolutionarily, the mammalian 12h oscillator likely evolves from the ancient circatidal clock of marine animals, whose behaviors are synchronized to the ~12h ebb and flow of the tides. 12h rhythms of orthologous gene expression are also found in species as divergent as crustacean, sea anemone, *C.elegans*, zebrafish, mouse and primates. The recent identification of 12h transcriptome in the prefrontal cortex region of humans, and altered 12h rhythms in genes associated with proteostasis and mitochondrial function in schizophrenia subjects further indicate the importance of 12h oscillator. Due to the absence of tidal cues for terrestrial animals, we conjecture that the 12h oscillator is co-opted to adapt to the 12h cycle of metabolic stress that peaks at transition times at dawn and dusk in in-land animals.

B580/P2959

A central helical fulcrum controls eIF2B conformation and metabolic signaling

R. E. Lawrence[1], S. Shoemaker[2], A. Deal[3], L. Wang[3], S. Marqusee[2], P. Walter[3]; [1]University of California, San Francisco, San Francisco, CA, [2]University of California at Berkeley, Berkeley, CA, [3]University of California at San Francisco, San Francisco, CA

The Integrated Stress Response (ISR) is an ancient cellular pathway that allows cells to remodel metabolism and translation in response to a wide variety of stresses. ISR signaling is mediated by dynamic interactions between members of a core circuit that regulates the rate of nucleotide loading of the GTPase eIF2. eIF2's heterodecameric guanine nucleotide exchange factor, eIF2B, contains core regulatory subunits eIF2Bβ and eIF2Bδ that have homology to archaeal ribulose 1-5-bisphoshate isomerases. eIF2B is dynamically controlled by phosphorylation of its eIF2 substrate, which ultimately inactivates eIF2B GEF activity, converting eIF2B from an active "A-state" conformation to an inactive "I-state conformation." A key open question in the field was how exactly eIF2-P binding at a site distal from eIF2B's catalytic domain allosterically induced the transition into the "I-state". Using hydrogen-deuterium exchange, biochemistry, cryo-EM, and cellular assays we uncovered a highly conserved helical switch in the eIF2Bδ core regulatory subunit ("δhelix13") that acts as a fulcrum for eIF2B's transition between the A-state to the I-state. In particular we found i) that δhelix13 can adopt two distinct switch conformations, and ii) that mutations that lock the switch into a particular state are sufficient to drive the entire eIF2B complex into the A-state or I-state. Furthermore, δhelix13 mutations clamp eIF2B activity and ISR signaling into defined states in cells, presenting attractive tools for the development of ISR-targeting drugs for neurodegenerative disease, as well as exploring metabolic consequences of chronic ISR activation.

B581/P2960

Investigations into Hsc70 phosphorylation in response to DNA damage

T. Moss, S. Moss, A. Wooldredge, O. Johnson, K. Shokat, J. Gestwicki, S. Mukherjee; University of California, San Francisco, San Francisco, CA

Hsc70 is a constitutively expressed member of the Hsp70 family of chaperone proteins. Hsc70 has numerous and diverse roles in the cytoplasm and nucleus, which include maintaining basal cellular functions and response to stress. Due to its myriad functions, Hsc70 activity must be tightly regulated, and dysregulation can lead to neurodegenerative disease and cancer. Given that Hsc70 is a highly abundant protein, its activity is often regulated via post translational modifications (PTMs). Using a *Legionella pneumophila (L.p.)* kinase, LegK4, we identified threonine 495, a highly conserved amino acid, as a phosphosite in Hsc70 with strong regulatory potential. In the context of *L.p.* infection, LegK4 phosphorylates cytosolic Hsc70, resulting in a reduction in both its ATPase activity as well as its ability to fold proteins. As a result, protein synthesis is severely reduced. The mechanism by which this single phosphorylation affects Hsc70 function remains unknown. Given that pathogens often hijack and/or mimic host enzymes, we investigated whether a host kinase can phosphorylate T495 of Hsc70. Indeed, we identified that this phosphorylation also occurs in response to stress — prolonged treatment of cells with the DNA alkylating agent methyl methanesulfonate (MMS) leads to an accumulation of phospho-Hsc70(T495) (pHsc70) in the nucleus. This phosphorylation is dependent on the DNA-damage response kinases DNA-PKcs, Chk2, and CK-1, and correlates with changes in nuclear architecture previously linked

to apoptosis. Thus, using *L.p.* as a tool, we have discovered a previously unknown role of Hsc70 phosphorylation during DNA damage.

Cryo-EM reveals the dynamics interplay between mitochondrial Hsp90 and SdhB folding intermediates

Y. Liu; Chemistry and Biochemistry, University of Maryland, College Park, College Par, MD.

TRAP1 is a mitochondrion specific Hsp90, a ubiquitous chaperone family that mediates the folding and maturation of hundreds of "client" proteins. Through the interaction with client proteins, TRAP1 regulates mitochondrial protein homeostasis, oxidative phosphorylation/glycolysis balance, and plays a critical role in mitochondrial dynamics and disease. However, the molecular mechanism of client protein recognition and remodeling by TRAP1 remains elusive. Here we established the succinate dehydrogenase B subunit (SdhB) from mitochondrial complex II as a client protein for TRAP1 amenable to detailed biochemical and structural investigation. Cryo-EM structures of the TRAP1:SdhB complex show TRAP1 stabilizes SdhB folding intermediates by trapping an SdhB segment in the TRAP1 lumen. Unexpectedly, client protein binding induces an asymmetric to symmetric transition in the TRAP1 closed state. Our results highlight a client binding mechanism conserved throughout Hsp90s that transcends the need for cochaperones and provide molecular insights into how TRAP1 modulates protein folding within mitochondria. Our structures also suggest a potential role for TRAP1 in Fe-S cluster biogenesis and mitochondrial protein import. In addition, we used a combination of solution, biochemical and cryo-EM approaches to show that, independent of nucleotide state, a subpopulation of TRAP1 exists as tetramers. The biological function of TRAP1 tetrameric states remain to be explored.

Characterization of a putative *C. elegans* ortholog of the ERAD protein, Valosin-containing Protein-interacting Membrane Protein (VIMP)

L. Dahlberg[1], L. Ellgaard[2], A. Dhalla[3], T. Marks[1]; [1]Western Washington University, Bellingham, WA, [2]University of Copenhagen, Copenhagen, Denmark, [3]Antelope Valley College, Palmdale, CA

The ER-associated Degradation machinery consists of large protein complexes whose makeup can change depending on the stress level of the ER. The Valosin-containing Protein-interacting Membrane Protein (VIMP, SelenoS) is a member of the ERAD machinery that can interact directly with the adaptor protein, p97, which shuttles misfolded proteins to the proteasome for degradation. Despite VIMP's central position in ERAD protein complexes, its precise roles in ERAD and cellular stress responses are still unclear. VIMP levels increase during ER stress, and some studies suggest that cells that lack VIMP have reduced response to ER stress, as measured by the induction of Unfolded Protein Response (UPR) genes including *xbp1 and hspa5* (BiP). In *C. elegans,* a putative ortholog to VIMP is the gene F26F4.9. F26F4.9 has high sequence homology with mammalian VIMP except for at its C-terminus, where it contains a glutaredoxin domain instead of the unstructured selenocysteine-containing domain. We used the ER stress reporter transgene, P*hsp-4*::GFP to determine if F26F4.9 is required for regulating *hsp-4* during an ER stress response. We find that a genetic deletion in F26F4.9 (*tm2433*) reduces the activation of P*hsp-4*::GFP that usually occurs when animals are treated with the ER stress inducing drug, Tunicamycin, or when animals are lacking other ERAD machinery. In particular, RNAi against *hsp-4* dramatically increases the activity of GFP expressed under the *hsp-4* promoter. However, in RNAi-fed

animals, the loss of F26F4.9 reduces the high P*hsp-4*::GFP expression by 50%. Our current work is addressing the mechanisms by which F26F4.9 may work within the ERAD machinery to regulate gene transcription as part of the unfolded protein response.

Impairment of Endoplasmic Reticulum-Associated Degradation by Perturbed Lipid Biosynthesis

E. M. Rubenstein, S. M. Turk, C. J. Indovina, D. L. Overton, A. M. Runnebohm, C. J. Orchard, E. M. Doss, K. A. Richards, C. B. Irelan, M. M. Daraghmi, C. G. Bailey, J. M. Miller, J. M. Niekamp, S. K. Gosser, M. E. Tragesser-Tiña, K. P. Claypool, S. M. Engle, B. W. Buchanan, J. B. Olesen, P. J. Smaldino; Ball State University, Muncie, IN

The relationship between membrane lipid composition and endoplasmic reticulum (ER) protein homeostasis is complex and incompletely understood. We performed a screen to identify genes required for efficient ER-associated degradation (ERAD) of the Hrd1 ubiquitin ligase substrate *Deg1*-Sec62 in *Saccharomyces cerevisiae*. We identified and validated *INO4*, which encodes one component of the heterodimeric Ino2/Ino4 transcription factor, as required for *Deg1*-Sec62 degradation. Ino2/Ino4 regulates expression of genes encoding several enzymes contributing to lipid biosynthesis. *Deg1*-Sec62 degradation in *ino4* yeast was restored by supplementation with inositol, choline, and ethanolamine, metabolites whose synthesis and/or uptake are mediated by Ino2/Ino4-regulated genes. Mutation of several genes encoding enzymes contributing to phospholipid or sterol biosynthesis delayed *Deg1*-Sec62 degradation. Further, *INO4* deletion stabilized a panel of ER protein quality control substrates of the Hrd1 and Doa10 ubiquitin ligases and sensitized yeast to hygromycin B, which is associated with an elevated burden of aberrant and misfolded proteins. These results suggest ERAD is broadly sensitive to membrane lipid composition. Several human diseases are characterized by disrupted lipid synthesis. Impaired lipid homeostasis may delay ER protein degradation in individuals with these conditions.

The RIDD activity of *C. elegans* IRE1 in sensory neurons supports survival in stressful environments.

M. Ying, Male[1], Y. Argon[1], T. Gidalevitz[2]; [1]Children's Hospital of Philadelphia, Philadelphia, PA, [2]Drexel University, Philadelphia, PA

Regulated IRE1-dependent RNA decay (RIDD) and *xbp-1* splicing are two RNase activities of ER stress sensor IRE1. Unlike *xbp-1* splicing, RIDD is only identified in few species, and its substrate repertoire is not well defined. Similarly, while it serves to reduce biosynthetic burden on ER under stress, the roles of RIDD in normal physiology are only beginning to emerge. We asked whether *C. elegans* IRE1 can cleave RIDD substrates and what are the physiological consequences to their degradation.To test RIDD capability of the worm IRE1, we fused its cytosolic kinase and RNase domains with the human transmembrane and luminal domains, to retain proper protein interactions within the ER, and expressed it in human *ire1(-/-)* cells. The chimeric protein efficiently spliced human *xbp-1*; this was increased by ER stress and inhibited by IRE1-selective inhibitor, 4μ8c, confirming chimera's activity. Importantly, chimeric IRE1 downregulated the canonical RIDD target *blos-1* mRNA, which was also inhibited by 4μ8c. Thus, the worm IRE1 possesses RIDD activity.To understand the physiological role(s) of RIDD in *C. elegans*, we looked for endogenous substrates. Using existing transcriptomic data, we identified messages whose downregulation during tunicamycin (Tm)-induced ER stress depended selectively on IRE1, including that of a TGFβ homologue, *daf-7*. Importantly, *daf-7* mRNA was efficiently degraded

under ER stress by human IRE1, along with its authentic RIDD substrate *blos-1*, establishing *daf-7* as a strong candidate for RIDD substrate.DAF-7 protein is secreted from sensory neurons in early larval stages, and if its secretion is decreased, it signals stressful environments and triggers several adaptive responses. We found that upon Tm exposure of young larvae, *daf-7* mRNA is selectively downregulated in IRE1-dependent manner. Remarkably, Tm concentrations too low to activate *xbp-1* splicing efficiently induce RIDD of *daf-7*, suggesting a sensing functionality. Because Tm is a natural metabolite of some *Streptomyces spp.*, which prey on the worm food bacteria, and because DAF-7 secretion signals food, we asked whether low Tm exposure may trigger an adaptive response. We found that low Tm improved survival by worm population of combined starvation and temperature stress. Thus, by utilizing RIDD to sense a danger signal, *C. elegans* prepares for upcoming environmental challenges.

***In-Vivo* Detection of Stress-Dependent Sumoylation in the Budding Yeast Cytosol**

B. Humphries, O. Kerscher; College William & Mary, Williamsburg, VA

SUMO, a small ubiquitin-like modifier protein, modulates protein function to regulate essential cellular processes, including the response to stress. In yeast and mammalian cells, exposure to stressors such as elevated temperatures or oxidizing agents, initiates a wave of sumoylation that propagates throughout the nucleus and cytosol. This SUMO Stress Response (SSR) has been reported to protect protein complex integrity, prevent protein aggregation, and enhance stress-specific transcriptional responses. However, the choreography and functional targets of this stress-induced sumoylation in the cytosol are not well understood. Therefore, the objective of our research is to establish a novel SUMO stress reporter assay to visualize and quantify cytosolic sumoylation targets that respond to heat shock and peroxide stress. Our SUMO stress reporter assay is based on a bimolecular fluorescence complementation (BiFC) or Split-GFP approach. Two complementing fragments (GFP 1-10 and GFP 11) of the green fluorescent protein are fused to the SUMO ligase Siz1 and a *bona fide* cytoplasmic SUMO substrate of this E3 ligase, respectively. Our results indicate that Siz1 interacts specifically with a GFP 11-fusion protein tethered to the cytoplasmic side of the mitochondrial outer membrane. In contrast, a soluble fusion protein, GFP11-HXK1 was enriched with GFP1-10-Siz1 in the yeast cell nucleus. In conclusion, refining this assay may hold great utility for the study of SUMO-dependent stress-induced protein interactions in the cytosol and the study of genetic pathways that control them.

Transcriptional control of proteome remodeling with cell size

D. You[1], M. Lanz[1,2], J. Elias[1,2], J. Skotheim[1,2]; [1]Stanford University, Stanford, CA, [2]Chan Zuckerberg Biohub, Stanford, CA.

Generally, growing cells pair increase in size with proportional increase in their biological components to maintain cell function. However, recent studies demonstrated that both cell function and proteome composition are not necessarily constant with cell size. Indeed, many proteins change their relative concentrations with cell size, and large cells are more likely to enter senescence, implicating cell enlargement as a potential source of stress. Whether these proteomic changes reflect a stress response and how these changes occur are unknown. To understand the mechanisms of proteome remodeling with cell size, we examined two pathways in the biosynthetic process - transcription and protein turnover. We employed pulsed-SILAC mass spectrometry and RNAseq in inducible cyclin-D knockdown

cells that yielded near steady-state cells of varying volumes. We find that changes at the transcriptomic level explains most of the proteome remodeling with cell size, and that protein turnover also partially contributes to this phenomenon. Our study points to a size-dependent transcriptional response program that reshapes the cell proteome

B588/P2967
Structure of the PAPP-A/IGFBP5 complex reveals mechanism of substrate recognition
Q. Hao; Calico Life Science (AlphaBet), South San Francisco, CA

Insulin-like growth factor (IGF) signaling is highly conserved and tightly regulated by proteases including Pregnancy-Associated Plasma Protein A (PAPP-A). PAPP-A and its paralog PAPP-A2 are metalloproteases that mediate IGF bioavailability through cleavage of IGF binding proteins (IGFBPs). Here, we present single-particle cryo-EM structures of the catalytically inactive mutant PAPP-A (E483A) in complex with a peptide from its substrate IGFBP5 (PAPP-A_{BP5}) and also in its substrate-unbound form, by leveraging the power of AlphaFold to generate a high quality predicted model as a starting template. We show that PAPP-A is a flexible *trans*-dimer that binds IGFBP5 via a 25-amino acid anchor peptide which extends into the metalloprotease active site. This unique IGFBP5 anchor peptide that mediates the specific PAPP-A-IGFBP5 interaction is not found in other PAPP-A substrates. Additionally, we illustrate the critical role of the PAPP-A central domain as it mediates both IGFBP5 recognition and trans-dimerization. We further demonstrate that PAPP-A trans-dimer formation and distal inter-domain interactions are both required for efficient proteolysis of IGFBP4, but dispensable for IGFBP5 cleavage. Together the structural and biochemical studies presented here reveal the mechanism of PAPP-A substrate binding and selectivity.

Ubiquitin and Proteasome Function

B589/P2968
Degradation of ubiquitinated post-ER membrane proteins via Ddi1, Rbd2 and the proteasome
A. Y. Minard, R. Piper; University of Iowa, Iowa City, IA.

Misfolded or surplus membrane proteins in the endosomal system are hazardous to cells and thus, in healthy cells, are typically subject to degradation by ER-Associated Degradation (ERAD) or, if the protein resides outside of the ER, by the multivesicular body (MVB) pathway. Proteins are marked for degradation with a ubiquitin (Ub) tag which, can vary in its topology. In the case of ERAD, membrane proteins are marked with K48-linked polyubiquitin (polyUb^{K48}), which directs retrotranslocation and Cdc48-mediated delivery to the proteasome. In contrast, substrates for the MVB pathway are modified with monoUb or polyUb^{K63}, which engages the ESCRT machinery to deliver membrane protein substrates into intralumenal vesicles. It is unclear, however, whether the topology of the ubiquitin chain dictates entry into either pathway, or if cells are able to process post-ER membrane proteins that are modified by polyUb^{K48}. Here we show that post-ER membrane proteins that are modified by polyUb^{K48} chains are in fact engaged by a degradative pathway distinct from ERAD and MVB sorting. By targeting a set of synthetic ubiquitin ligases to TGN/Endosomal membrane proteins, we find that polyUb^{K48} modified proteins are delivered to the proteasome, but without retrotranslocation from the membrane. Rather, they are subjected to two cleavage events: one by the ubiquilin Ddi1, which cleaves the cytosolic portion concomitant with degradation by the proteasome; and a second by the rhomboid protease Rbd2 in the lumenal portion of the protein, which is degraded in the lysosomal lumen. Importantly, polyUb^{K48}-

modification of post-ER membrane proteins does not sort them into the MVB pathway, despite the capacity of some of the ESCRT machinery to recognize a wide variety of polyUb linkages. These data reveal a new post-ER degradation pathway 'pERdeg' that we hypothesize operates in tandem with the MVB pathway and may be a major degradative route for a subset of membrane proteins as well as those artificially targeted for degradation by PROTAC drugs.

Molecular Mechanisms for the Activation of 26S Proteasomes by ZFAND5

D. Lee[1], Y. Zhu[2], **L. Colson**[3], X. Wang[4], E. Tkacik[3], L. Huang[4], Q. Ouyang[5], A. L. Goldberg[1], Y. Lu[3]; [1]Department of Cell Biology, Harvard Medical School, Boston, MA, [2]Division of Structural Biology, University of Oxford, Oxford, UNITED KINGDOM, [3]Department of Systems Biology, Harvard Medical School, Boston, MA, [4]University of California Irvine, Irvine, CA, [5]Peking University, Beijing, CHINA.

Various factors increase intracellular protein degradation by stimulating the 26S proteasome's activities. We present the mechanisms of the proteasome activator ZFAND5, a 213 amino acid protein that contains a ubiquitin-binding, A20 zinc finger domain near its N-terminus and an AN1 zinc finger domain near its C-terminus (1, 2). Skeletal muscles upregulate ZFAND5 during atrophy, when proteolysis by the ubiquitin proteasome pathway increases leading to muscle wasting (1). Addition of ZFAND5to purified 26S proteasomes stimulates the hydrolysis of ubiquitinated proteins up to fourfold, short peptides up to six fold, and ATP up to twofold (2). This stimulation in the degradation of ubiquitinated proteins requires the A20domain, and the enhancement of the peptidase activity requires the AN1 domain.
To uncover the mechanism by which ZFAND5 stimulates the activities of the 26S proteasome, we determine the structures of ZFAND5-bound 26S proteasomes using cryo-electron microscopy. ~68% of all particles contain ZFAND5 (Z+) and show ZFAND5's AN1domain interacting with the 26S proteasome's ATPase subunit Rpt5 and core particle (CP) subunit α;;;;7.~20% of the Z+ particles exhibit a novel proteasome conformation where the diameter of the entrance to the ATPase's substrate translocation channel is threefold larger than in the basal state. In this novel conformation, ZFAND5'sC-terminus interacts with the ATPase subunit Rpt1 and the ubiquitin-binding subunit Rpn1. ZFAND5's stimulation of peptidase and ubiquitinated protein degradation activity requires this C-terminal region. The other ~32% of all particles lack ZFAND5 and exhibit an open gate on the CP, a fourfold larger population than 26S proteasomes alone (3). Using single-molecule fluorescence microscopy invitro, we find 26S proteasomes only degrade ~20% of ubiquitinated proteins that bind without ZFAND5 but degrade ~70% of the ubiquitinated substrates that bind with ZFAND5. ZFAND5 dissociates before deubiquitylation of the substrate. These findings suggest ZFAND5's C-terminal interaction with proteasomes triggers a substrate capturing state that directly precedes a translocation-competent state to promote the proteolysis of substrates.1. B591/P2970

Rescue of proteotoxic stress and neurodegeneration by an endoplasmic reticulum Zn2+ transporter

X. Guo[1], **M. C. Mutch**[1], A. Y. Torres Espinosa[1], W. Dai[2], D. J. Montell[1]; [1]Molecular, Cellular & Developmental Biology, University of California, Santa Barbara, Santa Barbara, CA, [2]Fudan University, Shanghai, CHINA.

Proteotoxic stress drives the progression of numerous degenerative diseases including Type I diabetes, Huntingtin's Disease, Parkinson's Disease, and retinitis pigmentosa. In response to misfolded proteins, cells adapt by activating the endoplasmic reticulum (ER) stress response including ER-associated protein degradation (ERAD). However, persistent stress overwhelms the response and triggers apoptosis. Identifying mechanisms that enhance ERAD and mitigate ER stress are expected to lead to new therapeutic approaches. Here, we show that overexpression of the conserved, ER membrane-localized, Zn^{2+} transporter ZIP7, potently enhances ERAD and rescues retinal degeneration caused by misfolded Rhodopsin (Rh) in Drosophila. We found that overexpressing Zip7 dramatically reduces the abundance of ubiquitinated proteins, likely through enhancing proteasome function. In contrast to prior work suggesting that ZIP7 promotes trafficking of membrane proteins such as Notch, we show that ZIP7 is necessary for ERAD, which is essential for cell functions such as motility and survival. We propose that Zn^{2+} transport is limiting for ERAD and that ZIP7 gene therapy could ameliorate retinitis pigmentosa due to folding-defective mutations in rhodopsin. We will present progress in elucidating the mechanisms of Zip7 function in maintaining proteostasis, mitigating ER stress, and preventing neurodegeneration *in vivo*.

B592/P2971

Altering PA28gamma expression in 4T1 cancer cells with butyrate

N. Bowman[1], I. Ma[1], N. Saran[1], L. F. Barton[2]; [1]Austin College, Sherman, TX, [2]Biology, Austin College, Sherman, TX.

PA28γ is an ATP and ubiquitin independent proteasome activator overexpressed in many cancers. In normal cells, PA28γ is regulated through AP-1 by p38, a transcriptional activator, and microRNA-7, a translational inhibitor. Both pathways may be deregulated in cancers to impact the expression of PA28γ. One drug treatment that has been used previously to reduce PA28γ expression is sodium butyrate, but the mechanism for reducing PA28γ expression is not understood. Immunoblots and qPCR were used to understand how sodium butyrate impacts PA28γ levels in 4T1 mouse mammary carcinoma cells. Sodium butyrate does reduce PA28γ protein concentration in a dose and time dependent manner. In contrast, *psme3* mRNA levels remained relatively constant, indicating that butyrate treatment is not affecting mRNA synthesis or degradation. These data suggest butyrate is impacting the expression of PA28γ post transcriptionally, but further testing is needed to elucidate the specific mechanism.

B593/P2972

Characterizing the role of the E3 ligase Rsp5 in stress granule clearance

M. K. Rivera, J. R. Buchan; University of Arizona, Tucson, AZ

Stress granules (SGs) are conserved cytoplasmic condensates of non-translating mRNA and associated RNA-binding proteins, whose assembly is induced by the accumulation of non-translating mRNAs during adaptation of cells to stressful environments. While SG assembly is relatively well understood, many

mechanisms including chaperone function, post-translational modifications, proteasomal and autophagic (granulophagy) clearance have been reported. However, the mechanisms, utilization and integration of these clearance pathways is poorly understood, likely impacting post-transcriptional gene expression. Studying SG clearance may aid in furthering our understanding of diseases such as ALS and Cancer, where aberrant persistence of SGs is theorized to contribute to disease pathology. In this work, we performed an unbiased genome wide screen Saccharomyces cerevisiae (budding yeast) to identify regulators of SG clearance via granulophagy. This screen identified several genes involved in Ubiquitin-related factors, including co-factors of the essential E3 ligase Rsp5, known to add K63-linked ubiquitin chains to substrates and facilitates vacuolar/lysosomal trafficking. Using conditional genetics, we find that Rsp5 strongly promotes SG clearance after transient heat shock (HS), but not sodium azide. Currently, we are characterizing if/when Rsp5 colocalizes to SGs during stress or stress recovery. Furthermore, we will purify HS-induced SGs, +/- Rsp5 activity, in efforts to identify Rsp5 interactors and modification substrates that facilitate SG clearance in an unbiased manner. Understanding the role of Rsp5-mediated SG clearance may aid in the development of novel therapeutic, finding alternative solutions to treat related diseases.

Quantitative ubiquitination assays to rapidly design PROTACs and molecular glues

N. A. Warren, K. Wallace, D. Padykula, A. Russell, **J. Pedroza**; LifeSensors, Inc., Malvern, PA

PROTACs have emerged as a new class of drugs that can target the “undruggable” proteome by hijacking the ubiquitin proteasome system. Despite PROTACs’ success, most current PROTACs interface with a limited number of E3 ligases, hindering their expansion into applicable therapeutic uses. Currently, PROTAC drug discovery relies heavily on traditional Western blotting and reporter gene assays which are insensitive and prone to artifacts, respectively. New reliable methods to monitor true PROTAC function (i.e., ubiquitination and subsequent degradation of targets at physiological expression levels) without external tags are essential to accelerate the PROTAC discovery process and to address many unmet therapeutic areas. In this study, we developed a new high-throughput screening technology using “TUBEs” as ubiquitin-binding entities to monitor PROTAC-mediated poly-ubiquitination of native target proteins with exceptional sensitivity. As a proof of concept, targets including BRD3, Aurora A Kinase, and KRAS were used to demonstrate that ubiquitination kinetics can reliably establish the rank order potencies of PROTACs with variable ligands and linkers. PROTAC-treated cell lysates with the highest levels of endogenous target protein ubiquitination - termed “Ub_{Max}” - display excellent correlations with DC_{50} values obtained from traditional Western blots with the added benefits of being high throughput, providing improved sensitivity, and reducing technical errors.

B595/P2974

Expanding Chemical Libraries of E3 Ubiquitin Ligases to Unlock Targeted Protein Degradation

G. Jalagadugula, A. Russell, K. Wallace, J. Pedroza, **A. Haseeb**; LifeSensors, Inc., Malvern, PA

PROteolytic TArgeting Chimeras (PROTACs) have emerged as a new class of drug that can target the “undruggable” proteome to develop novel therapeutics, with specific focus on oncological therapeutics. PROTACs hijack the ubiquitin proteasome system (UPS) to ubiquitinate target proteins and subsequently degrade them in the proteasome. PROTACS are heterobifunctional small molecules with two active domains one binds to target protein and other binds to E3 ligase linked with a linker. The human

genome encodes ~ 600 E3 ligases that differentially expressed across various tissues. Only a few E3 ligases have been utilized to date for PROTAC applications. Expanding the chemical space to recruit largely unexplored E3 ligases can unlock the true potential degraders. This can be designed selectively to target proteins in selective tissues by regulating them under certain conditions, or by inducing specific type of ubiquitination and degradation through proteasome or lysosome. Therefore, identifying novel ligands for E3 ligases that perform non-degradative function can broaden the applicability in drug discovery. LifeSensors has developed technologies to identify novel ligands for E3 ligases that can recruit ligases to degrade undruggable proteome. In the current study, LifeSensors will highlight multiple approaches to identify novel ligands, and validate them to demonstrate their selectivity and applicability for target protein degradation (TPD).

Novel Exosome-based Platform for Rapid Production of Nano-vaccines with Enhanced Safety, Efficacy and Precision

J. Ku, R. A. Flojo, G. Chen, C. Olson, B. Lu; Santa Clara University, Santa Clara, CA.

Background: Technical advancements in bioinformatics, synthetic biology and surface display technology have opened new avenues for a rapid production of exosome-based nanovaccine with enhanced safety, efficacy and precision [1-3]. **Methods**: Using a combination of computational analysis, synthetic biology and exosome surface display technology [2-3], we designed and produced engineered exosome-based vaccines that display highly selective epitopes derived from the full-length antigens. **Results**: We initially developed a computational software and successfully used it to identify, extract and assemble highly immunogenic epitopes from both virus and cancer antigens. We then demonstrated that this software tool was able to condense highly immunogenic epitopes by removing low immunogenic segments from inclusion. We subsequently used DNA synthesis and gene cloning methods to incorporate these epitopes into an exosome-targeting scaffold, and successfully constructed a series of mammalian expression vectors. Finally, by transfecting these vectors into cultured human 293T cells, we were able to produce engineered exosomes that displayed the highly selective epitopes on their outer surface of secreted exosomes, therefore validating the vaccine production system.**Conclusion:** We have developed and validated a novel exosome-based platform that enables a rapid production of surface-displayed nanovaccine with improved safety, efficacy and precision.

Bacterial cell size and growth regulation in fluctuating nutrient environments

J. C. Kratz[1], S. Banerjee[2]; [1]Biological Sciences, Carnegie Mellon University, Pittsburgh, PA, [2]Physics, Carnegie Mellon University, Pittsburgh, PA.

Bacteria dynamically regulate cell size and growth rate to thrive in changing environments. Previous work has found that bacterial cell size is coupled to nutrient-specific growth rate at steady-state, and that bacteria remodel their proteome in different environments to increase fitness. However, a mechanistic understanding of how bacteria dynamically regulate cell size and growth physiology in time-varying nutrient environments is lacking. We have developed a mathematical model based on cellular proteome allocation that accurately predicts *E. coli* cell size and growth rate control in response to nutrient shifts in both exponential and stationary phase. The model utilizes a threshold accumulation framework for cell division control, in which cells divide after accumulating a set amount of division proteins, and connects growth rate and division protein production rate to proteome allocation in time-varying environments. In response to pulsatile nutrient concentration, our model predicts that during upshift, *E. coli* transiently prioritize biomass accumulation and ribosome production over production of cell division machinery. This results in a rapid increase in single-cell growth rate, and a temporary overshoot in intergenerational added volume, leading to an increase in average cell size. Surprisingly, our model predicts the opposite behavior during downshift, namely that bacteria prioritize division over growth, despite needing to upregulate costly division machinery and increasing population size when nutrients are scarce. The transient upregulation of division protein production results in rapid cell division without biomass accumulation, leading to a sharp decrease in cell size, but a rapid increase in population growth rate. Importantly, we also find that both growth rate and cell size stabilization time after nutrient pulse is dependent on the pulse duration. Specifically, stabilization time increases with increasing nutrient pulse length until saturating at a constant stabilization time. Our model suggests that this transient memory of previous environments is a result of slow dynamics of proteome reallocation, and can confer increased fitness in fluctuating environments.

B599/P2977

Emergent dynamics and force generation in motor-free active contractile networks (Experiment)

X. Lei[1], T. Chakrabortty[1], J. Honts[2], S. Bhamla[1]; [1]Georgia Institute of technology, Atlanta, GA, [2]Drake Univeristy, Des moines, IA.

Living cells exploit contractile structures in the cytoskeleton to achieve various functions such as cell division and motility. Here we show in experimental and computational studies on a Ca^{2+}-triggered contractile cytoskeletal network composed of cortical proteins from ciliates (Tetrahymena). Our results demonstrate that this Ca^{2+}-triggered network exhibits viscoelastic behaviors that, under certain conditions, can be reversed. We propose a unifying phase diagram for these calcium-driven contractile dynamics. From simulations, we find that the difference in the molecular dynamics between the phases, such as diffusion coefficients, controls the network's morphology and contractility. Based on the simulation result, we created a new phase, experimentally combing the contractility and maintaining the micro-structure by pulsating energy input. We demonstrate how this viscoelastic system can be useful in generating controlled active forces and could have potential in an artificial cytoskeletal network in synthetic cells.

Determining the neural circuits underlying female aggression in Drosophila

K. M. Martinez, I. J. Santiago, S. Sengupta, C. B. Palavicino-Maggio; Basic Neuroscience Divison, McLean Hospital, Belmont, MA.

Aggression is an intrinsic behavior that aids in defense, resources, and survival. The fruit fly, *Drosophila melanogaster*, is an excellent model for studying neural circuits. While both males and females elicit aggression, female aggression research has received less attention. Previously, our work in *Drosophila* identified a female-specific subgroup of cells in the pC1 brain region, known as pC1α neurons. Activation of pC1α neurons triggered female flies to fight at high-intensity levels. With this observance, our aim was to identify the neuronal clusters that relay sensory information to the pC1α neurons and ultimately lead to the activation of the female high aggression circuitry. To build on the circuitry of the pC1α neurons, our lab used an available electron microscopy database of the adult female fruit fly brain (FAFB). Our tracings revealed that pC1α neurons are morphologically distinct and present in both hemispheres of the female brain and are comprised of five neurons (pC1a-e). It also revealed interconnectivity between five subtypes. In general, pC1α neurons exhibited interconnectivity within the hemisphere (ipsilateral) and between hemispheres (contralateral). Interestingly, we uncovered several asymmetries in connectivity between and within the right and left hemispheres. We determined that pC1α neurons in the right hemisphere exhibit interconnectivity, while those in the left hemisphere do not. Additionally, we found more contralateral connections from left to right (207) than right to left (50). We also searched for non- pC1α neurons that send presynaptic inputs into the pC1α population. One major input contributor and presynaptic partner, the SMP093 L/R neurons, is in the superior medial protocerebrum (SMP) area, which is involved in circadian rhythm, feeding, and courting behavior. SMP093 showed a great deal of projections onto the left and right pC1α neurons indicating inputs not only bilaterally (L>R:263; R>L:157) but having interconnectivity (L>L: 163; R>R:387). Although it was examined that the left had limited interconnectivity, SMP093 L/R showed strong projections to those left pC1α neurons (320). We thus hypothesize that neurons found in the SMP region play a vital role in the circuitry of female aggression. Since pC1α neurons are only found in females, understanding how the circuitry behind fruit fly aggression works can be used to find new principles of how a sexually dimorphic brain works. In addition, this model might serve as a foundation for the development of therapeutic targets that can ameliorate aggression and behavioral abnormalities observed in psychiatric and neurodegenerative illnesses.

Uncovering principles of cell organization using soft X-ray tomography and whole-cell integrated modeling of inter-organelle spatial relationships and physical interactions in *S. cerevisiae*

M. Mirvis, W. F. Marshall; Biochemistry & Biophysics, University of California, San Francisco, San Francisco, CA.

Cell organization - the cumulative morphology and relative arrangement of subcellular structures - forms distinct spatio-geometric patterns. Establishing causative links between cell organization and function is a major goal of cell biology. Robust methods are needed to define cell organization and distinguish organization of healthy cells from disorganization in stress and disease. Mesoscale cell organization arises from interactions between organelles. While the biochemical basis of organelle interactions has been well-studied, the role of physical interactions, such as packing, is poorly understood. To what

extent is cell organization a reflection of organelle confinement within the limited space of the crowded cytoplasm? We are developing a whole-cell integrated modeling approach to quantify the key constraints and variations in cell organization based on organelle physical and spatial relationships in *S. cerevisiae.* Adapting an approach developed by the Allen Institute (Viana, *et al*, doi: 10.1101/2020.12.08.415562), we perform single-cell and -organelle 3D morphometrics and spherical harmonic shape modeling from volumetric imaging. This generates a shape space for each structure, and integration of cell, nucleus, and vacuole shapes produces an "average cell" and a range of variant configurations. Sampling variation along various axes in the dimensionally-reduced shape space identifies principal components. A preliminary model based on a small confocal microscopy dataset suggests that cell volume, organelle-cell and inter-organelle scaling, and position are candidate top contributors to organizational variation, with a larger contribution by the vacuole than the nucleus. For higher spatial resolution and statistical power, we collected a dataset of 200-300 wild-type cells imaged with isotropic nanometer resolution by soft X-ray tomography in collaboration with the National Center for X-ray Tomography. Morphometric analysis of organelle volume and shape correlations indicates differential relative scaling patterns among organelles, and suggests asymmetric deformations due to vacuole-nucleus packing. Integrated shape modeling and analyses of co-varying geometric features in interacting organelle pairs are currently being developed. Future work will include comparative analysis between WT and large-vacuole mutants, characterizing physical packing relationships based on correlated morphological changes between the enlarged vacuole and neighboring organelles. This work will ultimately aim to quantify the magnitude of disorganization in a highly packed cytoplasm and characterize the impacts of shifting morphological and physical interdependencies between interacting organelles on global cell organization.

Synthesis, characterization, and cellular imaging of a novel cyan emitting fluorescent α-amino acid

A. Gupta, B. Yan, M. Guo; Department of Chemistry and Biochemistry, University of Massachusetts Dartmouth, Dartmouth, MA.

The development of microscopy and fluorescent-based approaches to tag proteins have been advancing the fields of cellular and molecular biology, biotechnology, and medicine. Among others, small molecule-based approaches like incorporation of fluorescent unnatural α-amino acids (FAA) into proteins have been of particular interest to study protein interactions with other biomolecules, protein dynamics, and in live-cell imaging. The wide range of applications have attracted much scientific research interests. Here, we report the synthesis of a novel fluorescent α-amino acid 4-dibenzothiophen-4-yl-L-phenylalanine (DBT-FAA) capable of emitting cyan light in the visible region using optimized Suzuki cross-coupling reaction methodology in a reasonably good yield. The synthesized FAA has emission signals at ~440 nm, ~480 nm and ~540 nm with a tail extended beyond 600 nm. Upon incubation in Hela cells, the DBT-FAA at 10 μM gives strong fluorescent signals (upon 405 nm laser excitation) in cytosol. The cells remain viable with normal morphology with up to 50 μM DBT-FAA, suggesting no or very minimal toxicity of the novel fluorescent amino acid. It has high quantum yield (0.74) and is photostable as studied through a series of 100 fluorescence spectra for 5 hours in aqueous condition. These data indicate that DBT-FAA is biocompatible for imaging in live-cell. Being an *L*-α-amino acid, DBT-FAA may be utilized to site-specifically incorporate into peptides and proteins to unravel the biological processes for broader applications in therapeutics and biochemical research. We thank the NIH for funding this project.

Computational Strategies for the Identification of a Robust Transcriptional Biomarkers Panel to Sense Multi-Stress States in *Bacillus subtilis*

Y. Huang[1], W. Smith[1], C. Harwood[1], N. Sinha[2], A. Wipat[1], J. Bacardit[1]; [1]Newcastle University, Newcastle upon Tyne, UNITED KINGDOM, [2]University of Pennsylvania, Philadelphia, PA.

Objective: One challenge in the engineering of biological systems is to be able to recognise the cellular stress states of bacterial hosts, as these stress states can lead to suboptimal growth and lower yields of target products. Our current knowledge of how different environmental treatments modulate gene regulation and bring about physiology adaptations is limited, and hence it is difficult to determine the mechanisms that lead to their effects. To enable the design of genetic circuits for reporting or mitigating the stress states, our study aimed to identify a relatively reduced set of gene biomarkers that can reliably indicate relevant cellular growth states in bacteria. Methods: We analysed transcriptome data for *Bacillus subtilis* which reveals patterns of gene expression of 269 samples grown in 104 different conditions. We proposed a pipeline of computational methods for the selection of a robust multi-stress states sensing biomarker panel: a) an unsupervised machine learning approach to extract clusters of samples with differentiated gene expression profiles; b) a feature selection model to identify biomarker genes that can predict different cellular growth states; c) a recommendation system incorporating complementary information from machine learning model, gene regulatory network and co-expression network to prioritise a robust biomarker panel with best predicted multi-stress states sensing power.Results: We revealed 10 clusters of samples that can be characterised as different cellular growth states and 949 panels of biomarker genes can indicate the cellular state. We identified a biomarker panel consisting of 10 genes with various functions corresponding to DNA repair, endopeptidase activity, the synthesis of essential proteins, etc. This biomarker panel showed great predicative performance in sensing a variety of stress states from the dataset used for biomarker identification as well as extended stress states from 9 independent datasets (average f1-score achieved at 0.99 and 0.98 respectively).Conclusion: The computational strategies introduced in our study has the potential for recognising biomarkers that show great sensitivity and robustness to a wide range of cellular stress states, enabling the implementation of a stress sensing system that can monitor the growth and stress state for bacteria host in biotechnology applications.

The novel PAICE Suite reveals circadian timing of non-coding RNAs and the spliceosome components, indicating multiple levels of clock control in the post-transcriptional regulation of macrophages

S. Buel; Rensselaer Polytechnic, Troy, NY.

Background/ObjectivesThe innate immune system is the body's first line of defense against foreign pathogens. One of the cell types of interest in this system is the macrophage, for its ability to phagocytize and clear the area of pathogens, activate the adaptive immune system, and release cytokines which activate other immune cells. Macrophages are tightly regulated on many levels to ensure appropriate responses to foreign pathogens, with one of these layers being circadian rhythms (Keller 2009). In a circadian time course in *M. musculus* macrophages, Collins et. al (2021) determined

that the clock controls expression of 15% of the transcriptome and 29% of the proteome. However, there is only a 250-gene overlap in the circadian transcripts which are translated into circadian proteins, predicting a high level of post-transcriptional regulation by the clock. Using these comprehensive RNAseq and proteomic data sets (Collins 2021), we aimed to uncover these clock-controlled post-transcriptional mechanisms, particularly in the non-coding transcriptome and the spliceosome pathway.
Methods/ResultsUtilizing the PAICE suite to analyze the RNAseq and proteomics circadian time series data of *M. musculus* macrophages published by Collins et. al (2021), we found that, lncRNAs were enriched in circadian oscillations relative to the detectable non-coding transcriptome. Importantly, LncRNAs can bind to and regulate classes of DNA, RNA, and protein, and control expression and binding of genes (Statello, 2021). Additionally, we observed oscillations in the coding mRNA (89%), non-coding snRNA (15.6%), and proteins (37.5%) of the spliceosome machinery, indicating robustness in the clock's ability to control splicing events, suggesting a further mechanism of circadian post-transcriptional regulation. ENCORE's ontological analysis resolved that the overall proteome displayed damped waveforms, including immune pathways. Joint modeling of the transcriptome and proteome using MOSAIC improved upon ECHO's analyses, identifying more circadian transcripts and proteins than previously reported by Collins et. al (2021).
Conclusions
Using the PAICE suite of programs, we discovered previously unrecognized clock-controlled post-transcriptional regulation mechanisms at the level of the spliceosome and non-coding snRNA and lncRNA in macrophages.

MinDE bacterial reaction-diffusion system generates synthetic spatiotemporal protein patterns in metazoan cells

R. Rajasekaran, S. Coyle; University of Wisconsin–Madison, Madison, WI.

Cells are molecular systems that use spatiotemporal patterns of biochemical activities to perform complex biological tasks. Thus, artificial systems that generate self-organizing subcellular protein patterns could enable novel cell morphologies, signal processing, or biological activities to be engineered. However, few synthetic biology tools exist that can perform these functions. Here, we repurpose the bacterial Min system as an orthogonal general-purpose spatiotemporal signaling node in metazoan cells. In bacteria, MinD and MinE proteins undergo pole-to-pole membrane oscillations to specify the midpoint of the cell; *in vitro*, these two proteins are sufficient to form a broad range of dynamic and stationary reaction-diffusion patterns on lipid bilayers. We demonstrate that the Min system can self-organize into synthetic oscillations, traveling waves, and stable sub-cellular patterns when expressed in metazoan cells. We have developed analytical workflows to quantitatively characterize reaction-diffusion phenomena across thousands of cells to identify trends that relate biochemical parameters to the frequency, power, and phase structure of patterning behavior. This allowed us to harness the orthogonality of MinDE circuits in metazoan cells to design artificial signaling networks that can interact with and regulate host-cell biology: MinDE circuits that react to host-cell biological processes enable dynamic encoding and amplification of real time cell-state information into MinDE reaction-diffusion behavior; MinDE circuits that regulate host-cell signaling can artificially drive subcellular protein activity to the synthetic patterns we genetically encode. By developing tools that can program dynamic protein distributions and biological activities within the cell, our work will establish a new class of strategies for cellular engineering in metazoans.

B606/P2984

Coordination of p53 and MAPK dynamics controls heterogeneous responses to genotoxic agents in single cells

R. Hanson, **E. Batchelor**; Department of Integrative Biology and Physiology, University of Minnesota, Minneapolis, MN.

Heterogeneous cellular responses to chemotherapy are a significant obstacle in cancer treatment. One source of such heterogeneity is variability in the temporal expression and activity of key signal transduction pathways that detect cell stresses and coordinate appropriate responses in individual cells. We have shown that variable p53 expression dynamics can generate distinct cellular responses to genotoxic agents. However, in some cases distinct stresses can generate the same p53 dynamics but different cell fate outcomes, suggesting integration of dynamic information from other pathways is important for cell fate regulation. We focused on pancreatic cells and quantified the dynamics of p53 and the MAPKs, signaling systems frequently mutated in pancreatic cancer. To determine how MAPK activities affect p53-mediated responses to DNA double strand breaks and oxidative stress, we used time-lapse microscopy to simultaneously track p53 and ERK, JNK, or p38 MAPK activities in single cells. While p53 dynamics were comparable between the stresses, cell fate outcomes were distinct. Combining MAPK dynamics with p53 dynamics was important for distinguishing between the stresses and for generating temporal ordering of downstream cell fate pathways. Cross-talk between MAPKs and p53 controlled the balance between proliferation and cell death. These findings provide insight into how individual cells integrate signaling information from separate pathways with distinct temporal patterns of activity to encode stress specificity and drive heterogeneous cell fate decisions. Furthermore, our results identify timing windows during which combination drug treatments can effectively alter cell fate responses to genotoxic agents.

Early and late IFNγ-responsive genes decode dynamic IFNγ stimulus in opposing ways in macrophages

B. Naigles[1], A. Narla[2], N. Hao[1]; [1]School of Biological Sciences, University of California, San Diego, La Jolla, CA, [2]Department of Physics, University of California, San Diego, La Jolla, CA.

It is essential for innate immune cells to respond appropriately to pathogens and other pro-inflammatory stimuli so that they exhibit the appropriate functional outcome to a given stimulus and neither under-, over-, or mis-react. One way in which inflammatory stimuli can vary is in their dynamics - that is, the amplitude and duration of stimulus experienced by the cell. In this study, we investigate how macrophages respond to dynamic interferon-gamma (IFNγ) stimulus. *In vivo*, macrophages experience IFNγ stimulus during both the innate and adaptive immune responses, and IFNγ induces pro-inflammatory gene expression and diverse functional outcomes, including the secretion of cytokines and chemokines. We specifically use long-term live-cell imaging in a microfluidic device to investigate how the genes IRF1, CXCL10, and CXCL9 respond to dynamic patterns of IFNγ stimulus. To do this, we use a mouse macrophage cell line with endogenous fluorescent reporters for IRF1, CXCL10, and CXCL9. IRF1 is an early-responding gene encoding a transcription factor for large portions of the downstream pro-inflammatory gene expression response. CXCL10 and CXCL9 are later-responding genes and encode chemokines that recruit T cells to further amplify the immune response. We find that IRF1 responds to low amplitude or short duration stimulus, while CXCL10 and CXCL9 require longer or higher-amplitude

stimulus to be expressed. We also investigate the heterogeneity in each gene, finding that CXCL10 has very high cell-to-cell variability and that this heterogeneity appears to be largely stochastic across all dynamic conditions and does not correlate with response amplitude. CXCL9 and IRF1 are more homogenous. We additionally perturb the response with inhibitors of chromatin regulators and find that inhibiting p300 delays CXCL10 gene expression but does not affect the cell-to-cell variability. We develop an ordinary differential equation model to capture the response of each gene to the dynamic IFNγ stimulus. We conclude that these three genes in the same signaling pathway respond to dynamic IFNγ stimulus with very different response features, including different levels of heterogeneity. This implies that each gene is employing a different strategy to decode dynamic IFNγ stimulus so that they each exhibit appropriate expression for the cell's functional outcomes downstream of each stimulus pattern.

Local and global control of protein synthesis in a syncytium

A. P. Jalihal[1], C. M. Chai[2], S. Quinodoz[3], A. S. Gladfelter[1]; [1]University of North Carolina, Chapel Hill, NC, [2]HHMI Janelia Research Campus, Ashburn, VA, [3]Princeton University, Princeton, NJ.

Multinucleate "syncytial" cells are found widely across all eukaryotic kingdoms, notably in filamentous fungi and mammalian tissues like placenta and muscle. It is unknown what mechanisms allow nuclei in syncytia to collaboratively build these large and spatially complex cells. Previous work in the Gladfelter lab has demonstrated that neighboring nuclei in the multinucleate fungus *Ashbya gossypii* show high degrees of heterogeneity in gene expression and timing of nuclear division despite sharing a common cytoplasm. This suggests that the cytosol in these cells is composed of compositionally and functionally heterogeneous nuclear "territories" that regulate local cytoplasmic function. However, these locally autonomous nuclei must also coordinate across the cell to ensure integrated mycelial growth. The goal of this work is to dissect the basis of local and global coupling of the cell cycle to growth in a large syncytium.

It is known from prior work on large cells such as neurons that local compositional variability can be achieved via differences in local translation. We investigated the role of spatial variation in protein synthesis in shaping variable cytosolic territories. We first investigated spatial differences in mRNA translation using a fluorescence in situ hybridization (FISH) based approach that monitors translating mRNAs, which revealed heterogeneity in nuclear-proximal translation of cell-cycle transcripts. This indicates local translation is likely an element of asynchronous nuclear division. We hypothesized one basis for this difference in translation may be variable ribosome production between nuclei. Probing ribosome production via metabolic labeling of rRNAs in *Ashbya* revealed a high degree of inter-nuclear variability in rRNA output. Together, these lines of evidence suggest that local differences in protein synthesis may strongly influence local cytosolic composition over the micron scale and these may be accentuated by differences in ribosomal output. We next asked how overall mycelial growth is maintained despite variability in local translation. Mathematical modeling of ribosomal diffusion suggested that hyphal-scale (100s of microns) ribosomal concentrations may be buffered despite local inter-nuclear (5 microns) variation in rRNA production. Overall, this work provides insight into how length-scale dependent cytosolic function can emerge from differences ribosome production and activity in syncytial cells.

Structure and mechanism of key enzymes involved in*M. tuberculosis*GDP-Heptose biosynthetic pathway: potential drug targets

S. Karan, **A. Saxena, Male**; School of Life Sciences, Jawaharlal Nehru University, New Delhi, INDIA.

D-α-D-Heptose is the fundamental constituent in the S layer or the capsular polysaccharide ofmycobacteria. Incorporation of D-α-D-heptose in arabinogalactan layer is crucial for themaintenance of mycobacterial cell wall. Hence, complete elucidation of the nucleotide activatedD-α-D heptose pathway will be critical to understand the biosynthetic mechanism and willcontribute in drug development against *M. tuberculosis.*The D-α-D heptose in *M. tuberculosis* is produced in four steps, (i) isomerization of S7P to M7P byGmhA isomerase (ii) phosphorylation at C1 position of D-glycero-D-manno- heptose-7 phosphate byHddA kinase (iii) Dephospho -rylation at C7 position of D-glycero-D-manno-heptose-1,7 bisphosphateby GmhB phosphatase and (iv) activation of D-glycero-D-manno-heptose-1 phosphate by HddCguanylyl-transferase to produce GDP-D-glycero-D-manno heptose.In current project, we have identified the substrate binding mechanism and low-resolution structures of allkey enzymes, *Mtb*GmhA, *Mtb*HddA, *Mtb*GmhB involved in this pathway using biochemical, SAXS anddynamics simulation techniques. Based on discovered mechanism, we are developing specific inhibitorsand will test *in vitro* and *in vivo* assays to determine clinical efficacy of these compounds. Gene expression noise accelerates the evolution of biological oscillators

Y. Lin[1], **N. Buchler**[2]; [1]Information Sciences Group (CCS-3), Los Alamos National Laboratory, Los Alamos, NM, [2]Molecular Biomedical Sciences, North Carolina State University, Raleigh, NC.

Gene expression is a biochemical process, where stochastic binding and un-binding events naturally generate fluctuations and cell-to-cell variability in gene dynamics. These fluctuations typically have destructive consequences for proper biological dynamics and function (e.g., loss of timing and synchrony in biological oscillators). Here, we show that gene expression noise counter-intuitively accelerates the evolution of a biological oscillator and, thus, can impart a benefit to living organisms. We used computer simulations to evolve two mechanistic models of a biological oscillator at different levels of gene expression noise. We first show that gene expression noise induces oscillatory-like dynamics in regions of parameter space that cannot oscillate in the absence of noise. We then demonstrate that these noise-induced oscillations generate a fitness landscape whose gradient robustly and quickly guides evolution by mutation towards robust and self-sustaining oscillation. These results suggest that noise helps dynamical systems evolve or learn new behavior by revealing cryptic dynamic phenotypes outside the bifurcation point.

Exploring Forces During Hybrid Collective Cell Migration Using Synthetic Magnetic Cells (syMcells)

J. A. De Lora, 1, L. Motyckova, S. Pashapour, P. Fischer, I. Platzman, J. Spatz; Max Planck Institute for Medical Research, Heidelberg, Germany

The functioning of synthetic cells that are designed to execute predetermined biophysical tasks could be directly evaluated by interfacing with natural cells. This biophysical approach would validate built-in operations such as synthetic cell-natural cell adhesion interactions. It follows that hybrid cultures may, in the least confirm task achievement or, at the most trigger unpredicted emergent properties. In this work, a hybrid cell migration system that emulates E-cadherin-mediated cellular adhesions is built while implementing remote control of synthetic cells using magnetic fields. SyMcells are established using an emulsion to create a lipid-derived chassis that encapsulates magnetic cytoplasm comprising an oil-based ferrofluid. SyMcells are then functionalized with recombinant E-cadherin proteins by polyhistidine-Ni-NTA complexation. Finally, syMcells are cultured with natural cells genetically engineered to express E-cadherin-EGFP and within confinement chambers. Upon releasing the hybrid cultures from confinement, hybrid cell migration dynamics are observed by time-lapse, traction force, and monolayer stress microscopy. Parameters such as cell migration velocity, E-cadherin clustering, actin cytoskeleton organization, and traction fields are measured as a function of the presence/manipulation of syMcells. The morphologies of syMcells are actuated during the observation period by applying a homogeneous electromagnetic field from our custom-built microscope. We use this system to investigate the manipulation of hybrid cell migration characteristics including to gauge forces within migrating monolayer hybrid cultures and in the future to control leader *vs* follower phenotypes.

Establishing measures for 'Innate Morphological Heterogeneity' in cell cultures

P. Pragya, A. Mittal[,1]; IIT Delhi, Delhi, India

Observations of asymmetries within cell populations, and within single cells, with respect to variables such as protein expression(s), cellular polarity (e.g., apical or basolateral) etc. continue to assist in better understanding of architecture-defined-functionalities in living cells. The concept of 'average phenotype' of a cell population, a supposed representative of a cell population based on assumption of the cells being similar (oblivious to deviations as noise/cell-culture-artifacts), is in contrast to an increasing appreciation for existence of heterogeneity amongst cells. This heterogeneity, resulting-from/in-form-of genetic/phenotypic/morphological variations, can be explored using various assays coupled with single-cell imaging techniques in cell cultures. In this work, we explicitly quantitate 'innate morphological heterogeneity' (IMH) in cell cultures by rigorous quantitative analyses of bright field image data, along with image data of fluorescently labelled subcellular organelles/features (e.g., nucleus, plasma membrane, tubulin, actin, lysosomes, endoplasmic reticulum and mitochondria) at a single-cell level for cell cultures of some common cell lines (RAW264.7, HeLa and Hek293T), acquired using a confocal microscope. We report cellular-density-based IMH in three-dimensional (3D) space for adherent cell cultures, i.e., in terms of X-Y, Y-Z and X-Z planes from bright field images. Similarly, we report fluorescence-based IMH at subcellular levels in 3D. We discuss the importance of our findings in the context of apical/basolateral asymmetries, and other aspects of cellular polarities, reported in literature pertaining to cell physiology. Representation of IMH for RAW264.7 cells (and their nuclei), in form of distribution of Average Pixel Values (APVs) per plane for each of the X-Y-Z axes along with Total Pixel

Number (TPN) for each of the octants in a 3D cartesian system, show a remarkable alteration in distributions of pixel intensities and inferred cellular polarities upon synchronization of cell cultures using thymidine and nocodazole treatment. Our results highlight possibly important "diagnostic" applications of IMH in general cell biology, which may not be limited to comparing non-synchronized (regular-passaged) and synchronized cells but also useful in investigations of other environmental/experimental cell culture variations.

A modular, deep learning-based analysis framework for high resolution 3D timelapse imaging of cells and nuclei in hiPSC colonies

B. Morris, .. Allen Institute for Cell Science, S. M. Rafelski; Allen Institute for Cell Science, Seattle, WA.

The Allen Institute for Cell Science (allencell.org) aims to understand the principles by which human induced pluripotent stem cells (hiPSCs) establish and maintain cellular organization, and how they transition between states during differentiation and disease. To this end, here we aim to characterize and understand how cell and nuclear size and shape behave over the course of a cell cycle. This requires high-resolution 3D movies and accurate determination of the cell and nuclear boundaries via segmentation within the same cell. However, high resolution imaging in 3D (e.g. 100x/1.25 NA) has many limitations such as high levels of phototoxicity and small fields of view that make imaging and tracking cells over long time periods difficult. To overcome these difficulties, we imaged colonies of hiPSCs expressing mTagRFP-t-CAAX (i.e. fluorescently labeled plasma membrane) in 3D for two days at five minute intervals at low magnification and resolution (20x/0.8NA). We developed deep-learning-based image processing modules to obtain accurate 3D cell and nuclear boundaries necessary for shape analysis and tracking. First, our transfer function module is used to generate predicted images of high magnification and resolution (100x/1.25 NA) from 20x images of cells expressing mTagRFP-t-CAAX. Next, a label-free module is employed to predict the nuclear boundary from bright-field images of cells expressing fluorescently tagged lamin B1 (demarcating the nuclear envelope). Then, semantic and instance segmentation modules are used to generate accurate 3D cell and nuclear segmentations, which a tracking module uses to track nuclei and cells over time. Finally, a time-point classifier module is used to identify cell division events. Each step in this pipeline is validated using metrics relevant to the downstream use of the data. For example, if the ultimate use of the segmented tracks is to examine nuclear and cellular shape over time, stepwise validation can consist of comparing the shape descriptors between segmentations of the real and model-predicted images. To make the data processing fully automated, scalable, and easily reproducible, these modules are linked using Snakemake, a Python-based workflow manager. The resulting dataset from a single colony movie consists of tracks of hundreds of cells and nuclei that can be temporally aligned for data analysis.

Recent Deep Learning Studies for Microfluidics Assays of Yeast Lifespan

H. Qin[1], M. Ghafari[2], W. Dang[3]; [1]University of Tennessee At Chattanooga, Chattanooga, TN, [2]Sanford Burnham Prebys Medical Discovery, San Diego, CA, [3]Baylor College of Medicine, Houston, TX

We wish to highlight our deep learning methods to facilitate the microfluidic-based high throughput assay of the replicative life spans of the budding yeast [1-3]. The budding yeast is a proven model of cellular aging and has revealed many longevity-related genes with conserved roles in eukaryotic cells.

Microfluidics-based assays have become an effective way to monitor the aging process for a large number of cells, resulting in hundreds of time-lapse microscopic images. We are the first groups to demonstrate that the deep learning method can accurately classify cell division events. We developed a maximal likelihood approach to infer the cell family tree and cell lineages. We showed that YOLO and Mask-RCNN are complementary for cell object detections. We will compare our results with two other groups. Overall, it is promising that deep learning methods could potentially transform cellular aging research.

B615/P2993

Endogenous tagging for the intra-cellular cartography of the human proteome

S. Vaid[1], M. Vangipuram[1], K. C. Cheveralls[1], K. Kim[1], H. Kobayashi[1], L. A. Royer[1], M. Mann[2], M. D. Leonetti[1]; [1]Chan Zuckerberg Biohub, San Francisco, CA, [2]Max Planck Institute for Biochemistry, Martinsried, Germany

Elucidating the wiring diagram of the human cell is a central goal of the post-genomic era. Here, we combined fluorescent CRISPR tagging, confocal live-cell imaging, mass spectrometry, and data science to systematically map the localization and interactions of human proteins. Our approach provides a data-driven description of the molecular and spatial networks that organize the proteome. Unsupervised clustering of these networks delineates functional communities that facilitate biological discovery. We found that remarkably precise functional information can be derived from protein localization patterns, which often contain enough information to identify molecular interactions, and that RNA binding proteins form a specific subgroup defined by unique interaction and localization properties. Paired with a fully interactive website (opencell.czbiohub.org), our work constitutes a resource for the quantitative cartography of human cellular organization.

B616/P2994

Nuclear-cytoplasmic compartmentalization of cyclin B1-Cdk1 promotes robust timing ofmitotic events

G. Maryu, Q. Yang; University of Michigan, Ann Arbor, MI

The cyclin-dependent kinase (Cdk1) oscillator is widely characterized in homogenized cytosolic extracts, leaving unclear the impact of nucleocytoplasmic compartmentalization. Here, by developing a Förster (or fluorescence) resonance energy transfer (FRET) biosensor, we track Cdk1 spatiotemporal dynamics in reconstituted nucleus-present and nucleus-absent cells side-by-side and find compartmentalization significantly modulates clock properties previously reported in bulk studies. While nucleus-absent cells display highly tunable frequency, the nucleus-present cells maintain constant frequency against cyclin variations. Despite the high expression variability, all cyclin proteins degrade within the same mitotic duration, further ensuring robust timing. Moreover, Cdk1 and cyclin B1 cycle rigorously out-of-phase, producing wide phase-plane orbits, essential for oscillation robustness. Although homogenized Cdk1 is well-known for delayed spiky activation, we found steady nuclear accumulation of activated cyclin B1-Cdk1 until the nuclear envelope breakdown (NEB) before another abrupt activation to trigger anaphase. Cdk1 biphasic activation and spatial compartmentalization may together coordinate the accurate ordering of different downstream events.

B617/P2995

How to visualize weird multidimensional infection data.

D. Schneider; Stanford University, Stanford, CA

All our our science communications are metaphorical and we limit ourselves to a small set of these metaphors. This helps us communicate, but are we missing something? Would it be useful if we tried new metaphors? Are there some problems that are not solvable using one set of metaphors, but the solution becomes obvious when you look at the problem in a different way? I started using playful artistic ways of describing my data when I felt that my audiences seemed to be missing my point. I find these visualizations useful in a couple of ways: First, they help me think about things differently and can point to answers that aren't obvious from all points of view. Second, they help me talk about my science to people who aren't in my head. I'll be sharing both successful and unsuccessful attempts and creative data visualization and talk about what insight it can provide.

Engineering Tissue and Scaffold Models

Generating a Perfusable Vascularized Cerebral Organoid Model

E. LaMontagne[1], L. J. Macdougall[2], F. Papes[3], E. L. Teng[1], J. Mayner[1], B. P. Sutherland[4], K. S. Anseth[2], A. M. Kloxin[4], A. R. Muotri[3], A. J. Engler[1]; [1]Bioengineering, University of California, San Diego, La Jolla, CA, [2]Chemical & Biological Engineering, University of Colorado, Boulder, Boulder, CO, [3]Pediatrics, University of California, San Diego, La Jolla, CA, [4]Chemical & Biomolecular Engineering, University of Delaware, Newark, DE.

Although brain organoids have advanced our understanding of the human brain, their growth, cellular complexity, and functionality are limited by the absence of vasculature. Current organoid vascularization efforts rely on either: (1) the *in situ* formation of neo-vessels in endothelial co-cultures, or (2) microfluidics channels that flow adjacent to organoids. Neither produces vasculature that resembles native cerebral vessels. We hypothesize that a system in which patent vessels form throughout the organoid as it matures will enable organoid growth beyond the diffusion limit of oxygen and promote the formation of more complex cerebral structures. To fabricate this system, we first developed a microfluidic device containing posts onto which a fiber scaffold is woven in a lattice resembling the cerebral vascular network. Photodegradable fibers are formed by extruding and crosslinking a solution of two multi-arm polyethylene glycol (PEG) components that contain allyl sulfide to facilitate degradation via radical addition. Brain organoids that we have generated from pluripotent stem cells (PSCs) are to be placed within the woven fiber network when at the neuroprogenitor cell (NPC) stage so that they grow around fibers as they enlarge. Upon radical addition, the polymer scaffold will solubilize and provide the framework for a continuous, hollow lumen that will be seeded with PSC-derived endothelial cells to generate vasculature. The microfluidic channels are perfusable at high flow rates and produce low wall shear stresses, confirmed using computational physics models. Photodegradable PEG fibers can be extruded, woven into a scaffold, and degraded via 365nm, 5mW/cm^2 light in under 5 minutes. All components of the sacrificial scaffold are biocompatible with brain organoids. Future experiments include the fabrication of multielectrode arrays to stimulate and read electrical activity of the organoids, long-term perfusion at varying shear stresses, and single-cell RNA sequencing analysis to evaluate maturation markers. To our knowledge, this will be the first vascularized brain organoid model

with highly integrated vasculature that can be perfused over long periods of time. This will generate opportunities to study neurovascular development, brain cancers, or other neurological conditions affecting vasculature using a completely human and *in vitro* system.

DNA-programmed tissue patterning and controlled cell-cell interactions on hydrogel substrates

L. S. Prahl, C. M. Porter, A. J. Hughes; University of Pennsylvania, Philadelphia, PA.

Replicating the organizational principles that establish fine scale tissue structure - such as epithelial-mesenchymal interfaces and compartment boundaries - is critical to our understanding of organismal development and our capacity for building functional replacement tissues. Despite the wealth of technologies available to control *in vitro* tissue size, shape, and mechanical environment, fine-scale spatial control of cellular composition remains an engineering challenge. To overcome this challenge, we present a DNA-based cell micropatterning approach on photosensitive hydrogels that can support hierarchical patterning of multiple cell types onto the same substrate with high spatial precision. We photopattern single-stranded DNA (ssDNA) onto benzophenone-polyacrylamide (BP-PA) hydrogels and introduce lipid-ssDNA-labeled cells, which are specifically captured onto gel-bound ssDNA deposits. This means multiple cell types can be efficiently co-patterned onto the same hydrogel in a spatially controlled fashion using different ssDNA sequences. To promote cell adhesion for long-term 2D culture, we find that extracellular matrix proteins can be attached to the BP-PA gel surface using standard hydrogel chemistry without compromising cell capture fidelity. Finally, we apply this approach to study several biological processes: stiffness-dependent fibroblast spreading on ssDNA-patterned hydrogels, spatial and temporal quantification of Ret tyrosine kinase signaling dynamics in migrating epithelial colonies, and the interfacial behaviors of tissues containing multiple micropatterned cell populations over time. This technology therefore enables independent control of cell patterning, adhesion, and mechanical environment, constituting a powerful strategy for programming complex multicellular interactions and interfaces into engineered tissues.

Production of biodegradable gelatin-elastin cryogels for excellent mechanical properties

E. Bahar[1], B. Reece[1], S. R. Russell[2], D. Oyetibo[3], U. Stevic[1,4], K. M. Myers[2], K. E. Kasza[2], K. E. Kasza[2], K. Kita[1]; [1]Department of Biology, St. Francis College, Brooklyn, NY, [2]Department of Bioengineering, Columbia University, New York, NY, [3]St. Francis College, Brooklyn, NY, [4]Keck School of Medicine, University of Southern California, Los Angeles, CA.

One of the important areas in regenerative medicine is to develop appropriate scaffolds to support the proper growth and differentiation of cells. There are reams of studies reporting the development of scaffolds to support cell growth. However, many of them require relatively complicated procedures for the synthesis. Ideal scaffolds should be easy to manufacture, biodegradable, and still possess excellent biophysical characteristics. Cryogels are porous scaffolds with interconnected pores that allow cell migration as well as an efficient exchange of nutrients inside scaffolds. Although gelatin-based cryogels were reported more than a decade ago, there is not much progress in that particular area since then. We also think that the improvement of biophysical parameters, such as elastic module and tensile strength, would be critical to developing clinically applicable scaffolds, because our body parts are flexible but also undergo mechanical forces. Among several extracellular matrices, we postulated that

the addition of elastin may give better flexibility as well as the stretchability of biodegradable scaffolds. We mixed and poured gelatin and the various concentration of elastin into casting plates after crosslinking with glutaraldehyde to create a smooth, sheet-like cryogel. After freezing at -20°C overnight followed by thawing, the remaining aldehyde was quenched with carbonate buffer containing sodium borohydride. Based on our preliminary measurement, the addition of elastin could increase the tensile strength of cryogels up to four-fold. In contrast, the linear elastic modulus appeared to be in the same range compared to gelatin-only (0% elastin) gel. The previously reported formula, the gelatin-fibrinogen (0.03%) cryogel, showed lower elastic module as well as tensile strength. Thus, it looks promising to utilize elastin as an additional component to develop biodegradable cryogels in regenerative medicine.

Role of preconditioning with oxygen and glucose deprivation in promoting differentiation of dental pulp stem cells in 3D culture

I. A. Okkelman, W. Vandenberghe, **R. I. Dmitriev**; Ghent University, Ghent, BELGIUM.

Dental pulp stem cells (DPSC) are promising for bone tissue engineering and repair. To support angiogenesis and long-term viability within microfabricated and 3D-printed tissue constructs, they are often grown and differentiated together with endothelial cells in multicellular spheroids. However, this is often associated with the decline of endothelial cells and slow rate of DPSC differentiation towards osteoblasts. Interestingly, hypoxia affects cell viability and at the same time promotes angiogenesis with osteoblast differentiation. Here, we hypothesized that oxygen and glucose deprivation pre-conditioning can improve the process of DPSC differentiation in 3D culture with endothelial HUVEC cells. To do this, we performed oxygen and glucose deprivation experiments with 2D cultures of DPSC and HUVEC and tested effects on cell viability, redox potential and morphology. Interestingly, glucose deprivation did not significantly affect redox state of both HUVEC and DPSC. We therefore preconditioned these cell types with 0% O_2, followed by 24 h reperfusion, and produced heterocellular spheroids. To understand the effects of preconditioning in this 3D culture, we performed fluorescence microscopy analysis of cell death (Sytox Green) together with monitoring of spheroid oxygenation (ratiometric red/near-infrared O_2-sensing nanoparticles) during 7 days of differentiation. We found that cell death was not significantly different in the spheroids from non-differentiated and differentiated groups of cells. However, the periphery-to-core O_2 gradients were significantly lower ($p=0.05$) in non-differentiated hDPSC 21% / HUVEC 0% and hDPSC 0% / HUVEC 0% groups in comparison to hDPSC 21% / HUVEC 21% spheroids. During differentiation, this difference in spheroid oxygenation was slightly ameliorated, keeping the same trend as in non-differentiated spheroids. Thus under the deeper hypoxia, the heterocellular spheroids formed with 0% O_2-preconditioned endothelial cells demonstrated cell viability comparable to spheroids formed from non-preconditioned cells. This data correlates with the results on the alteration of redox potential in adherent (2D) DPSC and HUVEC cultures, where hypoxia-conditioned HUVEC cells demonstrated more profound response. We also found that preconditioned cells displayed stronger accumulation of hydroxyapatite and osteogenic differentiation. Collectively, our preliminary data indicates that hypoxia preconditioning, combined with imaging of oxygenation and cell death, can improve the quality of the spheroid-based ‘tissue building blocks’ in biofabrication.Supported by the Special Research Fund (BOF) grant of Ghent University (BOF/STA/202009/003).

B622/P3000

Automated Neural Network Solver for Cell Biology Applications

C. Lew; Palos Verdes Peninsula High School, Rancho Palos Verdes, CA.

Artificial intelligence (AI) has found increasing applications in cell biology. AI can analyze genetic sequences, predict chemical properties, and predict protein structure. However, AI also has indirect applications. One example is the use of AI to solve math models of biological processes. In cell biology, there are 2D and 3D models for simulating tumor growth, cell transport, cell chemistry, and cell signaling. In order for these models to work, they must be solved using a solver program. Traditional solvers use math methods such as the finite element method and the finite difference method. While traditional solvers have been a boon to cell biology, they have one major drawback: they can only solve a model by stepping forward in time one step at a time. This means that traditional solvers can be slow. For a 3D model at high resolution, a traditional solver can take hours to complete a simulation. The objective of this study is to reduce this time latency by creating an AI-based solver. We hypothesize that AI-solvers can solve 2D and 3D models hundreds of times faster than traditional solvers. Our method for building an AI solver followed multiple steps: we created a graphical user interface that allows users to enter a partial differential equation (PDE), initial conditions, parameters, and boundary conditions; we then created a Python code that automatically discretizes and solves the PDE within a grid; we set the Python code to run numerous random trials to generate a solution set; finally, we fed the dataset into a neural network to train it to understand the PDE. With sufficient training, the neural network will be able to solve the PDE for any time step within its training domain. As a trial run, we used a traditional solver and our AI-based solver to simulate the 2D reaction-diffusion Turing equation for 20 seconds of real time. The traditional solver required 30 seconds, while our AI-based solver required 0.078 second, a 385-fold improvement. We also performed trial runs on Fisher's equation for the spread of invasive cells, an mRNA-sRNA binding model, and the oxygenation of a red blood cell. In all cases, the AI-based solver was faster. We conclude that our AI-based solver will benefit those who use math models for their cell biology research. These researchers can train the AI-solver overnight and have a completed AI-based solver by morning.

B623/P3001

Evidence for intracellular glucose binding to proteins involved in secretion

T. Pramanik, F. Firdos, A. Mittal[,1]; IIT DELHI, Delhi, India

For glucose-stimulated-insulin-secretion (GSIS) by pancreatic β-cells in animals, it is believed that ATP generated from glucose metabolism is primarily responsible for GSIS. However, this ignores possible generation of intracellular ATP from other sources also. Thus, specificity of glucose in GSIS is not attributable to ATP from glucose metabolism alone; in fact, the reason behind this specificity remains undiscovered till date. In our group, transcriptomic analyses of hyperglycemic-exposed-Min6 cells identified upregulation of 3 secretion-specific genes corresponding to proteins KIF11, ATP6V0A4 and CACNB4. KIF11 is a motor protein which is involved in vesicular transport. ATP6V0A4 is required for acidification and maturation of secretory vesicles. CACNB4 is a voltage gated calcium channel subunit involved in β-cell insulin secretion. These had not been previously related, in any way, specifically to GSIS. Thus, we specifically asked whether these 3 proteins, obviously involved in insulin secretion, had any possible direct interaction with intracellular (but un-metabolized) glucose. Using AutoDock Tools 4.2.6, glucose was investigated as a possible ligand for the above 3 proteins. Glucose metabolites

involved in glycolysis (namely G6P, F6P, F-1,6-BP), and other epimers of glucose (Mannose and Galactose; aldohexoses - Altrose, Allose, Gulose, Idose, Talose; ketohexoses - Fructose, Psicose, Tagatose and Sorbose) as possible ligands were also investigated. Remarkably, glucose showed a statistically significant better score (in Kcal/mol) among all metabolites and hexoses ($C_6H_{12}0_6$'s) with all 3 proteins. Further, the glucose-affinity/binding scores with the 3 proteins were also compared with scores (in Kcal/mol) for glucose as a ligand for positive controls (proteins known to interact with glucose - GCK and GLUT2) along with negative controls (proteins known not to interact with glucose - RPA1, KU70-80, POLA1, ACAA1A, POLR1A). Again, remarkably, binding affinity scores of glucose molecules for KIF11, ATP6V0A4 and CACNB4 were found to be closer to positive controls with statistically significant higher scores compared to negative controls. Therefore, while reporting strong evidence for glucose binding ability of 3 secretion-related proteins in GSIS, we provide the first ever evidence of a possibly direct role of intracellular glucose molecules in GSIS.

Imaging-ready model systems to study physical factors contributing to pre-metastatic niches

J. Flournoy, O. Perry, E. Chen, J. Michel, D. Yan, M. Brock, F. Housseau, Y. Chen; Johns Hopkins University, Baltimore, MD.

Metastases are the leading cause of cancer death and accounts for 90% of all cancer deaths. Metastasis occurs when cells disseminate from the primary tumor and colonize distant organs. Recent evidence showed prior to colonization, the tissue in the distant organs undergo compositional changes in cell population and structural changes in extracellular matrix (ECM) to form the pre-metastatic niche (PreMN). However, the cause that triggers such changes is unknown. We aim to dissect the process of PreMN formation and identify the key players for clinical intervention. Given significantly increased risk of death in patients with comorbidity of secondary lung cancer and muco-obstructive pulmonary diseases such as cystic fibrosis (CF), idiopathic pulmonary fibrosis (IPF) and chronic obstructive pulmonary disorder (COPD), we hypothesize that high viscosity of the abnormal mucus contributes to the formation of PreMN in the lung tissue. Indeed, we have observed that mesenchymal cells that are activated by elevated viscosity, exhibit phenotypes similar to carcinoma-associated fibroblasts (CAFs). CAFs are known to remodel ECM and secrete tumor-promoting cytokines, thus enabling tumor progression. It is likely that the viscosity-activated fibroblasts in the distant organ behave similarly and form PreMN to accommodate the invasion of disseminated tumor cells (DTCs). It is ideal to observe the PreMN formation longitudinally by documenting cellular behaviors with detailed dynamic and spatial resolution. Therefore, we use a 3D biofabricated microphysiological model in mimicry of human tissues and an *ex vivo* model, both allowing multispectral live cell imaging. Our microphysiological model consists of melanoma-bearing skin mimetic tissue, blood vessels, and lung-mimetic tissue cultured in viscous mucus similar to that of IPF. During biofabrication, the mechanical properties representative of each tissue are recapitulated. For the *ex vivo* model, we use precision-cut lung slices (PCLS) from mice bearing Lewis Lung Carcinoma (LLC). Both the microphysiological system and PCLS are imaging-friendly. The features, such as ECM organization, cell morphological changes, cell migration and proliferation, are extracted from the 4D image data. We also examine the model systems using micro-CT, so that the changes in the tissue can be interrogated using techniques developed in radiomics. The result of micro-CT radiomics can provide valuable insight to screening PreMN formation thus granting the possibility of intervention before metastasis even occurs.

B625/P3003

Enhanced small green fluorescent proteins as a multisensing platform for biosensor development

G. Liang[1,2,3,4], **C. Lai**[1,2,3], Z. Yue[1,2,3,5], H. Zhang[1,2,3], D. Li[1,2,3], Z. Chen[6], X. Lu[6], L. Tao[1,2,3], F. Subach[7], K. Piatkevich[1,2,3]; [1]Westlake University, Hangzhou, China, [2]Westlake Laboratory of Life Sciences and Biomedicine, Hangzhou, China, [3]Institute of Basic Medical Sciences, Westlake Institute for Advanced Study, Hangzhou, China, [4]The Hong Kong Polytechnic University, Hong Kong, China, [5]Xi'an Jioa Tong University, Xi'an, China, [6]Key Laboratory of Precise Synthesis of Functional Molecules of Zhejiang Province, School of Science, Instrumentation and Service Center for Molecular Sciences, Westlake University, Hangzhou, China, [7]Complex of NBICS Technologies, National Research Center "Kurchatov Institute", Moscow, Russian Federation

Engineered light, oxygen, and voltage (LOV)-based proteins are able to fluoresce without oxygen requirement due to the autocatalytic incorporation of exogenous flavin as a chromophore thus allowing for live cell imaging under hypoxic and anaerobic conditions. They were also discovered to have high sensitivity to transition metal ions and physiological flavin derivatives. These properties make flavin-binding fluorescent proteins (FPs) a perspective platform for biosensor development. However, brightness of currently available flavin-binding FPs is limited compared to GFP-like FPs creating a need for their further enhancement and optimization. In this study, we applied a directed molecular evolution approach to develop a pair of flavin-binding FPs, named miniGFP1 and miniGFP2. The miniGFP proteins are characterized by cyan-green fluorescence with excitation/emission maxima at 450/499 nm and a molecular size of ~13 kDa. We carried out systematic benchmarking of miniGFPs in Escherichia coli and cultured mammalian cells against spectrally similar FPs including GFP-like FP, bilirubin-binding FP, and bright flavin-binding FPs. The miniGFPs proteins exhibited improved photochemical properties compared to other flavin-binding FPs enabling long-term live cell imaging. We demonstrated the utility of miniGFPs for live cell imaging in bacterial culture under anaerobic conditions and in CHO cells under hypoxia. The miniGFPs' fluorescence was highly sensitive to Cu(II) ions in solution with Kd values of 67 and 68 nM for miniGFP1 and miniGFP2, respectively. We also observed fluorescence quenching of miniGFPs by the reduced form of Cu(I) suggesting its potential application as an optical indicator for Cu(I) and Cu(II). In addition, miniGFPs showed the ability to selectively bind exogenous flavin mononucleotide demonstrating a potential for utilization as a selective fluorescent flavin indicator. Altogether, miniGFPs can serve as a multisensing platform for fluorescence biosensor development for in vitro and in-cell applications.

B626/P3004

Understanding the Molecular Mechanisms Regulating Cell Growth and Protein Production in CHO cells to Improve the Performance of CHO-Based Bioengineering

R. Singh, N. Kumar; Translational Health Science And Technology Institute (THSTI), Haryana, India

Chinese Hamster Ovary (CHO) cells are the most preferred host cellular machinery for industrial-scale production of modern-day protein bio-therapeutics. Currently, biphasic culture, where cells, once achieve requisite cell density in culture, are treated with sodium butyrate (NaB) to reduce cell growth and improve cell-specific productivity, is among the most commonly used methods to improve the yield of biotherapeutics from CHO-based cultures. However, the cost of such bio-therapeutics still remains high requiring improvement in the performance of the bioprocess to make them affordable. And, knowledge of the molecular mechanisms by which NaB improves cell-specific productivity is the only key

to achieving the objective. It is known that plasma cells are the natural and professional antibody-producing cells. During B-cell development, fast-grower but low-producer pre-B cells differentiate into non-growing but high-producer mature plasma cells. This B-cell development is associated with the expression of a cascade of molecules, each of which plays a key role in deciding the fate of the cell. The timing of the appearance of each of these molecules may be critical. Therefore, in this investigation, we mimicked different stages of the B-cell development process in CHO cells grown using gradually increasing concentrations (0, 0.125, 0.25, 0.5, 1, 2, 4 & 8mM) of NaB. The cell growth-arrest was observed at ≥0.5mM NaB ($p < 0.05$) and viability decreased gradually with increasing NaB concentration (2mM to 8mM) 24hr post-treatment. The increased mitochondria and ER content and decreased nucleus content were observed using flow cytometry following 0.5-1mM NaB treatment, a concentration known to cause growth arrest and improve productivity. The expression analysis of 10 genes that are well-known in the literature to regulate plasma cell differentiation and maturation enabled the identification of potential targets that may play a critical role in the regulation of cell growth and productivity. The untargeted intracellular metabolite analysis also enabled the identification of metabolites potentially involved in the regulation of cell growth (such as adenine, dihydroxyuracil, deoxycarnitine), cell-death (such as glutathione, spermine, spermidine) and productivity (such as acetate phenylalanine, glutamine, citrulline). The work is ongoing to validate the cell growth, viability- and/or productivity-associated targets in order to improve the CHO cell performances for recombinant protein production in bioprocess.

B627/P3005

Transfection of 3D bioprinted human skeletal muscle tissue to assess innate immune responses to mRNA vaccines

L. H. Brunner[1], H. Soliman[2], E. Miller[1], T. Gales[3], M. Maglaty[3], J.-L. Klein[3], K. M. Wisdom[3], A. S. Pitek[1], G. Maruggi[1], K. Luisi[1], A.-M. Steff[1], S. J. Wadsworth[2], J. McAuliffe[1]; [1]GSK- Rockville Center for Vaccines Research, Rockville, MD, [2]Aspect Biosystems, Vancouver, BC, Canada, [3]GSK- Upper Providence, Collegeville, PA

Human 3D *in vitro* models have been used for improving predictions of the safety and efficacy of small molecule medicines for years. These models have been shown to better mimic the physiological complexity and function of native human tissue compared to 2D or animal models. The use of appropriate 3D *in vitro* models for evaluation of vaccine candidates could similarly inform vaccine development and advancement into the clinic. To this end, a skeletal muscle model for studying intramuscularly administered vaccine candidates was developed. A unique microfluidic 3D bioprinting technology was used to manufacture skeletal muscle tissues consisting of primary human myoblasts printed within multi-layer fibers, developed using composite biomaterials, resulting in aligned, multinucleated and differentiated myotubes that resemble native human myobundle architecture, as confirmed by histological staining. Importantly for studying antigen expression upon administration of vaccine candidates, these printed microtissues were shown to be transfectable with self-amplifying mRNA (SAM) vaccines formulated in lipid nanoparticle (LNP) delivery vehicles. The bioprinted tissues not only expressed the antigens encoded by the SAM-LNP vaccines, but they also responded with the production of cytokines and chemokines, including IFN-beta, IFN-gamma, IL-6, TNF-alpha, G-CSF, and IP-10. These cytokines and chemokines are known to play a key role in human innate immune responses. Some of these cytokines have been detected in clinical trial participants receiving mRNA vaccines and may be indicators of reactogenicity to vaccines. To improve the translational relevance of these models,

experimental data will need to demonstrate a correlation between *in vitro* data from this model and clinical observations. Overall, our results indicate that these 3D bioprinted skeletal muscle microtissues may serve as a physiologically relevant *in vitro* model for studying the response to vaccine candidates administered through the intramuscular route.

B628/P3006

Towards a quantitative understanding of mitotic waves in *Xenopus laevis* extracts

O. Puls, Q. Yang; University of Michigan, Ann Arbor, MI

Over the years, various models were developed to capture the mechanism behind the mitotic clock. In short, various checkpoints controlled by the activity of cyclinB-Cdk1 direct the cell through a series of steps which define one mitotic cycle. The regulation of these processes facilitates the longevity of multicellular organisms by enforcing a regular, clock-like timing of mitotic events. When a collection of these oscillators couple, they synchronize. In particular, in various systems—e.g. *Drosophila* and *Xenopus*—early embryogenesis is marked by a series of synchronous cell divisions across the length of the embryo. The size of these embryos implies a faster coordinating effect than diffusion alone. Work in the field proposes a mechanism for such spatial coordination in the form of mitotic waves. However, this literature largely focuses, and in some sense is dependent on, the role of nuclei acting as pacemakers. Here, we explore these waves directly and more broadly. Using *Xenopus* extracts and a Cdk1 FRET sensor, we exploit a novel approach utilizing metaphase-arrested extracts, producing one-dimensional directed mitotic waves without reconstituted nuclei. With this setup, we can probe the possible differences between mitotic waves in systems with and without nuclei, finding the speed of the former to be significantly slower. We observe the frequency of the latter system to consistently lag behind the former, possibly explaining this speed disparity. Further, we show the slowing is primarily due to a lengthening of the mitotic phase. Finally, we also investigate undirected waves with and without nuclei, primarily focusing on the possible transition from sweep-like to trigger-like waves as period slows. In total, we display a unique method for exploring biochemical waves and offer insight into their properties.

B629/P3007

Probing cell-cell communication during neutrophil swarming

J. Strickland; University of California, San Francisco, San Francisco, CA

As the most abundant white blood cell in the body, neutrophils are able to rapidly enter tissues in large numbers when responding to tissue injury or infection. Instead of seeking out these sites of damage alone however, neutrophils enhance their own recruitment in a process known as neutrophil swarming. This mechanism provides for a strong positive feedback system in the early immune response that can help rapidly deploy cells to an area while infections and injuries might still be easy to contain. When neutrophils begin to overwhelm other immune regulatory systems however, the swarming mechanism can also contribute to a number of inflammatory diseases by creating excessive tissue damage and inflammation. While some of the key signals of this process have been identified such as the pro inflammatory lipid LTB4, the molecular logic of the process is still poorly understood. For instance, what signals initiate the signal amplification process? How exactly are these signals then amplified to reach a large radius of cells? To address these questions, I propose a set of in-vitro experiments to isolate and precisely perturb the signaling mechanisms of neutrophil swarming. This approach will have direct

relevance for key risk factors associated with atherosclerosis such as endotoxemia and subsequent neutrophil-mediated plaque destabilization events. By understanding the underlying mechanisms neutrophils use to amplify their own inflammation, this work will help build a foundation for new therapies aimed at preventing excess inflammation while still maintaining neutrophil's host defense abilities.

B630/P3008

Characterization of functional activity of forebrain organoids using longitudinal multiphoton calcium imaging

P. Harary[1], R. Kurzion[2], K. Mensah-Brown[3], D. Jgamadze[1], H. Song[2], G. Ming[2], H. Chen[1]; [1]Neurosurgery, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, [2]Neuroscience, University of Pennsylvania, Philadelphia, PA, [3]Neurosurgery, Mayo Clinic Rochester, Rochester, MN.

Understanding the baseline functional activity of brain organoids is highly relevant to their use as a tool to study neurological conditions as well as a substrate for transplantation-based therapeutic applications. Although a small number of previous studies have assessed synchronized activity in organoids, the significant heterogeneity inherent to brain organoids and diffusion limitations have impaired precise, long-term characterization of functional activity. Here, the genetically encoded calcium indicator GCaMP8m and a custom-designed culture plate were used to perform longitudinal multiphoton imaging of forebrain organoids. Organoids were grown from an induced pluripotent stem cellline derived from a healthy volunteer. At differentiation day (dd) 40, the organoids were sliced at a thickness of 500µm, with repeated slicing every 30 days. Viral transduction was performed on dd45 with AAV expressing GCaMP8m under a human synapsin promoter. Neural activity at two different depths within the organoids was assessed up to dd180. Analysis of the videos was performed using the Mesmerize platform for motion correction and region of interest (ROI) selection followed by Python scripts for analysis. Firing rates were found to differ significantly across both age and depth with older and deeper regions demonstrating increased firing rate ($p<0.05$). The level of Pearson correlation also varied across both age and depth, with shallower regions in more mature organoids showing the highest correlation. This platform enables investigation of neural activity throughout organoid maturation and uniquely allows for repeated recordings from the same organoid with high-resolution imaging. Additionally, multiphoton calcium imaging makes it possible to reliably image neural activity at depths up to 800µm beneath the surface from ROIs on the same imaging plane. Full characterization of the functional connectome of intrinsic organoid activity may allow for comparison with in vivo data to assess the strength of organoids as models of human neurodevelopment and repair substrates.

B631/P3009

SmartSpheroPlates - A Novel High-Throughput 3D *In Vitro* Assay for the Formation of Reproducible Anchored Spheroids

S. F. Robben[1,2], P. Davidson[1], R. S. R. Robeiro[1], M. Le Berre[1], C. Cerveau[1], P. Thiebaud[1]; [1]4Dcell, Paris, France, [2]KU Leuven, Leuven, Belgium

Spheroids are one of the most used and versatile *in vitro* models enabling research on cells organised in 3D. However, conventional methods for the formation of spheroids present shortcomings related to the variability in spheroid size and the lack of reproducibility. Additionally, it is difficult for researchers to keep track of individual spheroids over time as simple manipulations, such as medium exchange, can

cause spheroids to be aspirated together with the medium. To overcome these issues, a high throughput assay was developed using a PEG based microstructured hydrogel allowing for the formation of homogeneous spheroids with reproducible size and shape which are fixed to a specific location. The hydrogel structure, containing between 19 and 91 microwells per gel, provides a microenvironment that enables the cells to sediment and self-assemble into spheroids within hours. The presence of a small contact point allows the spheroids to attach to the glass bottom on which the gels are made, preventing spheroid loss during manipulations. Due to the design of the microwells and the optical transparency of the hydrogel, the assay is completely compatible with conventional microscopy techniques and spheroid growth can be tracked over time. Experiments using mesenchymal stem cells showed that the relation between the number of seeded cells and spheroid diameter follows a cubic trend. The standard deviation of the diameter of different spheroids, measured after 10 days is of 1.94%. It was also observed that due to the presence of anchoring points, less than 12% of the spheroids were lost during exaggerated medium exchange conditions compared to 86% of spheroids in similar conditions without a contact point. Additionally, the structural composition of the PEG-based hydrogel enables the diffusion of nutrients all around the spheroids, allowing them to be kept in culture for up to six weeks. These experiments showcase the potential of the assay to conduct research on spheroids with higher precision and control at a higher throughput. This overcomes most shortcomings of the conventional spheroid formation methods, and the simplicity of this tool makes it highly accessible to study fundamental research questions or to speed up drug screening and toxicology studies.

B632/P3010

Shallow-angle illumination with low-magnification imaging reveals micro-scale changes in scaffold surface morphology that can promote epithelial cell barrier formation

C. F. Lewallen[1], J. T. Montford[1], A. Maminishkis[2], K. Bharti[1]; [1]Ocular Stem Cell and Translational Research Section, Ophthalmic Genetics and Visual Function Branch, National Eye Institute, National Institutes of Health, Bethesda, MD, [2]Translational Research CORE, Ophthalmic Genetics and Visual Function Branch, National Eye Institute, National Institutes of Health, Bethesda, MD

Retinal pigment epithelium (RPE) is located in the back of the eye, which forms a polarized barrier and helps maintain the health and function of the distal retina. Many degenerative eye diseases can benefit from RPE transplantation to damaged eye regions to restore sight or halt disease progression. We focus on RPE monolayers grown on poly lactic-co-glycolic acid (PLGA) substrate to refine surgical delivery options. PLGA offers a strong substrate for surgical delivery and a biodegradable option to remove artificial substrates when RPE is introduced into the eye environment. Towards this goal, it is essential to quantify how the growth substrate (PLGA) architecture impacts key cell health indicators such as trans-epithelial resistance (TER); an indicator of RPE barrier integrity. Consequently, we leveraged common, low-angle lighting techniques to exaggerate the surface features of PLGA scaffolds under low-magnification microscopy and then assessed the TER of cultured RPE, on these same scaffolds, over the duration of 5 weeks. In this paper, we show that scaffolds with less than 1.6 skewness (Ssk) and less than 4 kurtosis (Sku) provided the RPE monolayer a better growth substrate, which allowed for a better quality RPE monolayer and higher resistance. These data provide a simple, yet novel method for identifying optimal PLGA scaffold morphology, prior to cell culture for future therapeutic use.

Germ Cells, Gametogenesis, and Fertilization

Regulated Secretion Mediates Yeast Cell Fusion

U. Machi[1], E. Mazur[1], A. Sundlof[1], J. Smith[2], M. Rose[1]; [1]Biology, Georgetown University, Washington, DC, [2]Biology, Stetson University, DeLand, FL.

Cell-cell fusion is a critical event in many systems, including muscle development, fertilization, and immune response. In yeast mating, partner cells must first degrade the intervening cell wall material before plasma membrane fusion can be achieved. Cell wall removal is carried out by secreted remodeling enzymes such as glucanases, mannanases and chitinases. The action of these enzymes must be tightly controlled, as ectopic cell wall degradation causes cell lysis. Yeast cell fusion requires continuous secretion, as revealed by mutations in the standard secretory pathway. However, electron microscopy demonstrated the appearance of mating-specific vesicles in pheromone-responding cells and at the Zone of Cell Fusion (ZCF) in prezygotes. The vesicles dissipate after fusion is complete. The behavior of the vesicles appears to be regulated by the fusion proteins Fus1p, Fus2p, Rvs161p, and Cdc42p. Deletion of *FUS1* prevents vesicles from localizing to the ZCF; mutations of *FUS2, RVS161 or CDC42* appear to block fusion with the plasma membrane. All lead to defects in subsequent cell wall degradation, but do not show evidence of defects in general secretion. To study the possible role of a mating-specific regulated secretion pathway in yeast, we have developed a Fluorogen Activated Protein (FAP) assay to monitor secretion. The FAP assay works by fusing the FAP to a protein of interest and exposing the cell to a membrane-impermeable fluorogen. When the FAP binds the fluorogen, a fluorescent signal is emitted, allowing for visualization of protein secretion. We FAP-tagged Scw4p, Gas1p, and Scw10p, three pheromone-regulated glucanases, and monitored their secretion. We observed that Scw4p and Gas1p are secreted in a pulse to the ZCF in a Fus2p-dependent manner, whereas Scw10p secretion slowly accumulates and is Fus2p-independent. Interestingly, both *SCW4* and *GAS1* are downregulated in mating, in contrast to upregulation of *SCW10*. We conclude that Scw4p and Gas1p are preloaded into the mating-specific vesicles and specifically secreted during conjugation to help effect cell wall removal.

Investigating changes in proteasome complex composition during budding yeast meiosis

M. C. Reyes[1], J. A. Cheng[1], E. Doron-Mandel[2], J. Kim Kim[2], M. Jovanovic[2], G. A. Brar[1]; [1]Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, [2]Department of Biological Sciences, Columbia University, New York City, NY.

Protein complexes are essential for the proper execution of many cellular processes, including meiosis, the process in which diploid cells transform into haploid gametes. Our previous study leveraged parallel global measurements of translation and protein levels during meiosis and found that meiotic *Saccharomyces cerevisiae* synthesize the members of most protein complexes imprecisely. The protein levels of these complex members are post-translationally adjusted through degradation to achieve precise matching throughout meiosis. An interesting outlier to this high protein-level matching is the 26S proteasome, which is responsible for regulated degradation of ubiquitin-labeled proteins in the cell. The 26S proteasomes consists of two components: the 19S regulatory particle (RP), which is the best studied activator of proteasome and the 20S core particle (CP), in which proteolysis occurs. During late meiotic

stages, our data indicate that the RP is selectively degraded 2-3 hours before degradation of the CP, concurrent with an increase of the alternative CP activator Blm10. These findings suggest unanticipated stage-specific modulation of proteasome activity during meiosis. We performed co-immunoprecipitation on the CP over a meiotic time course and found that in late meiotic stages, there is a greater increase in Blm10-CP association compared to RP-CP association. The consequences of an increasing a Blm10-associated proteasome pool during specific meiotic stages remain mysterious. To further elucidate the role of Blm10 during late meiotic stages, we performed label free quantification (LFQ) mass spectrometry on wildtype and Blm10 deletion mutants. From these data, we have identified potential direct degradation targets of Blm10-proteasomes, and evidence that the absence of Blm10 delays timely completion of meiosis. In conclusion, we have defined a natural change in proteasome complex composition during meiosis and have begun to characterize functional roles for the late meiotic increase in Blm10-proteasomes.

Role of LOTUS-domain proteins in *C. elegans* germline development

B. Radhakrishna Pillai, P. Czermak, J. Bindics, S. Saha; Institute of Molecular Biotechnology, Vienna BioCenter, Vienna, AUSTRIA.

Germ cells ensure the continuance of life by giving rise to totipotent zygotes. A conserved feature of germ cells is the presence of perinuclear non-membrane-bound condensates of proteins and RNA, called 'Nuage'. Mutations in nuage proteins result in teratomas and cause infertility. Among conserved components of nuage are the ATP-dependent RNA helicase 'Vasa' protein, LOTUS domain proteins, Tudor domain proteins, and argonauts. The molecular mechanisms underlying the functions of LOTUS-domain proteins in the germline remains poorly understood. In the nematode worm *C. elegans,* nuage is proposed to contain a collection of condensates – P granules, Z granules, SIMR foci and mutator foci. P granules contain two LOTUS-domain proteins MIP-1 and MIP-2, mutations of which reduce the fecundity of animals. MIP-1 and MIP-2 each contain two LOTUS domains (hereafter called L1 and L2) in addition to two intrinsically disordered regions. Recent studies have identified a role of these intrinsically disordered regions in mediating the association of P granules with nuclear pores. However, the role of the two LOTUS domains in MIP proteins remains unclear. Studies in Drosophila have shown that LOTUS domains can bind the Vasa protein and stimulate its RNA-dependent ATPase activity. Here, we show that in *C. elegans*, MIP-1 stimulates the RNA-dependent ATPase activity of the Vasa orthologue GLH-1. We also show that in vivo, L2 cannot complement for L1 function. We speculate that the LOTUS domains of MIP proteins have distinct roles in supporting the integrity and function of P granules.

Cell Biological Analysis of Mouse Cryptorchidism Using *in vitro* Culture System

S. Tone[1], T. Nakatsuka[2], K. Hirata[2], S. Ohira[2], R. Hara[2], A. Kuriyama[1], A. Nagai[2]; [1]Graduate School of Science and Engineering, Tokyo Denki University, Hatoyama, Saitama, JAPAN, [2]Department of Urology, Kawasaki Medical School, Okayama, JAPAN.

Cryptorchidism is one of the most common abnormalities of male sexual development, and is characterized by the failure of the testis to descend into the scrotum. Despite extensive studies of cryptorchidism over the past century, the mechanisms for temperature-induced germ-cell loss are not well understood. All of the main cell types in the testis are believed to be affected by the elevated testis

temperature induced by cryptorchidism. The suitable temperature (about 34 °C) in the special environment of the scrotum is required for maintaining optional conditions for normal spermatogenesis. Many studies reported that experimentally induced cryptorchidism in mice caused germ cell apoptosis and suppressed spermatogenesis. However, other factors such as hormones, immunological circumstances or oxygen concentration must also be examined for cryptorchidism. To explore the mechanism for cryptorchidism, *in vitro* cultures of testes have been used, but complete spermatogenesis using *in vitro* methods has not been accomplished until 2011. In 2011, Sato *et al*. (Nature, 471, 504-507) reported the in vitro production of functional sperm in cultured neonatal mouse testes. Using this *in vitro* system, for the first time, we report that spermatogenesis was abrogated at 37 °C, in accordance with *in vivo* surgery-mediated cryptorchidism, while spermatogenesis proceeded at 34 °C in cultured testes. This result clearly showed that temperature is the sole determinant of cryptorchidism. Moreover, we found that spermatogenesis was arrested before early spermatocytes at 37 °C. While DNA synthesis could be detected in some germ cells at 34 °C in cultured testes, newly DNA synthesis could be hardly detectable at 37 °C. But after switching from 37 to 34 °C in culture, DNA synthesis was resumed within 24 hrs. In conclusion, using our *in vitro* system, we have demonstrated that (1) temperature is the determining factor for cryptorchidism, and (2) higher temperature (37 °C) suppresses DNA synthesis in spermatogenesis.

B638/P3015

Generation of functional primordial germ cells from embryonic stem cells in rats

M. Oikawa[1], M. Hirabayashi[2], T. Kobayashi[1,2]; [1]Institute of Medical Science, University of Tokyo, Tokyo, JAPAN, [2]National Institute for Physiological Sciences, Okazaki, JAPAN.

Primordial germ cells (PGCs), the precursors of sperm and eggs, are emerged from pre-gastrulating epiblast. It is important to understand PGC specification for the fundament of cell fate decisions, reproductive medicine and animal breeding. However, the fewness of PGCs (~40 in mice) and limited access to peri-implantation embryos had hindered to understand the process. To overcome these problems, *in vitro* system to induce PGC-like cells (PGCLCs) from pluripotent stem cells (PSCs) has been developed. This robust and scalable system allowed us to analyze PGC specification in several mammalian species. However, PGCLCs with function to produce fertile gametes had been only developed in mice. Here, we aim for the induction of functional PGCLCs from rat PSCs. We generated *Nanos3-T2A-tdTomato* (N3T) reporter rats to monitor the expression *Nanos3*, a marker specifically expressed in PGCs. We established embryonic stem cells (ESCs) from blastocysts of N3T reporter and used them to induce rat PGCLCs (rPGCLCs). Rat ESCs firstly differentiated into epiblast-like cells (EpiLCs) via floating aggregates, although adherent monolayer condition used in mouse ESCs did not work. Next, we transferred EpiLC-aggregates into the medium with BMP4, a critical cytokine for PGC fate. Within 2 days, N3T expression was started and almost maximized at day 2-3 in a part of cell aggregates. We also analyzed transcriptome of rPGCLCs and found their gene expression profiles was similar to migratory rPGCs. We next reconstructed gonads by rPGCLCs and gonadal somatic cells and observed maturation of rPGCLCs into gonadal stage PGCs with epigenetic reprogramming. Finally, we transplanted rPGCLCs into the seminiferous tubule of germline-less *Prdm14*-deficient rats to test their gametogenic capacity. After 10-12 weeks, spermatogenesis was found in rPGCLCs-transferred testis. Notably, rPGCLC-derived sperm/spermatids lead to birth of viable offspring via microinjection. These offspring appeared healthy and grow up to fertile adults for both sexes. In conclusion, we successfully generate functional PGCLCs from PSCs in rats, which is the first demonstration of fully functional non-mouse PGCLCs. We believe our

system will contribute to understanding fundamental mechanisms in pluripotency and germline development and help establish broad applicability for *in vitro* gametogenesis in various mammals.

B639/P3016

Precision reproductive genetics: pinpointing the effects of a maternally-inherited *Kif18a* variant on oocyte meiosis and aneuploidy

L. Biswas[1], M. Aboelenain[1,2], S. Sun[1], J. Xing[1], K. Schindler[1]; [1]Department of Genetics, Rutgers University, New Brunswick, Piscataway, NJ, [2]Theriogenology, Mansoura University, Mansoura, EGYPT.

A quarter of all pregnancies end in miscarriage; half of miscarriages are caused by chromosomal chromosome number imbalance, termed "aneuploidy." Aneuploidy most often arises in the egg and is almost always incompatible with life. Maternal age at ovulation is currently the only predictor of a given egg's risk of aneuploidy. However, for some individuals, egg aneuploidy occurs more often and earlier than would be predicted by maternal age. We hypothesized that genetic variants might directly cause aneuploidy in individuals for whom maternal age is an insufficient predictor. To test this hypothesis, we leveraged our novel biobank of whole-exome sequence data from infertility patients with extreme rates of aneuploid embryo conception relative to maternal age. From these sequence data, we identified a genetic variant enriched in patients with disproportionately high rates of embryonic aneuploidy, *KIF18A*^{MDM}. We found that overexpression of *KIF18A*^{MDM} causes dysmorphic meiotic spindles and increased aneuploidy in mouse oocytes. To validate our overexpression experiments, we generated a new knock-in mouse line bearing this variant, *Kif18a*^{MDM}. Eggs from *Kif18a*^{MDM} mice are more frequently aneuploid than those from wild-type counterparts and have unique morphological phenotypes, including micronuclei and fragmented cells. These studies lay the groundwork for further studies of *Kif18a*^{MDM}'s possible role as a maternal genetic variant leading to increased egg aneuploidy relative to maternal age.

Expression of Piwi family and their interaction with genes regulating ovarian follicle development

Y. Kim[1], **S. Ku**[2]; [1]Seoul National University Hospital, Seoul, KOREA, REPUBLIC OF, [2]Department of Obstetrics and Gynecology, Seoul National University Hospital, Seoul, KOREA, REPUBLIC OF.

An ovarian follicle is a unit of interaction with hormones by surrounding somatic cells for the maturation of the oocyte. Among the follicles, only one follicle is selected as the dominant follicle and develops into a mature follicle and this ability decreases naturally with age and leads to infertility. For the preservation of fertility, uncovering molecular regulators of follicular development has been reported using advanced transcriptomics. The correlation of Piwil2 with miRs was reported by our group (Kim et al., Int J Mol Sci., 2021). Based on these results, we analyzed the expression of the Piwi family on the maturation of ovarian follicles. Ovaries of 2-week- and 16-week-old mice were surgically retrieved, and single follicles were isolated. Pre-antral follicles of 100~120 μm in diameter were seeded in each media droplet. After 4 days of *in vitro* culture, the mimics and inhibitors of the Piwi family were transfected, then the follicles were further cultured until they reached the maturation stage. The expressions of Piwi and target genes were analyzed and their effects on follicle maturation were evaluated via the assessment of follicular maturation and oocyte fertilization. The expression of the Piwi family varied in 2-week- and 16-week-old ovaries. The expression of target genes, CYP19A1, HDAC6, ZP3, Figla, Nobox, and FSH receptors was downregulated in 16-week-old mice. Taken together, these data suggest that the Piwi regulates the

critical genes involved in female fertility in a reproductive stage-specific manner (2022R1A2B5B01002541).

The properties of moringa that promote sea urchin egg viability

M. R. Lee[1], C. Wu[2]; [1]Borough of Manhattan Community College, New York, NY, [2]Boston College, Boston, MA.

The Properties of Moringa that Promote Sea Urchin Egg Viability

Marshall Lee, Chenyang Wu and Dr. Lalitha Jayant Borough of Manhattan Community College, New York

ABSTRACT

Sea urchins, like humans, are deuterostomes, organisms whose anus forms first relative to their mouth during embryological development. Sea urchin embryos could provide valuable insight into embryological development of humans and other deuterostomes. However, when left by themselves, the eggs of sea urchins disintegrate and die within 24 hours. This study aims to expand upon a previous study, which found that aqueous extracts of Moringa oleifera, a tree found in the Indian subcontinent, was able to preserve the viability of eggs obtained from the sea urchin species Lytechinus variegatus for up to seven days. To identify the properties of moringa that allowed it to preserve sea urchin eggs, aqueous moringa leaf extracts were obtained by brewing commercial moringa leaf powder in water at different temperatures. The extracts were tested for their antibacterial, anti-protist, antiviral and anti-oxidant properties using slight modifications of standard methods. Results indicate that the aqueous extracts brewed at 90℃ and 100℃ showed increasing levels of antibacterial activity when used at 50% concentration. The extracts were also able to hinder the growth of protists that co-isolate as cysts with the urchin eggs. Furthermore, the extracts, especially the ones extracted at 90°C and 100°C, showed a Total Antioxidant Capacity (TAC) of 5 ± 0.5 mmol Trolox equivalent TR/g. Antiviral activity was not detected in these extracts. More studies are needed to further ascertain the role of aqueous moringa leaf extracts on the viability of sea urchin eggs especially, the effects of various flavonoids present in moringa that contribute to the TAC.

Biomolecular condensates in *C. elegans* oocytes are physiological markers for age-related viability loss

P. A. Bhatia, R. Amin, J. Woodruff; UT Southwestern Medical Center, Dallas, TX

Female age-related infertility is a growing field of research due to the increase in delayed motherhood and rise in demand for fertility treatment amongst older women. While we have methods to assist in pregnancies past the most fertile years, we do not have a good understanding of the underlying cellular processes that might be contributing to oocyte-specific aging.Since there are major limitations to studying human or even mammalian oocytes (both *in vivo* and *ex vivo*), our lab makes use of a *C. elegans* model. *C. elegans* nematodes naturally produce males and hermaphrodites but can be induced to a female phenotype. Our lab uses a temperature sensitive *fem-1* model that produces arrested oocytes that show a natural decline in viability with age. These arrested oocytes contain unique membrane-less condensates that are thought to store proteins and RNA.We hypothesize these condensates play a protective function, either through transcriptional regulation or by maintaining the integrity of RNA and proteins, in anticipation of fertilization. We analyzed a few key components in the condensates (IFET-1, CGH-1, CAR-1, mRNA) and are investigating their necessity/sufficiency and how changes to condensate

formation and morphology coincides with changes to oocyte viability. I've found that both by *in vitro* reconstitution and by *in vivo* knockdowns, I can understand the effect each protein has on condensate morphology and oocyte viability, which helps me elucidate their ultimate function. I have observed, with proteomics, that there is a large decrease in certain proteins in knockdown populations, suggesting that transcriptional repression is not be the primary mode of protection. Further studies will be done to elucidate the specific protective mechanism of the condensates that lead to alterations in oocyte viability.

Characterization of the SLC9C2 (NHE11) Protein in Mammalian Sperm

C. C. Gardner, J. A. Abele, P. F. James; Miami University, Oxford, OH

The Na^+/H^+ exchangers (NHEs) are a family of transporters that are found in the membranes of many cells. Na^+/H^+ Exchangers are encoded by the SLC9 gene family of solute carriers and mainly function to regulate pH. Twelve of the thirteen NHE proteins have been characterized to some degree, yet nothing has been published about SLC9C2 (encoding the putative NHE11 protein) beyond the existence of the gene in several mammalian species. We have thus sought to characterize the expression and localization of the final unstudied SLC9 gene family member, SLC9C2 (NHE11), to begin to identify its physiological role. We extracted RNA from a panel of rat tissues and RT-PCR was performed to discover that NHE11 expression is limited to the testis. We also cloned and sequenced NHE11 transcripts from both rat and human testis and found that the deduced full-length NHE11 proteins are expected to contain a NHE domain at the N-terminus, followed by a voltage-sensing domain (VSD), and an intracellular cyclic nucleotide binding domain (CNBD) at the C-terminus. The predicted protein structure NHE11 suggests that it is likely a NHE transporter that may be regulated by membrane potential and/or cyclic nucleotides. This predicted protein structure of NHE11 shares a similar predicted structure with its paralog NHE10, which also exhibits testis-specific expression and has been shown to be essential for male fertility in mice and humans. We developed a polyclonal anti-NHE11 antibody against the deduced rat NHE11 protein. Using this anti-NHE11 antibody we were able to confirm the expression of the full-length NHE11 protein in both rat testis and rat sperm via immunoblotting. When performing immunofluorescence experiments on rat testis sections, we found that rat NHE11 localizes to the developing sperm head in testis sections, specifically to the acrosomal granule. In mature rat sperm cells, NHE11 localizes specifically to the plasma membrane of the sperm head, overlaying the acrosome. Like rat, human NHE11 protein co-localizes with the acrosomal granule of developing spermatids. The localization of NHE11 to the sperm head is significant because there are no known NHEs shown to localize to the head of mature sperm. Our group's work to characterize the expression and localization of SLC9C2 (NHE11) suggests that this protein is likely important in mammalian sperm physiology.

B644/P3021

Identification of cadherin superfamily RNA and protein in the sea star mature egg

A. Whetzel, D. J. Carroll; Midwestern University, Glendale, AZ

Little is known about how sperm and egg interact at fertilization and initiate egg activation. In the sea star, the sperm protein bindin interacts with the egg bindin receptor EBR1, but it is unlikely that these interactions alone are sufficient for successful fertilization. To identify other potential egg cell surface proteins that could play a role at fertilization, the sea star mature egg transcriptome was examined for

the expression of RNAs encoding cadherins. The sea star is a useful model system with abundant, synchronized oocytes that can be easily collected and manipulated. Cadherins are a family of Ca^{2+}-dependent proteins involved in cell-cell adhesion and signal transduction. Outside of a few model systems, little is known about their expression in germ cells or their role in fertilization. There are thought to be over 100 different types of cadherins found in vertebrates. The shared features include at least two extracellular Ca^{2+}-binding domains called the *cadherin repeats*, a transmembrane domain, and a short cytoplasmic tail. Cadherin mRNAs in the sea star egg were discovered by examining orthologs of known cadherins in a mature sea star egg transcriptome (Accession PRJNA398668). Putative cadherin RNAs were identified using the National Center for Biotechnology Information (NCBI) tblastn software with known vertebrate cadherin proteins as the target sequences. The putative proteins were predicted using Open Reading Frame finder (ORFinder) followed by blastp against the NCBI nonredundant protein database. From 22 unique vertebrate cadherin sequences, six different cadherin RNAs were identified in the *Patiria miniata* egg transcriptome. The smallest is a protocadherin Fat 1-like isoform with an RNA open reading frame (ORF) of 5445 nucleotides and a predicted protein of 1814 amino acids and the largest a protocadherin Fat 4-like isoform with an RNA ORF of 15096 nucleotides and a prediction protein of 5031 amino acids. Expression of these transcripts was confirmed by RT-PCR with RNA freshly isolated from *P. miniata* eggs. Protein expression of one of the cadherins was subsequently verified via immunoblotting oocyte and egg protein with an antibody directed against vertebrate protocadherin-10. The discovery and detection of cadherins in the sea star egg provides beneficial information for future functional studies of the fertilization pathway.

B645/P3022

Identification of Receptor Tyrosine Kinase family RNAs expressed in the sea star mature egg

A. Holden, A. Whetzel, D. Carroll; Midwestern University, Glendale, AZ

Ca^{2+} release is regulated by Src kinases and PLCγ leading to IP3 production. The molecules upstream of this signaling pathway, including those at the cell surface that may interact with the fertilizing sperm, are unknown. Since Src family tyrosine kinases and PLCγ are known to be regulated by receptor tyrosine kinases (RTK), we identified the RTK mRNAs that are expressed in the sea star egg by searching for orthologs of known RTKs in the mature sea star egg transcriptome (Accession PRJNA398668) using the National Center for Biotechnology Information (NCBI) tblastn software. Putative proteins were predicted using ORFinder followed by blastp against the NCBI nonredundant protein database. Representative orthologs of each of the 20 known subfamilies of mammalian RTKs were found in the *Patiria miniata* transcriptome with varying degrees of similarity. Expression of these sea star RNAs was confirmed using RT-PCR on freshly isolated sea star egg mRNA. The percent identity between the putative sea star protein and the human orthologue can be very high, close to 50% in some cases, such as with the tyrosine-protein kinase transmembrane receptor Ror1, a protein that may function to inhibit WNT-mediated signaling. The largest RTK open-reading frame discovered shared 31% percent identity with the protooncogene Orphan receptor tyrosine kinase ROS1, with a length of 10,761 nucleotides and an *in silico* predicted protein of 2513 amino acids. Additional findings include an 81% identity match in the sea star transcriptome with the ErbB2 RTK which is a member of the epidermal growth factor family, known for its role in regulating cell proliferation. The fibroblast growth factor receptor also displayed a high percent match of 42% in the sea star transcriptome with a length of 4310 nucleosides. Domain analysis using the NCBI CDD (conserved domain database) shows that the predicted sea star proteins possess similar, or identical, domain architecture to their mammalian orthologs. Future experiments will focus

on determining which of these are translated into proteins in the egg using western blotting and commercially available anti-RTK antibodies, and which may play a role at fertilization by the production of recombinant dominant-negative constructs for injection into the mature eggs.

Mapping CBD-1 domains responsible for vitelline layer protein recruitment during *C. elegans* eggshell assembly

A. Wang, J. Prieto, S. K. Olson; Pomona College, Claremont, CA

To defend the embryo from polyspermy and foreign substances, the extracellular matrix of *C. elegans* oocytes undergoes rapid remodeling to form an impermeable protective eggshell after fertilization. Chitin-binding domain protein 1 (CBD-1), responsible for independently anchoring the EGG complex (EGG1-5/CHS-1/MBK-2) and the PERM complex (PERM-2/PERM-4) to the outermost vitelline layer, is crucial for eggshell formation. While previous studies indicate the PERM complex is reliant on the N-terminus of CBD-1 for proper localization, little is known about the relative contributions of CBD-1's various chitin-binding domains, interdomain loops, and predicted mucin chain sites to PERM-2 and PERM-4 recruitment. Fluorescence microscopy of CRISPR-generated *cbd-1* mutants revealed that removing chitin-binding domains 3 and 4 resulted in reduced and irregular recruitment of PERM-2::mCherry along oocyte and embryo surfaces, while loss of individual loops between chitin-binding domains 3-4, 4-5, 5-6, and 8-9 did not affect localization along oocyte membranes. In embryos, however, loop 4-5 knockout mutants exhibited a similar phenotype as domain 3-4 knockout mutants, with PERM-2::mCherry failing to be recruited to, or retained on, the eggshell. Further experiments to determine effects on PERM-4 and EGG complex binding will help to elucidate how vitelline protein binding domains contribute to vitelline layer remodeling.

B647/P3024

Mitotic Regulation in *Drosophila* pole cells

C. Smits[1], H. Nunley[2], E. Gavis[1], S. Shvartsman[1,2]; [1]Princeton University, Princeton, NJ, [2]Flatiron Institute, New York, NY

The proper development of an embryo often requires careful regulation of the timing and number of mitotic divisions. Here, we focus on mitotic regulation in the precursor cells to the germline in *Drosophila*: the pole cells. Pole cells are the first cells to form during embryogenesis, when syncytial nuclei migrating outward from the center of the embryo enter a specialized cytoplasm, the germ plasm, at the posterior of the embryo. Approximately 6 nuclei then bud out and form complete cells, while the somatic nuclei remain in a syncytium and continue to divide synchronously. The pole cells divide approximately 2 times (with some variability), eventually forming a cluster of ~30 cells that arrests in G2 and becomes quiescent until later stages of development. While many of the components and processes that lead to this specialized behavior have been well characterized, much of the previous research has relied on fixed embryos, precluding our ability to characterize single cell dynamics and understand how divisions are regulated in real time. Here, we use light sheet microscopy to visualize the process of pole cell formation and subsequent divisions in living embryos. Through our analysis of endogenously tagged Cyclin E-sfCherry, along with the pole cell marker Vasa-GFP, for each embryo we construct a forest of lineage trees, each tree corresponding to the lineage of a single pole bud. We first test whether one pole bud's tree affects the trees of other buds; for example, over-proliferation of one bud's tree may cause

under-proliferation in others. Then, using Cyclin E and Vasa levels, we test whether we can relate cell cycle asynchrony between daughters in a tree to unequal sharing of germ plasm at division. Our study sheds light onto how the number of proliferative divisions in this small population of cells is controlled during development.

B648/P3025

Investigating the role of a novel secreted protein in sperm development and fertilization in *C. elegans*

M. Hwang, **S. K. Olson**; Pomona College, Claremont, CA

Fertilization is an essential process in sexual reproduction where sperm and egg fuse together to create the next generation. Successful fertilization requires the proper development of gametes and subsequent sperm-egg recognition, binding, and fusion. Despite the importance of fertilization, the molecular underpinnings of this process remain elusive. In the nematode *Caenorhabditis elegans*, the specific proteins that govern sperm-egg fusion have not yet been described. We recently identified an uncharacterized gene, *spe-61*, that results in a sperm-specific fertility defect when a null mutation was introduced by CRISPR-Cas9 gene editing. *spe-61* is predicted to encode a secreted extracellular protein expressed specifically in the spermatheca. We are currently characterizing the localization pattern of a CRISPR-generated SPE-61::mScarlet fusion protein to better understand its site of action. Brood count assays led to the classification of the SPE-61 mutant as a spermatogenesis defective (SPE) mutant due to an observed low progeny count and abundance of unfertilized oocytes on the plate. The fertilization defect was rescued by mating with wild-type males, demonstrating that the *spe-61(null)* phenotype is specifically due to a sperm defect. We also found that *spe-61(null)* male and hermaphrodite mutants make spermatids that are morphologically normal and can properly differentiate into spermatozoa. Future studies will characterize sperm motility and migratory behavior, sperm competition, and sperm-egg interactions. This work will contribute to our understanding of the genes that play a role in spermatogenesis, spermiogenesis, and/or fertilization. In addition, the determination of the specific role of SPE-61 in fertilization may offer important insights into fertilization mechanisms across evolution, particularly as few fully secreted sperm proteins have been implicated in sperm-egg interaction to date.

B649/P3026

Investigating the functional role of PERM-2 and PERM-4 amyloidogenic domains in *C. elegans* eggshell vitelline layer assembly

Y. Alcaraz, **E. Sisay**, J. Carranza, S. Olson; Pomona College, Claremont, CA

C. elegans embryos are protected during early development by a multilayered eggshell, the outermost layer of which is called the Vitelline Layer. We are interested in exploring vitelline layer structure due to its importance in promoting fertilization, polyspermy prevention, egg activation, and eggshell barrier assembly. Previous work from our lab showed that the vitelline layer is comprised of at least three proteins, with CBD-1, PERM-2, and PERM-4 assembling together to build a structural barrier that prevents diffusion of high molecular weight compounds. To better understand how CBD-1, PERM-2, and PERM-4 interact to build the vitelline layer, we used the protein prediction programs PASTA and AmylPred to identify domains in each protein that may promote homo- and hetero-polymerization. Both PERM-2 and PERM-4 contain putative aggregation-prone and amyloidogenic domains, reminiscent of similar domains found in the ZP1-3 proteins that polymerize to form the mammalian zona pellucida. We therefore deleted the putative PERM-2 and PERM-4 aggregation domains using CRISPR-Cas9 in order to

investigate how these domains impact protein localization to the vitelline layer, eggshell integrity, and embryonic viability. Deletion of amino acids 161-184 in PERM-2 (the putative aggregation domain) prevented both PERM-2::mScarlet$^{\Delta 161\text{-}184}$ and PERM-4::mScarlet from localizing to the vitelline layer. Likewise, deletion of amino acids 70-86 in PERM-4 prevented PERM-2::mScarlet and PERM-4::mScarlet$^{\Delta 70\text{-}86}$ localization. However, CBD-1::GFP localization was not affected by the PERM-2 $^{\Delta 161\text{-}184}$ or PERM-4 $^{\Delta 70\text{-}86}$ domain deletions. These data suggest that CBD-1 serves to recruit PERM-2 and PERM-4, while PERM-2 and PERM-4, via their aggregation-prone domains, recruit and/or maintain each other on the vitelline layer. The *perm-2* $^{\Delta 161\text{-}184}$ and *perm-4* $^{\Delta 70\text{-}86}$ mutants also exhibited reduced brood sizes, similar in magnitude to those of *perm-2(null)* and *perm-4(null)* mutants, further highlighting the importance of the aggregation domains in PERM-2 and PERM-4 function. To further explore the role of the aggregation/amyloidogenic domains and determine whether PERM-2/4 assembly mirrors that of the mammalian ZP1-3 proteins, we are currently using CRISPR to mutate Cysteines predicted to be involved in stabilization of the domain structure via disulfide bridges. This work is crucial to understanding nematode fertilization and early embryonic development, and to identifying reproductive mechanisms that have been conserved or have diverged across evolution.

Identifying Genes Required for Nuclear Rejuvenation during Gametogenesis

B. Styler; University of California, Berkeley, Berkeley, CA

Lifespan is reset during gametogenesis. In budding yeast, senescence-associated factors are excluded from gametes through sequestration into a distinct nuclear envelope-bound compartment, known as the Gametogenesis Uninherited Nuclear Compartment (GUNC). This compartment is subsequently degraded through vacuolar lysis, contributing to cellular rejuvenation. However, the mechanism by which age-induced damage is selectively sequestered into the GUNC remains unknown. To approach this question, we are developing a genetic screen that aims to identify factors involved in GUNC compartmentalization and selective nuclear inheritance. The screen will be conducted by targeting a plasmid containing a selectable marker to the GUNC and using the yeast deletion collection to identify genes required for plasmid sequestration and subsequent elimination. To target the plasmid to the GUNC, we engineered a conditionally-excisable centromere, thereby mimicking an extrachromosomal circular DNA (ecDNA) from the rDNA locus that normally accumulates in aged cells but is excluded from gametes. However, this alteration alone is not sufficient to mimic ecDNA. To improve plasmid exclusion from gametes, we fused aggregate-prone nucleolar proteins to the plasmid. Excitingly, one such fusion enhanced plasmid exclusion by 2-fold. In parallel, we employed a candidate-based approach to determine whether genes involved asymmetric segregation during mitosis are also required for exclusion of senescence-associated factors during gametogenesis. Together, these approaches offer a mechanistic understanding of how gametes can become devoid of age-induced nuclear defects.

Tissue Development and Morphogenesis 2

B651/P3028

Mechanistic Understanding of Transepithelial Fluid Transport

M. Chugh, S. Megason; Harvard Medical School, Boston, MA.

Morphogenesis, the process by which tissues develop into functional shapes, requires coordinated mechanical forces. Most current literature ascribes contractile forces derived from actomyosin networks as the major driver of tissue morphogenesis. Recent works from diverse species have shown that pressure derived from fluids can generate deformations necessary for tissue morphogenesis. Here, using zebrafish inner ear morphogenesis and its fluid filled lumen as a model system, I aim to tackle one of the long standing questions in physiology: how does fluid/water transport occur across epithelia? Several models for water movement across epithelia have been proposed, but their accuracy in mature physiology and especially in development remain unclear. By employing high spatiotemporal live imaging and quantitative analysis, I aim to tease apart real time water transport across inner ear epithelia and its regulation. Water transport and induced hydrostatic pressure in interstitial spaces and epithelial lumens can help us uncover new principles of tissue organisation during development and disease.

Engineering septin disease alleles in *C. elegans*

J. A. Perry, D. E. Sloan, A. Brown, A. S. Maddox; Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Cell function and tissue integrity rely on the maintenance of cell shape and organization. The cytoskeleton, consisting of polymers and motor proteins, serves to structure and remodel the cell and determines tissue architecture. A highly conserved family of GTP-binding proteins called septins forms filaments and other higher-order structures, including gauzes and rings, from the non-polar arrangement of core proteins (ex. ABCDDCBA). Many cellular functions, including cell division and cell motility, are thought to involve the septin higher-order structures, where they serve to scaffold and recruit or sequester other proteins at the plasma membrane. Septin dysregulation by mutation or abnormally high or low expression occurs in many human diseases, including cancer, fibrosis, and neuropathies. Yet, how septin perturbation influences disease is unknown. A significant obstacle to defining septins' role in human health and pathology is the number of septin genes encoded in the human genome (13, some of which also have splice isoforms). Additional complexity arises from the functional substitution of septins within each of the four subfamilies. By contrast, the simple model animal *Caenorhabditis elegans* has only two septins. *C. elegans* septins, like septins in other species, can form filaments and localize to the cytokinetic ring during cell division. This project aims to understand how septins contribute to cell and tissue behavior and organization through the creation of transgenic *C. elegans* "avatars" containing septin mutations in conserved residues and mutations derived from human disease septin alleles. The phenotype of the *C. elegans* avatars will be compared to that of septin-null worms and previously characterized septin loss-of-function alleles. Preliminarily, we found that septins are required for normal development and function of the *C. elegans* germline, which is a simple single-cell model for stem cell biology, cell migration, and the regulation of cell cycle progression and differentiation. *C. elegans* bearing septin mutations have reduced brood size and oocyte production.

Mutant septin germlines also develop more slowly than control, perhaps indicating a defect in cell proliferation. Using *C. elegans* to study septin mutation will elucidate how septin dysfunction perturbs cell and tissue organization, with the long-term goal of providing insights into human development and disease.

Modeling epithelial tissue as a 3D, self-sculpting, viscoelastic slab with active surfaces

X. Du, M. Shelley; Flatiron Institute, New York, NY.

During morphogenesis, epithelial monolayers actively alter their shape to create future body parts of metazoans; this makes the epithelium one of the most active and critical structures in early animal development. Even though epithelial cells exist and move in three dimensions, mathematical models frequently describe them as merely two-dimensional. However, recent imaging technology has begun to reveal pertinent dynamics in the third dimension of the tissue. With the importance of the third dimension in mind, we have developed a self-sculpting, three-dimensional, computational model of epithelia whose dynamics are driven by active forces on its surface. We present an initial, fundamental study for a reduced version of an epithelia that investigates how surface forces affect its internal dynamics. Our model captures the 3D slab-like geometry of epithelia, viscoelasticity of tissue response, fluid surroundings, and driving from active surface forces. We represent epithelial tissue as a thick slab, a 3D continuum comprised of a viscous Newtonian fluid with an extra viscoelastic stress. Employing this model, we simulate and make quantitative predictions about 3D cell dynamics and cell shape deformations as they respond to surface forces in common morphological contexts. In particular, we elucidate the initiation of ventral furrow invagination and T1 transitions in Drosophila embryogenesis. In the former, we demonstrate the importance of fluid and geometric surroundings to drive invagination. In the latter, we show the limitations of surface forces alone to drive T1 transitions. Our methods allow for detailed, physics-based studies of animal morphogenesis in 3D that includes the full geometric, fluid context of live systems.

B654/P3031

Cell contacts undergo systematic planar angle rotation, continually replenishing the pool of contractile junctions and mechanistically contributing to tissue elongation in the early Drosophila embryo

T. Vanderleest[1], **L. J. Russell**[1], K. Bond[2], H. Miao[3], Y. Xie[3], J. T. Blankenship[3], D. Loerke[2]; [1]Biological Sciences, Physics and Astronomy, University of Denver, Denver, CO, [2]Physics and Astronomy, University of Denver, Denver, CO, [3]Biological Sciences, University of Denver, Denver, CO.

Tissue elongation through epithelial remodeling during morphogenesis is a fundamental process that occurs through dynamic cell behaviors. In the early *Drosophila* embryo, tissue elongation is achieved through organized cell intercalation through directional t1-transitions. Previous work has suggested that the initialization of planar polarity within the epithelial sheet creates an initial population of vertical cell-cell contacts/interfaces (aligned with the dorsal-ventral axis) that undergoes a single round of contraction into higher-order vertices, followed by the resolution of these vertices into new horizontal interfaces (aligned with the anterior-posterior axis) which promotes tissue elongation. Here, we show that the dynamics of specific interfaces - i.e. contraction/elongation behaviors - are not specified permanently by a single initialization event at the beginning of germband extension, but that the planar polarity of interface behaviors is instead continuously re-interpreted on the basis of planar orientation

angle. In addition, our data shows that interfaces systematically and continuously rotate from horizontal towards more vertical orientations. Intriguingly, as these individual interfaces change their orientation, their contraction or elongation behaviors also change, demonstrating an ongoing dynamic 'rectification' mechanism. These changes in interface behaviors are also observable at the level of molecular machinery that directs contractile behaviors, with rectifying interfaces acquiring Myosin II as they approach more vertical orientation angles. Disruptions to the contractile molecular machinery, namely in F-actin and Myosin II function, show reductions in rotation rates, consistent with rotation being driven, at least in part, by interface contraction. These data demonstrate that intercalation and planar polarity are continuous processes that are constantly updated within the tissue context. As a result of the angular rectification, cells in the germ band can have several interfaces that acquire a contractile identity over time, meaning cells are continually "refreshing" T1 interfaces that can then participate in multiple staggered rounds of oriented neighbor exchange to produce higher net tissue extension.

B655/P3032

Tissue Structure and Cell-cell Adhesion of the Fully Elongated Amnioserosa in the *Drosophila* Embryo

T. Ray, T. J. C. Harris; Cell and Systems Biology, University of Toronto, Toronto, ON, CANADA.

Epithelia are crucial for embryogenesis and exhibit diversity in the way they are shaped and arranged. Significant literature exists on the contribution of tall, or columnar, epithelial cells to embryogenesis through the cell shape changes, cell division, and neighbour exchanges that are often mediated through actomyosin activity. However, other types of epithelial cells are less understood. For example, the Drosophila embryo amnioserosa (AS) forms a squamous epithelium made up of elongating spindle-like cells that facilitate germ band extension, and later reshape themselves for germband retraction and dorsal closure. What are the tissue structure and cell adhesion properties of the fully elongated AS? We imaged multiple probes by confocal microscopy to characterize fully elongated AS tissue structure. Plasma membrane probes showed long, spindle-like cells that taper both laterally and in depth to points at either end of each cell. Probing the nuclei showed pseudostratification, with some nuclei at the tissue surface and others below tapered ends of neighbouring cells. Strong microtubule (MT) bundles were parallel to and concentrated at the level of adherens junctions (AJs), with both running the full length of the cells. Investigating these long AJs began with Canoe, a probe for tension at AJs, which was found accumulated only at the tips of elongated amnioserosa cells, whereas its bi-cellular junction levels were less than those of epidermal cells. Maternal knock down of α-catenin, a component of AJs that binds F-actin and Canoe, surprisingly revealed that E-cadherin was retained at AS AJs but strongly disrupted at epidermal AJs. Although AS cells still elongated in α-catenin RNAi embryos, they were no longer aligned in the same direction, possibly due to a non-autonomous effect of the germband disruption. With α-catenin depletion, AS cells also showed retention of MTs and the junctional organizer Bazooka at AJs. When depleted of Bazooka, AS cells showed a breakdown of AJs and disorganized MTs. Probing for Bazooka localization showed a unique distribution of large puncta along move evenly distributed AS AJs. Overall, my project highlights a unique organization of an elongated and pseudostratified epithelium with AJs that rely less on a tension-based α-catenin mechanism and more on a Baz-dependent mechanism.

Rab11 direction of lumen formation and pancreatic morphogenesis is required for proper cell differentiation

H. R. Barlow, N. Ahuja, L. Fassetta, Y. Htike, T. Bierschenk, D. Marciano, O. Cleaver; UT Southwestern Medical Center, Dallas, TX.

The molecular links between epithelial lumenogenesis, cell shape determination and the resulting tissue-level morphogenesis remain murky despite decades of rigorous studies. Here we describe a double knockout of Rab11A and Rab11B (Rab11) in the developing murine pancreatic epithelium that disrupts all three of these processes. Rab11-null pancreata are unable to form or connect their lumens. This is due at least in part to failures in vesicle trafficking, as apical components remain trapped within Rab11-null cells. Furthermore, these cells have severe defects in coordinating singular apical membrane initiation sites between groups of cells. In addition to polarity and lumenal defects, Rab11-null cells are significantly rounded, and the structure of acinar rosettes is disrupted. All these deficiencies combine to cause significant morphogenetic defects that eventually lead to a severe skewing of cell fate determination in the developing pancreas. These observations suggest Rab11 is indirectly or directly regulating lumenogenesis, cell shape and cell fate specification. These findings begin to link a number of cellular processes in vivo, and present tantalizing possibilities for decoding pancreatic morphogenesis.

Transcriptional profiles along cell programming into corneal epithelial differentiation

M. T. Ortiz Melo[1], M. J. Garcia Murillo[1,2], V. M. Salazar Rojas[3], J. E. Campos Contreras[3], F. Castro-Munozledo[2]; [1]FES Iztacala, UNAM Universidad Nacional Autonoma De Mexico, Mexico, MEXICO, [2]Department of Cell Biology, Centro de Investigacion y de Estudios Avanzados del IPN (CINVESTAV), Mexico, MEXICO, [3]UBIPRO, FES Iztacala, UNAM Universidad Nacional Autonoma De Mexico, Mexico, MEXICO.

To study the transitional stages along the differentiation of corneal epithelial cells and discern its differential regulation, we used cultured RCE1(5T5) cells, which reproduce in vitro the developmental stages of corneal epithelial cell differentiation, as a model. We analyzed three differentiation stages based on the growth state of the cells and after studying the expression of transcription factors such as Oct4, Pax6, ΔNp63α, and selected differentiation, signaling, and epigenetic markers. Namely, proliferative non-differentiated cells, committed cells, and cells that constitute a stratified epithelium with a limbal epithelial-like structure. RNAseq-based transcriptome analysis showed 4891 genes differentially expressed among these stages, displaying distinctive gene signatures: proliferative cells had 1278 genes signature and seemed to be early epithelial progenitors with Oct4+, KLF4+, Myc+, ΔNp63α+, ABCG2+, Vimentin+, Zeb1+, VANGL1+, Krt3-, Krt12- phenotype. Committed cells with 417 genes as signature, displayed markers indicative of the beginning of corneal differentiation and genes characteristic of proliferative cells; with possible participation of Six3 and Six4 transcription factors along this stage. The third stage matches with a stratified corneal epithelium (979 genes signature), showing an increase in the expression of WNT10A, NOTCH2, NOTCH3, and Cux1, besides Pax6, KLF4, or Sox9. The differentiated cells express about 50% of the Epidermal Differentiation Complex (EDC) genes. Analysis of differences between corneal epithelium and epidermis could be crucial to understanding the regulatory mechanisms of the differentiated phenotype.

Radial astroglia form large spherical structures during development in the zebrafish optic tectum

H. M. Barber[1,2], S. Kucenas[3,2,1]; [1]Cell & Developmental Biology Graduate Program, University of Virginia, Charlottesville, VA, [2]Program in Fundamental Neuroscience, University of Virginia, Charlottesville, VA, [3]Department of Biology, University of Virginia, Charlottesville, VA.

Radial glia (RG) are bipolar cells with long radial processes which serve as precursors for both neurons and glia. In zebrafish, RG persist into adulthood and share many properties with mammalian astrocytes, including interactions with blood vessels and neurons. In the zebrafish optic tectum (OT), RG bodies line the ventricular surface and extend long processes towards the pial surface, where they elaborate extensively. Using *in vivo,* time-lapse imaging of *Tg(slc1a3b:myrGFP-P2A-H2AmCherry)*-expressing zebrafish larvae, we observed OT RG extending projections from their pial processes basally towards the ventricular zone. These small processes often formed large spherical structures, measuring approximately 3 to 7 micrometers in diameter and lasting up to 6 hours before dissipating. Currently, the identity and function of these projections are unclear. Using molecular characterization, we have begun assaying the nature of this developmental phenomenon. From our preliminary data, at least some of the spherical structures contain markers of neuronal nuclei and dying cells but not of phagosomes. Due to their shape, size, movement, and containment of other cell nuclei, we tentatively dub these structures “scyllate heads”, in reference to the multi-headed Odyssean figure Scylla. Here we present our preliminary investigations and descriptions of OT RG scyllate heads. Due to an observed association with microglia, we hypothesize that scyllate heads sequester developmental debris, including exuberant neurons, for later phagocytosis by professional phagocytes.

B659/P3036

TEX264 induces reticulophagy in human keratinocytes to drive degradation of the endoplasmic reticulum during epidermal differentiation

C. Johnson, A. Tiwaa, **C. L. Simpson**; University of Washington, Seattle, WA

Formation of the cutaneous barrier depends upon a unique program of cellular differentiation termed cornification. As maturing keratinocytes reach the outermost layers of the epidermis, they initiate wholesale organelle breakdown to generate compacted cellular sheets that form a protective shield for the body. The mechanisms regulating organelle degradation during epidermal development remain unclear, but could reveal novel strategies to augment skin barrier function and restore tissue integrity in disorders of cornification. Our prior work uncovered that human keratinocytes engage the autophagy machinery via the mitophagy receptor NIX and the GTPase DRP1 to degrade mitochondria during their final stage of differentiation. These findings led us to ask if keratinocytes utilize distinct autophagy receptors to orchestrate breakdown of other organelle compartments as they form the epidermal barrier. To examine organelle dynamics in a live stratified tissue model, we coupled spinning-disk confocal microscopy with three-dimensional organotypic cultures of human epidermis grown from primary keratinocytes. We found the endoplasmic reticulum (ER) undergoes fragmentation in the outermost cell layers and subsequent routing into lysosomes. Supporting our hypothesis that keratinocytes utilize selective autophagy to degrade the ER, we found the reticulophagy receptor TEX264 is upregulated in the outermost cell layers in RNA sequencing and protein expression data from both murine and human epidermis. Ectopic expression of TEX264 was sufficient to induce the formation of ER fragments, which colocalized with the autophagosome marker LC3. Moreover, mutation of its LC3-

interacting region abolished the ability of TEX264 to fragment the ER, confirming that interaction with Atg8 family proteins is essential to its function in keratinocyte reticulophagy. Finally, treatment with tunicamycin, which induces ER stress and reticulophagy, upregulated TEX264 expression in keratinocytes and resulted in reduced tissue thickness and premature cornification of organotypic cultures, suggesting precocious ER breakdown accelerates maturation of the epidermis. In sum, our findings establish that TEX264 functions as a reticulophagy receptor in keratinocytes and reveal a novel role for ER remodeling and degradation in epidermal morphogenesis.

B660/P3037

Fluid Pressure Promotes Morphogenesis of the Lung

C. M. Nelson; Princeton University, Princeton, NJ.

The embryonic lung is comprised of a hollow epithelium, which is filled with an aqueous fluid and surrounded by a loose mesenchyme. The initially simple epithelium ramifies into the more complex architectures of the mature lung to enable sufficient airflow and gas exchange after birth or hatching. Reciprocal interactions between the epithelium and its adjacent mesenchyme have long been known to be essential for instructing morphogenesis of the lung. However, mechanical forces from the non-cellular compartment of the embryonic lung - namely, the pressure and flow of the luminal fluid - also appear to play a critical role in regulating morphogenesis of both the epithelium as well as the mesenchyme. Here, we combined genetic, imaging, and microfluidic approaches to uncover the specific effects of luminal fluid pressure on lung morphogenesis in mammals and reptiles. Using transgenic and reporter mice, we found that luminal fluid pressure regulates the rate of airway branching morphogenesis in the embryonic mouse lung, in part by activating mechanical signaling through the Hippo pathway effector, Yap. Activation of Yap in the epithelium leads to an increase in retinoic acid signaling, which induces the mesenchyme to differentiate into airway smooth muscle, the stiffness of which sculpts the growing epithelium into branches. Surprisingly, Yap is also required within the mesenchyme itself, suggesting that forces from fluid pressure are transmitted between tissue compartments. We found a more direct role for luminal fluid pressure in morphogenesis of the embryonic lizard lung. Using the brown anole lizard and timelapse imaging analysis, we found that the epithelium dramatically inflates with fluid. The pressure of this luminal fluid transmits forces that direct the migration of the smooth muscle layer into a mesh. Fluid pressure then pushes the epithelium through the holes in the mesh to generate the gas exchange surface of the lung. These data suggest a conserved role for mechanical signaling downstream of fluid pressure in lung morphogenesis.

B661/P3038

Increased intracellular pH promotes cell death in the developing*Drosophila* eye

J. Reyna Pacheco, J. Mendez, D. Orozco, R. Soriano, B. Grillo-Hill; San José State University, San José, CA

Constitutively increased intracellular pH (pHi) is common to most cancers regardless of their tissue of origin or genetic background. Cancer research has traditionally focused on cancer-associated mutations and dysregulated signaling pathways. However much less is known about how changes in cellular chemistry, including pHi, regulate cancer cell behaviors. One objective of our current work is to understand how pHi dynamics influences growth control during development, as previous studies suggest that higher pHi inhibits cell death through apoptosis. Our lab developed tools to increase pHi in the absence of other transforming mutations by over-expressing the *Drosophila* sodium-proton

exchanger, *DNhe2*, in the *Drosophila* eye. We previously showed that flies overexpressing *DNhe2* have a "rough" or mispatterned adult eye. To determine the underlying cause of this rough eye, we examined fly eyes at two earlier stages of development (larval and pupal), and characterized cell morphology and quantified cell numbers. We previously showed that flies overexpressing *DNhe2* show increased proliferation in larval eye discs. Paradoxically, we found fewer cells at the end of patterning in pupal eyes (11.4 compared to 15 cells per counting area in control). We next tested whether this decrease in cell number was due to increased cell death. We found that the pH-dependent cell death is p53-dependent but caspase independent, which is inconsistent with apoptosis, but suggests autophagy. We are currently testing whether molecular markers of autophagy correlate with increased pHi. Second, we want to identify the genes that mediate this increased cell death at higher pHi. A dominant modifier screen identified overexpression of the oncogene *Myc* as a strong suppressor of the *DNhe2*-induced rough eye. We tested whether this suppression is due to Myc attenuating the hyperproliferative effects of over-expressing *DNhe2*, but we saw no effect. However, we found that co-expression of *Myc* inhibits the cell death seen with over-expression of *DNhe2*. Together, our findings elucidate mechanisms for pH-regulation of conserved, critical developmental processes and provide evidence for new paradigms in growth control.

B662/P3039

A zebrafish model of CREB3L1 loss and gain-of-function to elucidate the role of CREB3L1 in bone development and regeneration

P. VanWinkle[1], T. Nawara[1], H. Rosengrant[1], H. Thomas[2], E. Lee[1], J. Parant[2], E. Sztul[1]; [1]Cellular, Integrative, and Developmental Biology, University of Alabama- Birmingham, Birmingham, AL, [2]Pharmacology and Toxicology, University of Alabama- Birmingham, Birmingham, AL.

cAMP-responsive element binding protein 3-like-1 (CREB3L1) is a bZIP transcription factor highly expressed in osteoblasts during mammalian development. This is demonstrated in mice deleted of CREB3L1, as they exhibit a fragile skeleton, with poor fracture healing capacity. Further, human patients with homozygous CREB3L1 mutations exhibit severe osteogenesis imperfecta with multiple fractures and severe decreases in bone mineralization. Despite a clear role in mammalian bone physiology, our data demonstrate that zebrafish lacking CREB3L1 do not exhibit gross abnormalities in developmental osteogenesis typical of other zebrafish models of congenital bone disease. However, zebrafish have unique regenerative abilities in many tissues, including bone. To evaluate the role of CREB3L1 in bone regeneration, we utilized two strains of zebrafish: CREB3L1$^{-/-}$, which lacks CREB3L1 function, or CREB3L1$^{TA/TA}$, which express a constitutively active fragment of CREB3L1 under the endogenous CREB3L1 promoter. Via tail-fin transection, we evaluated the regenerative capacity of both CREB3L1$^{-/-}$ and CREB3L1$^{TA/TA}$ fish. We observed an overall decrease in regeneration in the CREB3L1$^{-/-}$ fish, although physiological morphology of the bones was maintained. In contrast, fish expressing the constitutively active (TA) CREB3L1 fragment showed gross abnormalities in the regeneration of the fin, including fin ray fusion and malformation. Bone regeneration is an important topic in overall bone health, with applications to both traumatic and degenerative bone pathologies. The role of CREB3L1 in regeneration of whole bone has yet to be evaluated and as such, our model will help to elucidate the specific physiological function of CREB3L1 in regenerating bone tissue.

B663/P3040

Characterization of Intermediate cells during epidermal development

A. Prado Mantilla[1], W. Ning[2], T. Lechler[1]; [1]Cell Biology and Dermatology Department, Duke University, Durham, NC, [2]School of Life Sciences, Yunnan University, Kunming, Yunnan, CHINA.

The main role of the skin is to function as a barrier keeping external pathogens/toxins out and moisture in. This barrier is formed in the late stages of epidermal stratification. In mice, this process starts at E14.5, when basal cells start to divide asymmetrically and form the first layer of suprabasal cells, a transient cell population called intermediate cells (ICs). Then, at E15.5, basal cells start to produce spinous cells which subsequently mature into granular cells and later into corneocytes that form part of the epidermal barrier by E17.5. The role of ICs in this process has gone largely unstudied. These cells have unique characteristics in the epidermis such as their ability to proliferate without being attached to the basement membrane, and while expressing differentiation markers like Keratin1/Keratin10. Understanding the mechanisms behind these unique epidermal features could be beneficial for clinical applications. The aims of this study are to characterize/find markers specific for intermediate cells and to understand their role in epidermal stratification. To explore the differences between proliferating ICs and postmitotic spinous cells at E16.5, we performed RNA-Seq analysis of FACS purified cells from both cell types. From these data sets, we got a list of candidate markers that were enriched in each cell population. By immunostaining, we validated that the transcription factor MafB is not expressed in ICs and is a good marker for spinous cells. Further, mis-expression of MafB in intermediate cells results in loss of proliferation. We also found markers of ICs by validating the mRNA expression of St8sia6 and Scara5 only in ICs using RNAscope. Furthermore, we detected that transglutaminase1, an important protein for epidermal barrier formation expressed in granular cells, was expressed in ICs but not in spinous cells at E16.5. In addition, we did a gene ontology enrichment analysis of biological processes upregulated in ICs. We found that some of their enriched pathways were reminiscent of granular cell function, like establishment of skin barrier and lipid metabolic processes. Currently, the theory in the field is that ICs become spinous cells before maturing into granular cells. However, when we traced IC cell fate through EdU-pulse labeling, we found that ICs directly transitioned to granular cells without first expressing markers of spinous cells. Altogether, this suggests that, unlike the sequential cell maturation that happens in adults, ICs did not mature into spinous cells before becoming granular cells. Thus, ICs are precursors of the first granular cells during epidermal development.

Alcohol consumption in mice during puberty affects the normal development of the mammary gland

M. Dunbar, I. Shibley; Pennsylvania State Univ/Berks Campus, Reading, PA

Alcohol consumption by women is associated with an increased risk of breast cancer. While many studies have examined the effect of alcohol on the mature mammary gland, little is known about the effects of alcohol on the developing mammary gland. While it is becoming increasingly clear that early exposure to alcohol, especially during puberty, can affect a woman's lifetime risk of breast cancer, the mechanisms remain unknown. In the present study, we studied the effect of alcohol consumption on the pubertal development of the mouse mammary gland. Three-week-old female mice were fed a liquid diet containing ethanol at 0, 10 or 20% of calories throughout puberty. Structural development of the mammary glands was examined by whole mount analysis of the #4 inguinal gland. Alcohol treatment resulted in a significant increase in the overall length of epithelial ducts as well as the number of

terminal end buds and branch points of 8-week old mice. Additionally, there was a significant increase in the more mature alveolar bodies in mice that consumed 20% of calories of ethanol when compared to control mice. Proliferation of mammary epithelial cells in the TEB was increased in alcohol fed mice, as measured by BrdU incorporation. Previous studies have shown that overexpression of parathyroid hormone related protein (PTHrP) in the mammary gland inhibits estrogen induced growth of the mammary gland during puberty. Therefore, we were interested in determining what effect alcohol would have on the pubertal development in PTHrP-overexpressing mice. Interestingly, there was no difference in duct length, TEB number or epithelial proliferation in alcohol fed PTHrP-overexpressing mice when compared to pair fed controls. Together, these studies suggest that alcohol exposure during pubertal development alters the normal development of the mammary gland perhaps by interfering with estrogen signaling.

Developmental reprogramming of adipose tissue by maternal obesity.

M. BISWAS[1,2], S. Bayar[1], I. Splichalova[1], J. Zurkovic[3], C. Thiele[3], F. Shakeri[4], A. Buness[4], A. Pfeifer[2], E. Mass[1]; [1]Developmental Biology of Innate Immune System, LIMES Institute, Bonn, GERMANY, [2]Institute of Pharmacology and Toxicology , University hospital of Bonn, Bonn, GERMANY, [3]Biochemistry and cell biology of lipids, LIMES Institute, Bonn, GERMANY, [4]Institute for Genomic Statistics and Bioinformatics, University hospital of Bonn, Bonn, GERMANY.

Background: Macrophages have different developmental origin such as yolk sac derived tissue resident macrophage and bone marrow derived, monocyte derived macrophage. Adipose tissue macrophages (ATMs) are the predominant immune component in adipose tissue and they govern the metabolic fate of white adipose tissue (WAT), depending on their ontogeny. We propose that maternal obesity can impart unfavorable effects on the metabolic profile of offspring by developmental reprogramming of these adipose tissue macrophages. Our objective is to show these macrophages undergo chronic immune activation, possible epigenetic changes and pathological activation of specific signaling pathways such as Hif1a signaling and affects adipose tissue development and function, thereby contributing to the pathogenesis of metabolic diseases in offspring's later life. **Material & methods:** We created different dietary conditions consisting of maternal and post-weaning diet in mice. We used conditional HIF1α knockout mice model and studied effects of macrophages on the adipose tissue microenvironment in homeostasis, metabolic stress and maternal metabolic challenge. We used high dimensional flow cytometry and morphological assessment by histology, quantified by a specific machine learning algorithm. **Results:** Using specific immune markers, we could identify distinct subsets of macrophages and monocytes. Specific macrophage subsets like Tim4- macrophages and monocytes were associated with obese and maternal obese animals. Interestingly, adipocytes in the corresponding animals showed statistically significant increase in size. This adipose tissue hypertrophy was rescued by specific knockouts of HIF1α signaling in macrophages. Lipidomic analysis identified specific lipid subclasses associated with the maternal obese group. **Conclusion**: Maternal obesity modulates the metabolic profile in offspring and adipose tissue macrophages play a key role in it. Identifying specific genes or proteins responsible for expression of specific macrophage phenotypes can pinpoint potential therapeutic targets for obesity.

Characterization of irregular chondrocyte stacking during craniofacial development in a zebrafish model of *cblC* syndrome.

B. E. Pinales, D. Paz, B. S. Castellanos, N. G. Reyes-Nava, L. Jimenez Madrigal, I. Perez, V. L. Castro, A. M. Quintana; University of Texas at El Paso, El Paso, TX

Methylmalonic aciduria and homocystinuria, cblC type (*cblC*) is a multiple congenital anomaly syndrome caused by mutations in the *MMACHC* gene, which encodes an enzyme required for B12 metabolism that, when mutated, causes an accumulation of toxic metabolites, specifically, methylmalonic acid (MMA) and homocysteine (HC). Additional phenotypes of *cblC* include microcephaly, neurological abnormalities, hematological manifestations, ocular deficits, and craniofacial dysmorphia. Although craniofacial abnormalities are not typically regarded as a hallmark of *cblC*, a subset of individuals have been reported with these phenotypes. The deletion of *Mmachc* in mice is embryonic lethal, and therefore, craniofacial phenotypes have not been fully characterized. Specifically, it is unknown whether the accumulation of MMA/HC is a prerequisite for craniofacial deficits associated with the mutation of *MMACHC*. Here we used a zebrafish model of *cblC* syndrome to determine metabolic accumulation in relation to the onset of craniofacial phenotypes. MMA levels were measured at 1-, 3-, and 6-days post fertilization (DPF) and facial development was evaluated at 1-, 2-, and 5-DPF. Our findings revealed moderate craniofacial anomalies such as increased Meckel's cartilage protrusion from the ceratohyal, increased palatoquadrate width, and irregular chondrocyte organization between neighboring chondrocytes in the hyosymplectic cartilage region. These moderate phenotypic modifications did not cause gross morphological defects in craniofacial development but were highly penetrant and were restored by a ubiquitin driven *MMACHC* transgene. Most fascinating was the fact that site-directed mutagenesis of the MMACHC cobalamin binding domain did not affect the ability of MMACHC to restore chondrocyte development to normal levels. Collectively, these data suggest that *mmachc* regulates craniofacial development independent of cobalamin binding and in the absence of accumulation of MMA.

Bisphenol A Exposure During Pregnancy until Lactation Affects Expression of Androgen Receptor in Adult Gerbil Prostate and Impairs Sperm Motility

S. J. Colleta, T. F. R. Ruiz, V. Reame, S. R. Taboga; Universidade Estadual Paulista "Júlio De Mesquita Filho" - UNESP, São José do Rio Preto, Brazil

Estrogens are crucial for sexual differentiation and modulation of sexual organs. Bisphenol A (BPA) has estrogens effects and act as an endocrine disruptor on reproductive system. This experiment was aimed to test whether gerbil (*Meriones unguiculatus*) exposure to bisphenol-A, on gestacional to lactation period, could cause impacts on ventral prostate in adulthood. For this, gerbil females were allocated with fertile males, randomly divided into 4 experimental groups: control (**C**) gavage free; oil control (**CO**) gavage vehicle; low dose (**LBPA**) (50 µg/kg BPA) and high dose (**HBPA**) (5000 µg/kg BPA) - the BPA was dilute in corn oil (0.1 ml), the pregnant gerbils were gavage daily, from the 8th day of gestation until lactation end. The male offspring were allocated in insulators until 90 days-age and then euthanized. Sperm motility was performed. Prostate was removed, weighted, fixed in 4% paraformaldehyde and processed in histology and immunohistochemistry (IHC) routines. Testosterone (T) and estradiol (E2) were analyses by ELISA in blood samples. Histological sections stained with Hematoxylin-Eosin were

used for the morphology, stereology and lesions analysis. IHC analysis for androgen receptor (AR) were performed. Quantitative analysis was based on parametric (ANOVA) and nonparametric (Kruskal-Wallis) tests for group differences. Exposure to BPA did not alter the body, ventral prostate and prostatic complex weight. BPA had a negative effect on sperm motility, **HBPA** group show a reduction in the rate of spermatozoa with progressive movement and an increase in the rate of immotile spermatozoa in relation to **C** groups. There were no drastic morphology alterations in the ventral prostatic lobe in the different groups and no differences in stereological analysis and on incidence and multiplicity of prostate lesions. **HPBA** group had a decreased in E2 levels when compared with **LBPA** group. There was a decrease in the number of AR-positive cells in the of animals in the **CO**, **LBPA** and **HBPA** groups relative to the **C** group. These data indicate that exposure to BPA from gestation to lactation, besides caused no alteration in morphology and lesion predisposition, can cause alterations on hormonal signaling in the prostate at adulthood, and these alterations are probably related to impairments in sperm motility. Furthermore, corn oil, a widely used diluent vehicle, also led to alterations in AR expression.

Changes in the dynamics of gastric cell proliferation are induced by early weaning

I. Rattes; University of São Paulo, São Paulo, Brazil

Epithelial cells proliferate along the gastric gland during rat postnatal development, whereas after weaning, they are concentrated between the isthmus and neck areas. In adult animals, an additional inactive, a reserve niche, is also found at gland base. Breastfeeding period is critical for stomach maturation in terms of supply of nutrients and growth factors, and so the abrupt cessation of breastfeeding can disturb the organ development. Thus, considering the importance of breastfeeding period, our hypothesis is that an abrupt change in diet with early weaning (EW) will lead to disturbances in the proliferative niches that can be extended to adulthood. Our current aims were to evaluate the late effects of EW in cell proliferation (PI) and expression of genes related to stem cell niches. Wistar rats were submitted to EW (15d) and gastric samples were collected at 18, 30, 60 and 120 d for RT-qPCR, tissue and cell morphology (Ethics Committee CEUA ICB USP 18/2015; 115/2017; 4532180222). Our previous results indicated that at 18 d EW increased the PI and pushed proliferative cells into the isthmus area, but at 60d, their distribution increased at the gland base (doi.org/10.3389). We found that later on, at 120d, the PI was lower than younger ages, and such decrease was more evident in the S group. We also registered that growth dynamics of the gland varied with the advancing age in the EW rat. As for genes involved in signaling and stem cell niches, EW induced differential effects at 18d and 60d, whereas at 120d, expression was not influenced. Among the responsive genes, Notch1 and Notch2 were the most affected by the abrupt diet change during development. Regarding the stem cell marker Troy, we found it during postnatal development: from the 3rd to the 15th postnatal day the number of Troy+ cells did not show differences, and from the 18th day on the number of Troy+ cells increased in the gastric mucosa. RT-qPCR shows an increase of Tnfrsf19 (Troy) at 60d EW, and Troy protein levels are elevated in 18d EW, but reduced at 60d. We can suggest that the dynamic of gastric growth was altered by EW through the regulation of genes involved in the signaling and organization of stem cell niches. Grant FAPESP: #2018/05064-0, #2018/07782-8, #2020/05117-7. Key words: early weaning, stomach, stem cell

Intracellular pH dynamics during zebrafish neural crest development

C. Chou-Freed, D. E. Wagner, D. L. Barber; University of California, San Francisco, San Francisco, CA

Many cell behaviors, including cell proliferation and migration, require dynamic changes in intracellular pH (pHi). Our group recently reported that pHi dynamics act as a critical regulator of cell fate determination, including the differentiation of mouse embryonic stem cells and lineage specification of adult intestinal stem cells. However, it remains unresolved how pHi dynamics impact embryonic development *in vivo*. To address this gap, we generated zebrafish lines expressing a ratiometric fluorescent pHi sensor and confirmed the ability to reproducibly quantify pHi using live cell imaging of 24-30 hpf embryos. Using this system, we are testing the hypothesis that pHi dynamics regulate the development of neural crest, a highly conserved vertebrate embryonic cell population that gives rise to diverse cell types, including neurons, cartilage, and bone. Given the many pHi-regulated cell behaviors necessary for neural crest development, including multilineage specification, epithelial-to-mesenchymal transition, and cell migration, neural crest is an ideal system to address the gaps in our understanding of pHi dynamics during embryonic development. We found a significantly higher pHi in migratory compared to premigratory neural crest cells, consistent with the established role of increased pHi in coordinating directed cell migration in many cell types. To resolve the functional significance of increased pHi in migratory neural crest cells, we are experimentally perturbing pHi in zebrafish neural crest by CRISPR-Cas9-mediated knockout of plasma membrane H+ transporters. The experimental models generated here will provide new insights into the cellular and molecular factors regulating neural crest development, with important implications for human congenital diseases and tissue repair.

Investigating the role of cyclooxygenase signaling in ectodermal derivative development

T. Leathers, C. Rogers; Anatomy, Physiology, and Cell Biology, University of California, Davis, Davis, CA.

During neurulation, the ectoderm-derived neural plate undergoes cytoskeletal rearrangements and folds until its borders meet and fuse at the dorsal side of the embryo, forming the neural tube. Differential expression of morphogens in the ventral and dorsal neural tube then patterns this tissue into separate lineages, the central nervous system (CNS) and neural crest (NC) cells. Though neural tube defects are the second most common congenital malformations in humans, the molecular mechanisms regulating neural tube closure and patterning are poorly understood. Additionally, dietary and environmental perturbations increase the risk of neural tube closure defects. Use of non-steroidal anti-inflammatory drugs (NSAIDs) during embryonic development is linked to a greater risk of neural tube defects, but the mechanistic reasons are unclear. NSAIDs inhibit cyclooxygenase (COX) enzymes, which synthesize the hormone-like lipid prostaglandin E2 (PGE2). To uncover the mechanistic pathway by which COX signaling inhibition leads to neural tube defects, we have characterized the expression of *Cox* genes and the genes encoding tissue-specific PGE2 receptors, *Ep3* and *Ep4*, during neurulation. *Cox1* expression is ubiquitous in early embryos, but *Cox2* is expressed in the anterior and trunk non-neural ectoderm. *Ep3* is localized to the developing neural tube, while *Ep4* is expressed in developing intermediate mesoderm. Knockdown of EP3 caused morphological defects in neural tube closure and significantly reduced the number and migration distance of NC cells. This phenocopies the defects observed after embryonic NSAID exposure, while knockdown of COX2 alone did not cause significant

developmental defects. Our work has identified a previously uncharacterized role of an enzymatic and lipid-based pathway in ectodermal derivative patterning.

Modeling Tissue Injury in a dish

Y. Woappi; Columbia University, New York, NY

Epithelial damage is the node for a variety of human conditions and diseases, including chronic wounding, inflammation, and over 80% of all human cancers. As the largest lining tissue, the skin epithelium is often subject to injury and has evolutionarily adapted by acquiring the cellular plasticity necessary to repair the damaged site. Over the years, several efforts were made to study epithelial plasticity using *in vitro* and *ex vivo* cell-based models. However, these efforts have been limited in their capacity to recapitulate the various phases of wound healing. To meet this challenge, we established the human skinoid culture system, developed by cultivating organoid-like 3D cultures of primary neonatal human keratinocytes in alternating adhesive and suspension culture environments. We found that this skinoid technology was capable of enriching for a subpopulation of epidermal stem cells with enhanced regenerative potential and enabled us to study a variety of processes, including oncogenic neoplasia, wound healing, and tissue biofabrication. Importantly, skionids patterned all four major phases of tissue reconstruction: a) homeostatic renewal, b) differentiation halt/reversal c) stress lineage activation, and d) tissue restoration, enabling us to conduct unprecedented spatiotemporal multi-omics analysis of the human wound healing procedure in a dish.

Investigating seamless tubulogenesis and unicellular branching morphogenesis in a course-based undergraduate research experience

J. Schottenfeld-Roames, T. Simpson, L. Lorenz; Princeton University, Princeton, NJ

Objective: To identify proteins required for seamless tube formation and branching morphogenesis in *Drosophila* tracheal terminal cells. Transformation of epithelial cells into complex functional organs is a critical step in development. Organs such as the lungs and kidney are composed of multicellular tubes (two or more cells attached to one other by junctions), whereas a large percentage of capillaries in the vertebrate vascular system are composed of seamless tubes (single cells that lack junctions). Although the morphogenetic events that help generate a multicellular tube can vary, it is clear how cells joined together by epithelial junctions create a membrane-bounded lumen; what is not obvious is how a single cell hollows out to create an internal lumenal membrane *de novo*. Specialized tips cells in the *Drosophila* tracheal system called “terminal cells” go on to form branched seamless tubes. Using terminal cells as a model, we have uncovered a number of cytoskeletal and membrane trafficking regulators that help orchestrate this seamless cell-to-tube transformation in previous work. Candidate RNAi screens to identify additional factors required for terminal cells morphogenesis have served as the foundation for an upper-level undergraduate research course. One such protein identified by students in the course is the actin contractibility regulator, Mysoin II. Here, we show a novel role for Myosin II during the process of seamless tubulogenesis and unicellular branching morphogenesis the fly tracheal system. RNAi against the fly *myosin II regulatory light chain* (*spaghetti-squash)* and *myosin II heavy chain* (*zipper)* results in changes to terminal cell architecture and discoordination between branch and lumen formation. Sholl and Strahler analyses, which capture changes in overall branch complexity, reveal

limited differences between control and *myosin II* knockdown cells; however, these analyses are limited in their ability to describe global changes to cell shape. A student-developed method for analyzing branch density within defined quadrants of space around a designated plane of a terminal cell reveals that Myosin II depleted cells do have reduced spreading compared to wild type control cells. Efforts to determine the mechanism by which Myosin II regulates branching and tube formation in terminal cells is currently underway.

How Do the MyoD Binding Regions Upstream and Downstream of the Acta1 Gene Influence Transcription of a-actin mRNA?

A. L. Littlefield[1], G. M. Beas[1], G. De Salvo[2], S. B. Sharp[1]; [1]California State University, Los Angeles, Los Angeles, CA, [2]California Institute of Technology, Pasadena, CA

The transcription factor MyoD contributes to myogenesis (muscle development) by binding to conserved regulatory sequences typically found upstream of target genes. Interestingly, binding sites for MyoD have been found downstream as well as upstream of Acta1, one of MyoD's target genes. The role of the downstream binding regions is unknown. I hypothesize that MyoD binding both upstream and downstream of Acta1 is necessary for developmentally regulated, muscle-specific Acta1 transcription. Testing this hypothesis will increase our knowledge of longer-distanced, downstream transcriptional regulation, and will provide regulatory mutations to test for in ACTA1-related myopathies that have not been ascribed to a coding-region mutation. I am performing transient plasmid transfections with normal and mutated Acta1 regulatory regions inserted upstream and downstream of a firefly luciferase reporter gene. The constructs are transfected into mouse pre-muscle and fibroblast cells, and a dual luciferase assay is performed at both myoblast (undifferentiated) and myocyte (differentiated) stages. I have determined the quantity of normalizer NanoLuc plasmid to use; have found that apparent NanoLuc activity is lower in growth versus differentiation conditions; and have observed an apparent effect of the specific plasmids present in the transfection mixture on NanoLuc activity. I address how these findings will inform in our data analyses. I have performed a single trial transient transfection and luciferase assay on constructs containing the 5', 5' and various 3', truncated 5', and mutated 5' binding sites. My results showed that normalized Acta1 promoter-driven firefly luciferase expression is higher in the presence of the upstream MyoD binding region than in its absence in myocytes, but not in myoblasts, consistent with previous reports. Additionally, constructs containing both the 5' and 3' binding sites, showed higher transcriptional activation when compared to constructs containing just the 5' binding sites. So far, these results show that the 3' binding site may play a role in increasing expression of Acta1 mRNA. More trials with these constructs, as well as experiments testing additional constructs are underway.(Funded by RISE NIH-R25 GM061331)

The AP-1 clathrin adaptor protein complex coordinates human cortical tissue morphogenesis and neurogenesis

A. E. Carleton[1], S. Wang[1], D. L. Gumucio[2], M. C. Duncan[2], K. Taniguchi[1]; [1]Medical College Wisconsin, Milwaukee, WI, [2]University of Michigan, Ann Arbor, MI.

A handful of rare human neurodevelopmental disorders has been linked to several mutation variants in the subunits of the AP-1 clathrin adaptor protein complex, a critical regulator of clathrin-dependent

polarized membrane trafficking. Mechanistically, the role of AP-1 in clathrin-dependent trafficking at the Golgi and endosomal networks has been extensively investigated, and, based on these studies, the AP-1-associated disorders are thought to be due to impaired AP-1-dependent trafficking of copper transporters, sortilins and/or secretases. To gain additional insights into the AP-1 pathology in the context of developing human brain, we generated human cortical organoids (HCO) derived from control human embryonic stem cells (hESC) and hESC lacking AP-1-γ1. Strikingly, AP-1-γ1-KO HCO displayed defective morphogenesis of cortical epithelium in which apical lumen fails to properly expand, an apical morphogenesis defect similar to in vitro AP-1-γ1-KO human epiblast models (Wang et al. Science Advances 2021). In addition to this defective neuroepithelium morphogenesis, single cell transcriptomic analysis comparing control and KO HCOs showed several cell subpopulations that are depleted in the KO, revealing a role of AP-1 in neural specification. Together, these studies provide the first comprehensive analysis for the role of the AP-1 complex during human cortical development, and provides a crucial insight into mechanisms underlying the AP-1 associated neural disorders.

Adipose Tissue Derived Mesenchymal Stem Cells Differentiation is Improved by Photobiomodulation Therapy

N. P. Bueno[1], R. L. Bighetti Trevisan[1], M. M. Beloti[2], P. Arany[3], M. M. Marques[4], **E. P. Ferraz**[1]; [1]School of Dentistry, University of Sao Paulo, São Paulo, BRAZIL, [2]School of Dentistry of Ribeirao Preto, University of Sao Paulo, São Paulo, BRAZIL, [3]University at Buffalo, Buffalo, NY, [4]School of Dentistry, Ibirapuera University, São Paulo, BRAZIL.

Mesenchymal stem cells (MSC) from different sources have been widely explored for bone tissue regeneration purposes. MSCs from adipose tissue (at-MSC) are an attractive alternative since a higher number of cells are easily harvested at lesser morbidity compared to cells obtained from other sources. In spite of it, their use for bone tissue regeneration is limited due to their lower osteogenic differentiation potential. To circumvent this problem, photobiomodulation (PBM) emerges as a non-invasive therapy, which is able to enhance cell differentiation accelerating the repair process. In this context, this study aimed to investigate the PBM as a therapeutic alternative to improve the osteoblastic differentiation of at-MSC. For this, rat at-MSC were cultured in an osteogenic medium to differentiate into osteoblasts (OB) and submitted to the PBM protocol (660 nm; 0.14 J; 20 mW; 0.714 W/cm2 and 5 J/cm2). Non-irradiated OB were used as Control. The effect of PBM on osteoblastic differentiation (OB-PBM) was evaluated by measuring gene and protein expression of alkaline phosphatase (*Alp*) and runt-related transcription factor-2 (*Runx-2*) on days 3 and 7 using quantitative PCR and Western Blot. The ALP activity in situ was evaluated at 7 and 10 days using Fast red protocol. Data were compared by ANOVA, and the p-value was set at 0.05. PBM therapy led to an increased gene and protein expressions of ALP and RUNX2 after 3 and 7 days compared to Control ($p<0.001$ for both gene/proteins at all experimental periods). ALP activity in situ was also higher on OB-PBM on days 7 and 10 compared to non-irradiated cells ($p<0.05$ for all periods). To superficially evaluate the PBM osteoinductive properties, at-MSCs were cultured in non-osteogenic conditions, and the same parameters were assessed. Under this condition it was observed a slight increased *Alp* gene expression and ALP activity were noticed on at-MSC-PBM at early days ($p<0.05$), without differences in later periods of culture. Our results indicate the positive effect of PBM in improving the osteoblastic differentiation of at-MSC cultured under osteogenic

conditions, which may contribute to strategies to improve the aesthetic-functional reconstruction of bone defects. Financial support Fapesp: #21/04874-1; 21/03665-0.

Islet-1 is differentially regulated by Scratch2 in the embryonic DRG and spinal cord.

V. Samartin Botezelli, S. Mirna Anticona, C. Purcell Goes, **C. Yan**; Cell and Developmental Biology, University of São Paulo, Sao Paulo, BRAZIL.

Sensory information is coded by peripheral sensory neurons in the dorsal root ganglion (DRG) and conveyed to interneurons in the spinal cord. The embryonic source of sensory neurons and spinal cord interneurons are distinct - neural crest and neural tube, respectively. However, both populations express a similar set of neural transcription factors after mitotic arrest. This suggests that intermediate progenitors of different sensory components could share genetic pathways. Here, we compared the genetic relationship between the same set of transcription factors (Scratch2, Islet-1 and NeuroD4) in the context of embryonic DRG and progenitors of dorsal spinal cord interneurons. In both tissues, Scratch2 (Scrt2), Islet-1, and NeuroD4 are expressed in early progenitor cells in the intermediate zone. However, in the DRG, Scrt2, Islet-1, and NeuroD4 are co-expressed, while in the embryonic spinal cord Islet-1 is only found in Scrt2-negative progenitors. Accordingly, overexpression of Scrt2 in the DRG increases Islet-1 labeling. In contrast, an increase of Scrt2 in the spinal cord decreases the dorsal most Islet-1-positive population. We then identified Scrt2 binding sites on the genome of embryonic spinal cord cells. The CUT&RUN tracks that overlapped with evolutionarily conserved non-coding regions were further analyzed for additional neural transcription factors target sites. We are now performing comparative functional studies of a genomic region ~100kb upstream of Islet-1 that is recognized by Scrt2 and has potential binding sites for multiple neural transcription factors.

B677/P3054

The folic acid receptor (Far1) regulates early development in *Dictyostelium*

K. Swier; Biological Sciences, Chicago State University, Chicago State University, IL.

Dictyostelium discoideum is a social amoeba that proliferates as a single-celled organism when nutrients are plentiful, but aggregates and develops into a multicellular fruiting body upon starvation. Many of the genes upregulated by acute starvation, such as the discoidin genes, are also turned on during proliferation as cell density increases and nutrients are depleted. Discoidin expression is negatively regulated by folic acid during proliferation. Some time ago, this regulation was shown to be dependent upon signaling through a G protein coupled receptor (GPCR) as Gβ-null cells could not suppress discoidin expression. Recently, the folic acid receptor (Far1) was identified. Far1 is a GPCR that binds folate and LPS and mediates both chemotaxis toward folate or LPS and phagocytosis of bacteria. The availability of far1 knockouts (KO) allowed us to test whether Far1 is indeed the GPCR mediating the negative signal provided by folate. Parental Ax2 cells and far1 KO cells were transformed with an expression vector encoding green fluorescent protein under control of the discoidin promoter. In axenic cultures, folate repressed the discoidin promoter in wild-type cells but not in far1 KO cells. LPS had no effect on expression from the discoidin promoter. When cells were grown in bacteria suspension, the activity of the discoidin promoter was completely repressed in both wild type and far1 KO cells. Surprisingly, far1 KO cells were unable to differentiate upon starvation in submerged cultures, whether grown axenically

or on bacteria prior to starvation. However, development on non-nutrient agar appeared normal. Far1 may have a role in early development of *Dictyostelium*.

B678/P3055

Investigating the roles of Etv4 and Etv5 during the self-renewal and differentiation of nephron progenitor cells in kidney organogenesis

K. Day[1,2], K. Thorner[3], A. Hosawi[4], B. Hammond[5,2], M. Fraunfelter[6], M. Kofron[6], F. D. Costantini[7], C. Cebrian[6,8]; [1]Molecular and Developmental Biology Graduate Program, Cincinnati Children's Research Foundation, Cincinnati, OH, [2]University of Cincinnati, Cincinnati, OH, [3]Developmental Biology/Admin & Core Services, Cincinnati Children's Research Foundation, Cincinnati, OH, [4]Division of Clinical Pharmacology, Cincinnati Children's Research Foundation, Cincinnati, OH, [5]Biomedical Research Technologies MS Program, Cincinnati Children's Research Foundation, Cincinnati, OH, [6]Division of Developmental Biology, Cincinnati Children's Research Foundation, Cincinnati, OH, [7]Department of Genetics & Development, Columbia University, New York, NY, [8]Department of Pediatrics, University of Cincinnati, Cincinnati, OH.

Kidney organogenesis is a complex process that relies on the interaction of different cell populations at defined spatial and temporal locales. In mammals, the reciprocal signaling between the ureteric bud (UB) and the metanephric mesenchyme (MM) drive the branching of the UB and the differentiation of nephrons from the MM. During nephrogenesis, nephron progenitor cells (NPCs) condense and epithelialize. Subsequently, morphogenetic movements and differential gene expression drive the progression from the nascent nephron into the specialized cell types and segments of the filtering units, including podocytes, proximal tubule, loop of Henle, and distal and connecting tubule. Each of these segments are essential to kidney function. My thesis project focuses on two genes that play a key role in signaling during kidney development: *Etv4* and *Etv5*. *Etv4/5* are members of the polyoma enhancer activator 3 (PEA3) subfamily of E-twentysix (ETS) transcription factors and are expressed in multiple tissues during development including in the MM, UB tips and developing nephrons. ETV4/5 act redundantly in the kidney and their ablation results in kidney agenesis.To identify any specific role for *Etv4/5* in nephrogenesis, we have used a *Six2-GFP-cre; Etv4*$^{-/-}$*; Etv5*$^{F/F}$ mouse model to interrogate the consequences of removing *Etv4/5* from the SIX2^{+} NPCs and its derived cells. Our data show that knocking out *Etv4/5* in the *Six2*$^{+}$ cells leads to hypoplastic kidneys, NPC premature depletion and a cystic phenotype. Moreover, immunofluorescent analyses of mutant kidneys indicate a decrease in the number of segments that stain for distal markers such as TFAP2B and SLC12A1, while other non-distal markers such as HNF1B do not exhibit a significant decrease. These results indicate that, while removing ETV4/5 reduces the overall number of nephrons, there is a disproportionate decrease in segments that are distal in nature. Furthermore, a large proportion of the cysts stain positively for AQP1, a marker of the upper thin descending limb of LOH, which could indicate that a blockage is occurring in the distal segments of these nephrons. In summary, our data support a model in which *Etv4/5* are required for the development of the distal segments of the nephron, and we hypothesize that the cystic phenotype seen in these mutants is a consequence of disrupting the development of these segments.

Single Cell Mapping of Cell Differentiation in a System Derived from a Single Cell Type, the Platelet

I. Pokrovskaya[1], S. Rhee[2], M. W. Sebb[1], J. Kamykowski[1], O. Zhao[3], D. Cruz[4], M. A. Aronova[5], R. D. Leapman[4], **B. Storrie**[1]; [1]Physiology and Cell Biology, University of Arkansas Medical Scis (UAMS), Little Rock, AR, [2]Pharmacology and Cell Biology, University of Arkansas Medical Scis (UAMS), Little Rock, AR, [3]NIH, NIH, Bethesda, MD, [4]NIBIB, NIH, Bethesda, MD, [5]PNIBIB, NIH, Little RockBethesda, MD.

One of the long-standing problems in cell biology is how a single cell type, here the platelet, can produce an organized structure comparable in complexity to an early-stage embryo or an organoid. In the case of a puncture wound clot in mice, be it in a vein or an artery, the structure formed is complex, consisting of several different stable platelet activation states that nucleate the formation of platelet-rich pedestals and columns that lead to the formation of an organized platelet aggregate, a thrombus, that produces bleeding cessation. Here, we have used computer automated electron microscopy approaches to map differentiation state, I.e., platelet activation state, across total thrombus volumes and at the individual platelet level across full thrombus cross sections. The goal was to morphologically define at 3-5 nm resolution, platelet activation state and overall thrombus organization in a structure of near millimeter size. In so doing, we also used a region of interest, ROI approach, to 3-dimensionally render individual platelets in situ to probe platelet-platelets interactions in 3D space. The net outcome of this analysis was to establish that the forming clot,i.e., thrombus, consisted of 5 morphologically distinct activation states based on platelet shape, adherence and granule content. Each of these states were derived progressively from a basal state circulating platelet and once achieved appeared to have varying temporal stability. Even at relatively late times in thrombus formation relative to bleeding cessation, multiple platelet activation states were present within the thrombus. Based on single cell neighbor analysis, 2-micron radius, these activation states were loosely zoned within the thrombus. i.e., a favored but not strict association of like with like. Efforts to automate platelet stratification across sections through machine learning to give full 3D outcomes are in progress.

Effect of Normoglycemia on the Disrupted Osteoblast Differentiation of Mesenchymal Stem Cells Induced by Type 1 and Type 2 Diabetes Mellitus

D. Weffort[1], L. F. Adolpho[1], A. T. P. Souza[1], G. P. Freitas[2], H. B. Lopes[1], F. S. Oliveira[1], R. L. Bighetti-Trevisan[1], L. Pitol-Palin[3], D. H. Matsushita[3], R. Okamoto[3], **M. M. Beloti**[1], A. L. Rosa[1]; [1]School of Dentistry of Ribeirão Preto, University of São Paulo, Ribeirão Preto, BRAZIL, [2]School of Dentistry, Federal University of Goiás, Goiânia, BRAZIL, [3]Araçatuba Dental School, São Paulo State University Júlio de Mesquita Filho, Araçatuba, BRAZIL.

Diabetes mellitus (DM) disrupts insulin secretion, action or both, which is characterized by hyperglycemia and most of the cases is categorized as type 1 (T1DM) or type 2 (T2DM), both causing damages to bone through several mechanisms, including effects on osteoblasts. Based on the different etiopathologies of T1DM and T2DM, we hypothesized that T1DM and T2DM induce distinct levels of inhibition of the osteoblast differentiation of mesenchymal stem cells (MSCs) that is recovered when the hyperglycemic stimulus is removed. Thus, the aims of this study were to evaluate the osteoblast differentiation of MSCs derived from rats with either T1DM or T2DM as well as the effect of a normoglycemic environment on the osteogenic potential of these MSCs. To induce T1DM, rats received a single injection of streptozotocin (60 mg/kg) and for T2DM induction, rats were fed with a high-fat diet

and received a single injection of streptozotocin (35 mg/kg). Rats that received the streptozotocin vehicle were used as control and animals with blood glucose levels above 300 mg/dL were considered with T1DM and above 198 mg/dL, with T2DM. MSCs from healthy rats were grown in normoglycemic medium (control) and MSCs from rats with either T1DM or T2DM were cultured under hyperglycemic or normoglycemic conditions. The data were submitted to appropriate statistical analyses ($p \leq 0.05$). Morphometric parameters of the rat femurs (n=5 for control and T1DM, and n=6 for T2DM) showed that T1DM and T2DM induced bone loss, with more deleterious effects of T2DM than T1DM. Both T1DM and T2DM reduced the osteoblast differentiation of MSCs grown in hyperglycemic media, with more pronounced effects of T1DM, as demonstrated by alkaline phosphatase activity (n=5), RUNX2 protein expression (n=3) and extracellular matrix mineralization (n=5), and modulated the gene expression of several components of the bone morphogenetic protein signaling pathway (n=3). The retrieve of the normoglycemic environment partially recovers the osteogenic potential of MSCs from rats with T1DM but not with T2DM. Our findings shed light on the need for specific therapeutic approaches to treat either T1DM- or T2DM-induced bone loss as both disrupt osteoblast differentiation at distinct levels and most likely by different mechanisms. **Financial support:** FAPESP (Grants # 2019/18711-7 and 2017/12622-7) and CNPq (Grant # 307698/2021-1).

Characterizing the sexual dimorphism in lung microvascular angiogenesis and the role of sex hormones

B. Hayward-Piatkovskyi[1], C. R. Gonyea[1], C. N. Clark[1], K. Lingappan[2], J. P. Gleghorn[1]; [1]University of Delaware, Newark, DE, [2]Children's Hospital of Philadelphia, Philadelphia, PA.

Bronchopulmonary dysplasia (BPD) exhibits a striking sexual dimorphism wherein prematurely born male infants are almost twice as likely to develop BPD compared to their female counterparts. While this difference is well established, the mechanisms contributing to this sexual dimorphism remain unknown. Previous work has identified sex differences in lung microvascular angiogenesis, though the exact nature of the dimorphism remains poorly characterized. Sex hormones are known to play a key role in early organ development, including lung development. Characterizing the sexual dimorphism in lung angiogenesis and identifying the role sex hormones play in this dimorphism is necessary to build the foundation for understanding the sex differences in BPD. The objective of this study was to characterize the sexual dimorphism in pulmonary microvascular angiogenesis and identify the way sex hormones modify these characteristics. We used a bead sprouting assay to model angiogenesis of neonatal human pulmonary microvascular endothelial cells (HPMEC). Standard culture mediums contain sex hormones in the form of fetal bovine serum (FBS) and phenols. We used commercially available charcoal-stripped FBS to create a hormone-free medium for these experiments. Using this hormone-free medium, we characterized angiogenesis, focused on the number of sprouts per bead and the maximum length of those sprouts. We found that male HPMECs produced fewer but longer sprouts compared to females. To identify which sex hormones were responsible for these changes, we dosed the medium with specific concentrations of β-estradiol (E2) or dihydrotestosterone (DHT). Female HPMECs maintained the female phenotype in angiogenesis, regardless of the presence of E2 or DHT. This suggests the female HPMEC phenotype is sex hormone independent. Interestingly, male HPMECs produce more sprouts in the presence of low doses of E2 or high doses of DHT. This data defines a male and female phenotype in angiogenesis while demonstrating that sex hormones modify the male, but not

female, phenotype. These findings provide a springboard for further investigation into the sex-dependent response to sex hormones in angiogenesis and warrant further investigation.

Regulation of muscle subtype-specific *Myomaker* expression in a chordate with facultative myoblast fusion

C. Johnson[1], H. Zhang[2], Z. Zhang[2], P. Bi[3], A. Stolfi[1]; [1]School of Biological Science, Georgia Institute of Technology, Atlanta, GA, [2]Center for Molecular Medicine, University of Georgia, Athens, GA, [3]Department of Genetics, University of Georgia, Athens, GA.

Vertebrate myoblast fusion allows for multinucleated muscle fibers to compound the size and strength of individual mononucleated cells, but we have only recently started to understand the evolution of this important process. The phylum Chordata hosts closely related groups that span distinct myoblast fusion states: no fusion in cephalochordates, facultative fusion and multinucleation in tunicates, and extensive, obligatory fusion in vertebrates, which comprise the sister group to the tunicates. We previously reported that the chordate-specific muscle fusogen Myomaker likely arose through gene duplication in the last common ancestor of tunicates and vertebrates, This revealed an unexpectedly complex evolutionary history of myoblast fusion in chordates. A pre-vertebrate phase of muscle multinucleation driven by Myomaker was followed by the later emergence of another factor, Myomixer, which enables the highly efficient fusion system of vertebrates. Here we show that facultative activation of *Myomaker* transcription in multinucleated muscles of tunicate juveniles (but not mononucleated larval tail muscles) is carried out by a post-metamorphic myogenesis program based on the cooperative activity of Myogenic Regulatory Factor (MRF) and Early B-Cell Factor (EBF) transcription factors. This regulatory logic stands in stark contrast to the transcriptional activation of *Myomaker* in mammalian myoblasts by the MRF ortholog MYOD1 alone. Thus, we reveal the *cis*-regulatory basis of facultative vs. obligate myoblast fusion in chordates.

Roles for the Planar Cell Polarity Pathway in postnatal intestinal patterning and architecture

R. Lee, K. Sumigray; Yale University, New Haven, CT

The coordination and patterning of cells required for proper tissue architecture play a critical role in organ development and function. This process is especially important in the small intestine, which relies heavily on its unique architecture of “hills” (villi) and “valleys” (crypts) to maximize nutrient absorption. Crypts are the architectural unit of the intestinal stem cell niche and form postnatally in mice. We have identified a role for crypts in mesoscale intestinal patterning through the regulation of villus ribbon patterning. Stem cell clones from a single crypt generate daughter cells that migrate up the villus in a linear ribbon pattern, while progressively differentiating into zonated cell states. This differentiation is tightly correlated to distinct digestive functions through compartmentalized expression of nutrient transporters. Despite the potential functional insights of intestinal patterning on both gross and mesoscale levels, *how this mesoscale patterning is established and maintained is not well understood.* We found that planar cell polarity (PCP) pathway genes expressed in crypts are essential to maintain villus ribbons. Furthermore, loss of PCP genes caused gross architectural defects, including villus branching, crypt translocation, and loss of epithelial cell attachment to the extracellular matrix. Our data suggest that PCP regulates directional cell migration out of the crypt and into the villus. In addition, as

the crypt is the architectural unit of the intestinal stem cell niche, this may imply that positioning and orientation of a crypt may affect gross villus architecture but may not be necessary for stem cell function. Future studies will focus on identifying the cellular and molecular mechanisms by which PCP regulates intestinal architecture and patterning and the physiological consequences of disrupted villus ribbon patterning. These studies demonstrate that mesoscale patterning plays an essential role in the organization and maintenance of intestinal architecture that is important for tissue physiology.

Guiding kidney organoid morphogenesis through size and compositional control

C. Porter, A. Hughes; Bioengineering, University of Pennsylvania, Philadelphia, PA.

Human kidney organoids offer an exciting future avenue for renal replacement therapy. However, current kidney organoids, derived from induced pluripotent stem cells, lack the reproducibility, physiologic structure, and functionality necessary to make organoid-based therapies a reality. Recently, production of kidney organoids from multiple progenitor cell types displayed more maturity than previous organoids derived from single precursors. However, in these studies, precursor cells were intermixed in uncontrolled ratios and numbers, resulting in heterogeneous organoids with unpredictable composition. This has motivated our objective to determine how controlling initial kidney precursor ratios and quantities modulates final organoid composition and structure. To this end, we developed a novel cell photopatterning technology to capture precise numbers of multiple cell types within microwell arrays. Using immortalized renal epithelial cells, we validated the ability of this culture system to: 1.) define initial cell numbers, ratios, and positions through 2D cell patterning, 2.) allow cells to seamlessly transition to 3D suspension culture, with a single organoid per microwell, and 3.) produce highly parallel and trackable cultures. We show that long-term, spheroid sizes and compositions directly depend on the initial number of cells and ratios. Applying our culture system to the production of human kidney organoids, we found that final nephron organoid size and composition (the proportion of proximal versus distal tissue structures) also depend on the initial number of nephron progenitors. We are currently examining the effect of nephron to ureteric epithelium precursor ratio on kidney organoid outcomes. We expect to identify ratios of renal cell types that will restrict and modulate emerging renal tissues toward more physiologic structures. Providing the appropriate cell ratios and timing to cultures could even foster the fabrication of designer organoids or lead to emergent self-organization not previously seen in cultures that lack engineering control.

Terminal cell differentiation by suppression of CDK4/6 activation to terminate clonal expansion

S. Sharma, M. N. Teruel; Dept. of Biochemistry, Drukier Institute for Children's Health & Weill Center for Metabolic Health, Weill Cornell Medicine, New York, NY.

Terminal cell differentiation is essential for the development and maintenance of tissues in all multi-cellular organisms. It is typically composed of an early “clonal expansion” period in which progenitor cells undergo one or more rounds of cell division, followed by a differentiation period when cells commit to differentiate and permanently exit the cell cycle. Different models have been proposed how proliferation and differentiation cooperate with each other during terminal cell differentiation. Here we used adipogenesis (fat cell differentiation) as a model for terminal cell differentiation and carried out live single-cell imaging to monitor cell cycle events and differentiation progression simultaneously in

thousands of progenitor cells undergoing adipogenesis. Our preliminary results support that CDK4/6 activity determines the duration of clonal expansion and number of cell divisions before differentiation. The CDK4/6 activity is regulated by a competition between cyclin D and timed expression of the CDK inhibitors p21, p27, and p18 during adipogenesis. Timed regulation of the competition allows high or low numbers of differentiated cells to be produced from a fixed number of progenitor cells.

Establishing Different Conditions to Generate Epithelial to Mesenchymal Transition (EMT) in Human Induced Pluripotent Stem Cells to Study Cell State Transitions

G. Dalgin[1], . Allen Institute for Cell Science[1], J. Theriot[2], C. Hookway[1], R. N. Gunawardane[1]; [1]Allen Institute for Cell Science, Seattle, WA, [2]University of Washington, Seattle, WA

The Allen Institute for Cell Science aims to understand the principles by which human induced pluripotent stem cells (hiPSCs) establish and maintain robust dynamic localization of cellular structures, and how cells transition between states during differentiation and disease. We are building a standardized framework by integrating 3D live-cell imaging with scRNAseq-informed multiplexed immunolabeling and RNA-FISH to understand the relationship between cell behavior, organization and cell identity. EMT serves as a powerful model system to investigate cell state changes where non-motile epithelial cells differentiate to form motile mesenchymal cells. EMT happens in both normal and pathological conditions, and it is identified in multiple different contexts (embryogenesis, wound healing, fibrosis, etc.) based on features such as switching from apical-basal to front-rear polarity and the homology of the genes involved. However, the progression from one cell state to another is not well understood. We aim to address this using multi-modal analysis, where we induce EMT in hiPSCs under three different conditions and compare them. In the first condition, we treated cells with a GSK3b inhibitor to upregulate WNT signaling to generate the mesoderm. For the second and third conditions, we treated cells with Activin^{low} BMP4^{low} or Activin^{high} BMP4^{high}, to generate the mesoderm and endoderm respectively. These experiments showed that conditions that generate both mesoderm and endoderm had similar impact on cell migration behavior. We are currently comparing the differences in spatiotemporal expression of key markers in between conditions. This experimental set up lets us perform extensive quantitative comparisons of EMTs generated under different conditions. We propose that this multi-modal, multi-scale approach can serve as a framework for studying EMT in varied settings and understanding cell states and transitions in a broader context. These studies have been performed on gene-edited cell lines from the Allen Cell Collection. Detailed information about these lines can be found at allencell.org.

Inhibition of BMP4-mediated cross-activation of signaling pathways enhances Totipotent-like stem cells with Blastoid forming potential

T. Meharwade[1,2], L. Joumier[1,2], M. Parisotto[1], V. Huynh[1,2], E. da Rocha[3], M. Malleshaiah[1,2,2,4,5]; [1]Montreal Clinical Research Institute, Montreal, QC, Canada, [2]University of Montreal, Montreal, QC, Canada, [3]Federal University of Santa Catarina SC, Brazil, Florianópolis - SC, Brazil, [4]McGill University, Montreal, QC, Canada, [5]McGill Regenerative Medicine Network,, Montreal, QC, Canada

Embryonic stem cells (ESC) are defined by their inherent ability to self-renew and give rise to all cell types within the organism. Recent evidence suggests that cultured mouse ESCs co-exist in multiple

phenotypic states such as unbiased pluripotent state (naïve), totipotent (2Cell-like), EpiSC (primed) and are driven by distinct transcriptional regulators. An important aspect of these specific cell states is that they have different developmental potency: while totipotent cells can give rise to both embryonic and extraembryonic tissues, pluripotent cells give rise to only embryonic tissues and primed only to certain embryonic tissues. However, the signaling mechanisms initiating this remarkable developmental plasticity (co-existence of diverse cell fates) in genetically identical cells are unclear. Moreover, it remains unresolved which signaling pathway (if any) among those commonly active in ESC culture conditions is important to induce the Totipotent state. In this study, by examining various ESC culture conditions, we identified BMP4 signalling to promote Totipotent state. In addition, we also observed alternative cell states to be co-expressed and found BMP4 mediated signaling to curtail the induction of totipotent state through cross-activation of FGF, TGF-β and WNT pathways associated in promoting pluripotent and primed cell states, respectively. Furthermore, perturbation of cross-activated pathways using putative small molecules enabled in identification of a reprogramming condition (namely LBPXRS) to enhance totipotent state in ESCs. Integrated single-cell RNA-seq analysis of pre- and post-implantation mouse embryo, various ESC culture conditions and LBPXRS confirm the molecular features of LBPXRS akin to totipotent cell stages of pre-implantation embryo. Lastly, generation of in-vitro blastocyst-like structures (Blastoid) and *in-vivo* analysis of phenotypically reprogrammed totipotent cells exhibited functional and molecular features akin to totipotent cell stages of preimplantation embryos. Therefore, our findings reveal a novel BMP4-mediated signaling mechanism in ESCs to regulate diverse cell fates, and close association between BMP4 signaling cross-activation and totipotent-like reprogramming.

Malaria parasites harness Rho GTPase signaling and host cell membrane ruffling for productive invasion of hepatocytes

A. Schepis, S. Kappe; Center for Global Infectious Disease Research, Seattle Children's Research Institute, Seattle, WA.

Plasmodium sporozoites are the motile forms of the malaria parasite that infect hepatocytes. The initial invasion of hepatocytes is thought to be actively driven by sporozoites with little contribution by the host cell. The sporozoite contacts the host plasma membrane and enters the cell using its own actin-dependent propulsion, concurrent with invagination by the hepatocyte plasma membrane. The sporozoite modifies this membrane generating the parasitophorous vacuole, which supports the replication and growth of the nascent liver stage. Using fast live confocal microscopy, we observed that the initial interactions with sporozoites induce hepatocyte plasma membrane ruffles and filopodia extensions. These changes were triggered by sporozoites of rodent malaria parasites as well as *P. falciparum* sporozoites that infect human hepatocytes. Importantly, we find that these host cell processes strongly facilitate invasion and increase infection. Furthermore, Rho GTPase signaling, which regulates membrane ruffling and filopodia extension, is critical for productive infection. Interestingly, sporozoite cell traversal stimulates these processes, suggesting that it might increase hepatocyte susceptibility to productive infection. Our study unveils host cell signaling involved in plasma membrane dynamics as a critical host component of malaria parasite infection of hepatocytes.

***Plasmodium falciparum* PfMORC is associated with nuclear proteins and controls the blood stage development**

M. Singh[1], G. Tesserin-Almeida[2], B. Dias[3], V. Santiago[3], J. M. Przyborski[4], G. Palmisano[3], C. R. S. Garcia[1]; [1]Department of Clinical and Toxicological Analyses, School of Pharmaceutical Sciences, University of Sao Paulo, Sao Paulo, BRAZIL, [2]Department of Physiology, Institute of Bioscience, University of Sao Paulo, Sao Paulo, BRAZIL, [3]Department of Parasitology, Institute of Biomedical Science, University of Sao Paulo, Sao Paulo, BRAZIL, [4]Department of Biochemistry and Molecular Biology (BiMoBi), Interdisciplinary Research Center (iFZ), Justus-Liebig-University, GIESSEN, GERMANY.

Malaria is one of the leading lethal parasitic diseases in developing countries where eradication efforts lack proper infrastructure. In 2021 malaria report of World Health Organization estimates 241 million new cases and more than 600 thousand deaths in 2020 (World Malaria Report 2021). Malaria is caused by a parasite of genus *Plasmodium*, a unicellular protozoan of Apicomplexa and *Plasmodium falciparum* is most virulent with the highest fatalities. The clinical symptoms of malaria are associated with the periodic rupture and exponential increase of parasites in the host's circulation system. The endogenous hormone plays a significant role in modulating parasite progression in both vector and the host. We have previously reported the role of melatonin and its metabolic intermediates in modulating the cell cycle of human *P. falciparum* and murine *P. chabaudi* within red blood cells [1]. Moreover, melatonin up-regulates a subset of genes involved in the ubiquitin-proteasome system (UPS) thus showing a complex and multi-tasking signaling cascade for hormone action in *P. falciparum*. The leading factors regulating the parasite cell cycle are poorly understood. Recently, we have found a nuclear protein PfMORC and shown that melatonin treatment increases PfMORC expression at asexual stage. We also found that cell cycle modulatory effect of melatonin is hampered when PfMORC is knocked down using a glmS self-cleaving ribozyme system [2]. Our data reveal the potential role of PfMORC during intraerythrocytic parasite development and also indicates the complex signaling mechanism linked with the host hormone melatonin. It would be interesting to investigate how PfMORC affect the parasite developmental cycle. Studies from various groups suggest that PfMORC is associated to *Apetala2* (ApiAP2) family of transcription factors and likely to play important role in transcriptional and epigenetic regulation. Further validation of the protein complex interaction is required to understand the molecular insights of apetela2 transcription factors in *Plasmodium* and exemplify the efforts to develop a new alternative therapeutic target **Key Words**: *Plasmodium*, Melatonin, Cell-cycle, PfMORC, *Apetala2*

***Legionella pneumophila* inhibits type I Interferon signaling to avoid cell intrinsic host cell defense**

D. Banks[1], **C. N. S. Allen**[1], M. Shuster[1], T. J. O'Connor[2], V. Briken[1]; [1]Department of Cell Biology and Molecular Genetics, University of Maryland, College Park, College Park, MD, [2]Department of Biological Chemistry, Johns Hopkins University School of Medicine, Baltimore, MD.

The type I Interferon (IFN) host response to *Legionella pneumophilia* infections provides some cellular protection. Other pathogens have been shown to inhibit type I IFN-mediated cell signaling, but the

interaction of *L. pneumophila* with this signaling pathway has not been described. We showed that *L. pneumophila* inhibited IFN-β cell signaling via increasing doses of IFN-β up to 1000 pg/ml. However, *L. pneumophila* failed to inhibit IFN-γ-mediated cell signaling. The addition of high doses of IFN-β to *L. pneumophila*-infected macrophages limited the bacterial growth. Infected host cells produced increased amounts of nitric oxide (NO) after the addition of IFN-β, and the inhibition of NO-production via a chemical inhibitor resulted in increased bacterial growth. Finally, we showed that the *L. pneumophila* type IV secretion system is required to inhibit IFN-β-mediated cell signaling. In conclusion, we identified a novel host cell signaling pathway inhibited by *L. pneumophila* to improve survival in infected macrophages.

B692/P3068

Exploring the cell death mechanism induced by *Vibrio parahaemolyticus* Thermostable Direct Hemolysin

P. Verma, K. Chattopadhyay, A. Mukhopadhaya; Department of Biological Sciences, Indian Institute of Science Education and Research (IISER) Mohali, Punjab, INDIA.

Thermostable Direct Hemolysin (TDH) is the key virulence factor secreted by the marine bacterial pathogen *Vibrio parahaemolyticus*, one of the major causal organisms for human gastro-enteric diseases. It is a potent pore-forming toxin and can damage cellular homeostasis, presumably due to its ability to form pores on the plasma membrane of the target cells. TDH exhibits potent cytotoxicity against nucleated mammalian cells. However, the mechanism of the TDH-mediated cell death pathway is yet to be elucidated. Here, we show that TDH evokes features of apoptosis-like programmed cell death, such as phosphatidylserine flipping and a laddering pattern of DNA fragmentation. However, we have observed that unlike apoptosis, TDH-induced cell death is independent of any caspase activation. Thus, a caspase-independent programmed cell death is induced by TDH in the nucleated mammalian cells. Further, our results have revealed that TDH causes mitochondrial membrane permeability transition (MMPT), resulting in the release of important mitochondrial factors that take part in the subsequent execution of the caspase-independent cell death pathway and apoptosis-like DNA laddering pattern induced by TDH. Interestingly, TDH alone fails to induce MMPT in isolated mitochondria suggesting the involvement of other cytoplasmic factors in the process. We have observed that TDH shows a remarkable ability to translocate to the mitochondria of the target cells. Furthermore, we have observed the interaction of TDH with the pro-apoptotic molecule Bax. Thus, we speculate that TDH and Bax together possibly constitute a functional mitochondrial permeability transition pore (MPTP)-like structure that may result into MMPT induction. In sum, our study elucidates a novel mechanism of cell death induction by TDH that, to the best of our knowledge, has not been documented earlier for any other PFT family member. Our study adds valuable new insights regarding the role of TDH in bacterial infection and host-pathogen interaction processes.

B693/P3069

***Cryptosporidium* Uses its Cspv1 Virus to Activate Host Type I IFN Signaling and Attenuate Epithelial Antiparasitic Defense**

S. Deng[1,2], W. He[2], A. Gong[1,2], M. Li[2], Y. Wang[2], Z. Xia[2], X. Zhang[2], A. S. H. Pacheco[3], A. Naqib[4], M. Jenkins[5], P. C. Swanson[2], K. M. Drescher[2], J. K. Strauss-Soukup[6], M. A. Belshan[2], X. Chen[1,2]; [1]Microbial Pathogens and Immunity, Rush University Medical Center, Chicago, IL, [2]Medical Microbiology and Immunology, Creighton University School of Medicine, Omaha, NE, [3]Pediatric Gastroenterology, University of Nebraska Medical Center, Omaha, NE, [4]Anatomy and Cell Biology, Rush University Medical Center, Chicago, IL, [5]Animal Parasitic Diseases Laboratory, the United States Department of Agriculture, Beltsville, MD, [6]Chemistry, Creighton University College of Arts and Sciences, Omaha, NE.

Cryptosporidium is an obligate intracellular apicomplexan parasite that infects mammalian gastrointestinal epithelium. It is a leading cause of infectious diarrhea and diarrheal-related death in children worldwide. There is currently no vaccines and no fully effective therapy available for the infection. Humans are infected by ingesting *Cryptosporidium* oocysts, mainly the *C. parvum* and *C. hominis* species. Intestinal epithelial cells provide the first line of defense and play a critical role in the initiation, regulation, and resolution of both innate and adaptive immune reactions in response to infection. It is well established that type I IFN (IFN-γ) and type III IFN (IFN-lambda) play a critical protective role in intestinal anti-cryptosporidial immunity. Nevertheless, the role for type I IFN signaling in intestinal anti-*Cryptosporidium* defense remains unclear. *Cryptosporidium parvum* virus 1 (CSpV1) is a double-stranded RNA (dsRNA) virus carried by many *Cryptosporidium* spp. We report here that intestinal epithelial conditional *Ifnar1*$^{-/-}$ mice (deficient in type I IFN receptor) show resistance to *C. parvum* infection. CSpV1-dsRNAs are delivered into host cells and trigger type I IFN responses in infected cells through activating the PKR/RIG-I/MAVS signal pathways. Whereas *C. parvum* infection attenuates epithelial response to type II IFN-γ stimulation, knockout of type I IFN signaling or inhibition of CSpV1-dsRNA delivery can restore IFN-γ-mediated protective response. Accordingly, CSpV1 could be a new therapeutic target for cryptosporidiosis as antiviral reagent can promote the inhibitory effects of antiparasitic drugs on *C. parvum* infection of intestinal epithelium using *in vitro*, *ex vivo*, and *in vivo* infection models. Our data indicate the detrimental effect of type I IFN signaling in intestinal epithelial cells on intestinal anti-*C. parvum* defense and reveal a new strategy of immune evasion by the parasite.

B694/P3070

Role of putative toxin in stress response and pathogenicity of mycobacterium tuberculosis

S. Zarin; National Institute of Pathology, ICMR, New Delhi, INDIA.

The extremely notorious *Mycobacterium tuberculosis* is a highly successful pathogen since it can sneakily proliferate for decades escaping the host immune system. *M.tb* encodes an exceptionally large number of toxin-antitoxin (TA) systems, suggesting their important role in pathogenesis. TA systems are linked to stress adaptation, persistence and drug tolerance. These genes are promising candidates for novel therapeutic development to target persistent bacteria. *M.tb* encodes 90 TA systems, of which 50 belong to VapBC family. Proteomics study revealed 9 TA genes are unique to MTBC of which Rvzzzz was found to be present only in *M.tb* and *M.bovis*. Rvzzzz codes for VapC toxin protein harbouring a PIN domain characteristic of Ribonucleases. So to explore the role of Rvzzzz toxin in stress adaptation and persistence, Recombinant *M. smegmatis* (Ms_zzzz) expressing VapC protein was subjected to different abiotic stresses (pH, oxidative, nutritional and antibiotics) mimicking the environment encountered by

the pathogen inside host phagosome and checked for survivability by CFU assay. Infection studies was carried out on RAW macrophages to check for enhanced survivability and modulation of cell death pathways. Rvzzzz protein interactome was studied using Phage display technique and was also characterised biophysically with an aim to find its inhibitors in future. **Result:** Rvzzzz-y genes are co-operonic proving to be a bonafide TA system. Rvzzzz is a surface localised protein present predominantly in cell wall. Interacting partners obtained are major players of stress adaptation pathways. . Ms_zzzz presented significant tolerance to different stresses. It induced biofilm formation and the cells isolated from biofilm were recalcitrant to antibiotics. Ms_zzzz survived better inside infected RAW macrophages, inducing pro-inflammatory cytokines using TLR4 as receptor. The expression of cell surface markers such antigen-presenting MHC II and co-stimulatory CD80 and CD86 molecules was increased post infection along with enhanced ROS and RNS production together indicative of M1 polarization. Ms_zzzz inhibited apoptosis of RAW cells using it as a protective niche avoiding exposure to host Immune system. Overall Rvzzzz is involved in adapting to environmental cues in the host and is a promising candidate for the development of novel therapies to target persistent bacteria.

Oxoeicosanoid signaling promotes early antimicrobial defense in zebrafish

Y. Ma[1], K. Hui[1], Z. Gelashvili[1,2], P. Niethammer[1]; [1]Cell Biology Program, Memorial Sloan Kettering Cancer Center, New York, NY, [2]Gerstner Sloan Kettering Graduate School of Biomedical Sciences, New York, NY.

5-oxoETE is a bioactive lipid derived from arachidonic acid (AA) generated when phospholipase A_2 activation coincides with oxidative stress. Through its G-protein coupled receptor OXER1, pure 5-oxoETE is a potent leukocyte chemoattractant. Yet, its physiological function, if any, has remained elusive for decades owing to the unusual OXER1 conservation pattern. OXER1 is conserved from fish to primates but not in rodents, precluding genetic loss-of-function studies in mouse. To determine its physiological role, we combined transcriptomic, lipidomic and intravital imaging assays with genetic perturbations of the OXER1 ortholog *hcar1-4* in zebrafish. *Pseudomonas aeruginosa* (PA) infection induced the synthesis of 5-oxoETE and its receptor, along with known inflammatory pathways. *Hcar1-4* deletion attenuated neutrophil recruitment and decreased post-infection survival, which could be rescued by ectopic expression of *hcar1*-4 or human *OXER1*. Our work reveals 5-oxoETE as a dominant lipid mediator of the early antimicrobial response in a non-rodent vertebrate. This is the first genetic proof for a conserved immune function of this enigmatic pathway with important implications for innate immune defense and perhaps sterile inflammation in humans.

B696/P3072

Parvovirus infection alters the nucleolar organization

S. Mattola[1], S. Leclerc[1], S. Hakanen[1], V. Aho[1], C. R. Parrish[2], M. Vihinen-Ranta[1]; [1]University of Jyväskylä, Jyväskylä, FINLAND, [2]University of Cornell, Ithaca, NY.

The nucleolus and nucleolar proteins are essential for the progression of infection by several viruses. Many viruses target the nucleoli to manipulate cellular antiviral defense and to facilitate their replication by recruiting nucleolar proteins. Consequently, viral infection often induces alterations in nucleolar structure and composition. Autonomous parvoviruses with small genomes and only a small number of encoded proteins depend on the cellular nuclear machinery for their efficient replication. Capsids of dependoparvoviruses, such as AAV, are assembled in the nucleolus. However, much less is known about

how autonomous parvoviruses interact with the nucleolus. Previously, we utilized proximity-dependent biotin identification (BioID), a powerful mass spectrometry-based tool capable of recognizing dynamic and transient interactions to elucidate the role of the viral NS2 protein in infection. The interactome linked NS2 to multiple proteins with possible relevance to the progression of infection. Notably, some gene ontology functions that were represented among the identified proteins were chromatin remodeling and DNA damage response. Moreover, the resolved BioID analysis revealed NS2 association with nucleolar proteins. Here, we applied a deep learning algorithm segmentation and nucleolin labeling to analyze the nucleolar changes induced by autonomous parvovirus infection. Our results show that the size of the detected nucleolin foci decreases, and nucleolin is released into the nucleoplasm in late infection. Analyses of ki-67, the strongest hit protein with the highest spectral count identified by BioID analysis, showed that the interaction between ki-67 with DNA increases in infection. In addition, the infection initiated by a viral clone lacking an intact NS2 failed to decrease the size of the detected nucleolin foci. All in all, our results suggest that parvoviruses modify and exploit nucleoli and nucleolar proteins during infection, and viral NS2 protein might play a role in regulating these processes.

***Bifidobacterium bifidum*prevents cytokine induced increase of intestinal epithelial tight junction permeability by a novel mechanism involving peroxisome proliferator activated receptor gamma (PPAR-g) inhibition of myosin light chain kinase**

R. Abdulqadir, R. Al-Sadi, T. Ma; Medicine, Penn State College of Medicine, Hershey, PA.

Background: Recent studies have shown that *Bifidobacterium bifidum* (BB) causes a marked enhancement of the intestinal epithelial tight junction (TJ) barrier in a strain-specific manner. TNF-α is a ubiquitous pro-inflammatory cytokine that contribute to the development of intestinal inflammation in part by causing an increase in intestinal permeability. The TNF-α induced increase in intestinal epithelial TJ permeability is mediated by an NF-κB-dependent activation of myosin light chain kinase (MLCK) gene. The peroxisome proliferator-activated receptor gamma (PPAR-γ) is a nuclear receptor which is known to have an anti-inflammatory activity by interfering with NF-κB activation. However, the role of BB (and the possible mechanism involved) in protecting against cytokine-induced increase in intestinal permeability remain unclear. **Aims:** The major purpose of this study was to delineate the protective effect of BB against the TNF-α induced increase in intestinal TJ permeability and the mechanism involved. **Methods:** Filter-grown Caco-2 monolayers (*in vitro*) and recycling intestinal perfusion of live mice (*in vivo*) were used to asses intestinal TJ permeability by a paracellular marker (dextran-10 kDa). **Results:** TNF-α caused a NF-κB and MLCK-dependent increase in intestinal TJ permeability in Caco-2 monolayers and in live mice, BB inhibited the TNF-α increase in intestinal TJ permeability in a strain-specific manner. BB enhancement of the TJ barrier was associated with an increase in PPAR-γ expression and activity and inhibition of NF-κB activation and MLCK activity in Caco-2 monolayers and in mouse enterocytes. The inhibitory effect of BB on TNF-α induced increase in intestinal permeability, NF-κB activation, MLCK expression, and activity was abolished by siRNA-induced knock-down of PPAR-γ in Caco-2 monolayers. We also generated Villin-cre intestinal epithelial-specific PPAR-γ knock-out mice to study the

involvement of enterocytes PPAR-γ in the BB effect. BB also inhibited the TNF-a induced activation of NF-κB, increase in MLCK expression and increase in mouse intestinal permeability in PPAR-γ intestinal deficient mice (Villin Cre). **Conclusion**: These studies provide a novel insight into BB the mechanism of protection against cytokine-induced increase in intestinal TJ permeability *in-vitro* and *in-vivo*. Our data show that BB protects against the TNF-α induced increase in intestinal TJ permeability by PPAR-γ mediated inhibition of NF-κB activation and MLCK gene activation.

Identifying *Brachyspira* virulence factors in infection of human colonic cells

A. Rajan, P. Gallego Alonso, M. Simrén, T. Pelaseyed; University of Gothenburg, Gothenburg, SWEDEN.

Irritable bowel syndrome (IBS) is a chronic gastrointestinal disorder affecting 10-15% of people in developed countries and 10-45% of the global population and having an impact on mental well-being, behaviour, attitude and overall quality of life. The definitive causes of IBS are still unknown, however a link between intestinal spirochetosis, caused by the anaerobic spirochete *Brachyspira*, and IBS has been suggested, where around 40% of patients with IBS are infected by the pathogenic bacteria *Brachyspira*. *Brachyspira* is an intestinal spirochete that colonises the colon. *Brachyspira aalborgi* and *Brachyspira pilosicoli* are two species that cause human intestinal spirochetosis. *Brachyspira* bind microvillus-studded apical surface of intestinal epithelial cells in a characteristic end-on manner giving an appearance of a "false brush border" as observed in human colorectal biopsies. The pathogenesis of *Brachyspira* infection in humans is not well understood. *B. pilosicoli* produce enzymes that can modify glycosaminoglycans to create attachment sites and to enhance colonisation, which along with the bacteria's twisting motility, aids in accessing underlying intestinal epithelial cells. However, bacterial outer membrane proteins responsible for attachment to intestinal epithelial cells remain unknown. **My project aims to identify *B. pilosicoli* outer membrane proteins that act as virulence factors and host cell surface proteins involved in the attachment step of *Brachyspira* to intestinal epithelial cells and subsequently determine molecular alterations in the brush border of IBS patients**, which cause susceptibility to *Brachyspira* infection. So far, **I have identified three *B. pilosicoli* outer membrane proteins that are potential adhesins. These proteins bind both cultured intestinal epithelial cells and human tissue sections. I have solved the structure for one of these proteins (OMP1) and preliminary data show that it binds to glycosylated mucin proteins.** The next steps are to validate the function of OMP1 as an attachment factor and to identify its ligand on the host cell.

***Borrelia burgdorferi* induces changes in the physical forces and immunity signaling pathways of endothelial cells early but not late during *in vitro* exposure**

R. Aparicio Yuste[1,2], **M. Münkel**[1], K. Axarlis[1], M. Gómez Benito[2], A. Reuss[1], G. Blacker[3], M. Caspi Tal[3,4], P. Kraiczy[5], E. Bastounis[1]; [1]Interfaculty Institute of Microbiology and Infection Medicine, (CMFI, EXC 2124), University of Tuebingen, Tuebingen, GERMANY, [2]Department of Mechanical Engineering, University of Zaragoza, Zaragoza, SPAIN, [3]Institute for Stem Cell Biology and Regenerative Medicine, Stanford University School of Medicine, Stanford, CA, [4]Department of Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA, [5]Institute of Medical Microbiology and Infection Control, University Hospital of Frankfurt, Goethe University Frankfurt, Frankfurt am Main, GERMANY.

Borrelia burgdorferi (*Bb)* is the causative bacterial agent of Lyme disease which is on the rise in the USA and Europe alike. Once transmitted to the human host via an arthropod vector, *Bb* spreads through tissues by traveling along and through the vasculature, whose inner lumen is lined by a monolayer of endothelial cells (ECs). What the precise mechanisms that *Bb* employs to achieve efficient dissemination through the vasculature are is not well understood. Could extracellular *Bb* induce alterations in the EC force generation machinery like several other intracellular bacterial pathogens, promoting its own spread by potentially weakening the EC barrier integrity? Using videomicroscopy coupled with traction force and monolayer stress microscopy, we monitored the response of ECs to prolonged exposure to *Bb* and found a sharp, transient increase in EC traction and intercellular stresses, followed by a prolonged decrease in EC traction and monolayer stresses 15 hours post exposure (hpe). At a later stage of exposure though (>24 h) all variables return to levels similar to those observed for never-exposed ECs. Using RNA-sequencing to better understand the underlying biochemical mechanisms involved, we discovered an upregulation of EC innate immune signaling pathways during early but not late exposure to *Bb*. In marked contrast to exposure of ECs to live *Bb*, when we generated heat-inactivated *Bb* and exposed them to ECs, we evidenced no sharp increase in traction forces at early exposure, neither reversal at late exposure, but found a sustained weakening of physical forces all throughout the exposure. Thus, we discovered a differential response of EC physical force generation and innate immune signaling to live versus heat-inactivated *Bb*. This indicates a tight interplay between the two and is suggestive of an active modulation of both processes that might be key in establishing infection.

Malaria derived extracellular vesicles inhibit primary neutrophils reactive oxygen species production and neutrophil extracellular trap formation.

K. Babatunde[1], M. Walch[2], P.-Y. Mantel[2]; [1]University of Calgary, Calgary, AB, Canada, [2]University of Fribourg, Fribourg, Switzerland

Introduction A dysfunctional innate immune response is believed to provide immune evasion of the malaria parasites, but also to cause increased susceptibility to bacterial infections. Neutrophils are the most abundant cells found in the blood circulation in direct contact with parasite-infected red blood cells (iRBCs). However, the neutrophil populations with reduced oxidative burst activities is present during malaria infection. These observations suggest that neutrophil responses are fundamentally defective in malaria patients. In this present work, we investigated, how extracellular vesicles (EVs) derived from iRBCs and containing both parasite and host materials, including microRNAs, modulate neutrophil response by transferring regulatory micro-RNAs. **Methods and Results** We have previously reported that malaria EVs contain miR451a, a microRNA that is known to regulate neutrophil activity when EVs are phagocytized by neutrophils. Thus we monitored the uptake of EVs by neutrophils through fluorescence microscopy, confocal microscopy, and real-time polymerase chain reaction techniques as well as potential pathways involved in their uptakes by neutrophils. Furthermore, our data demonstrated the influence of malaria-induced EVs on human neutrophil functions in vitro by inhibiting their ability to produce ROS and suppressing cytokine secretion. Neutrophils are known to produce neutrophil extracellular traps (NETs) during an immune response to pathogens; therefore, we quantified the production of NETs with incubation of EVs. **Conclusion** Our data indicate that EVs are actively taken up by neutrophils to deliver miR451, thereby interfering with their capacity to kill bacteria by inhibiting ROS and NETs formation. We describe a new mechanism of cellular communication between parasites and the host immune system. While EVs might increase tolerance to the parasites, they dramatically

affect the resistance to a coinfection by bacteria. The elucidation of the immune regulatory role of EVs might lead to the development of new therapies.

***Pseudomonas aeruginosa*Extracellular Vesicles Regulate Innate Immune Responses in Corneal Epithelial Cells and Neutrophils**

R. Ayilam Ramachandran, D. M. Robertson; UT Southwestern Medical Center, Dallas, TX

ABSTRACT

Pseudomonas aeruginosa Extracellular Vesicles Regulate Innate Immune Responses in Corneal Epithelial Cells and Neutrophils

Purpose: *Pseudomonas aeruginosa* (PA) keratitis is a devastating complication that can arise as a result of trauma or contact lens wear. Extracellular vesicles (EVs) are nanoscale membrane vesicles secreted by various cells including gram negative bacterial pathogens. These EVs are known as bacterial-derived vesicles or bacterial EVs (BEV). BEVs carry biomolecular cargo, including virulence factors, and can play a role in cellular communication. The objective of this study is to characterize the biomolecular cargo and host innate immune responses during PA-keratitis. **Methods:** A standard invasive test strain of PA (strain PA01) was used in these studies. BEVs were isolated from supernatant collected from an overnight suspension culture and isolated using size exclusion chromatography. Pooled BEV enriched fractions F1/F2 and secretory protein enriched fractions F4/F5 were subjected to mass spectrometry at the UTSW Proteomics Core Facility. EV size and concentration was determined by nanoparticle tracking analysis (NTA). Telomerase-immortalized human corneal epithelial cells and a dimethyl sulfoxide (DMSO) differentiated neutrophil cell line HL-60 were treated with BEVs and secretory proteins to determine their functional role during ocular PA infection. **Results:** BEVs from F1/F2 were < 150 nm in size. Protein concentration was much lower in BEVs and highest in secretory fractions. The BEV particle:protein purity was ratio was > 7×10^9. 954 and 359 unique proteins were identified in BEV and secretory fractions, respectively. Gene enrichment analysis indicated that most of the proteins from both groups belonged to

metabolic and cellular processes. BEVs and secretory proteins were not cytotoxic, but increased corneal epithelial intracellular PA survival. BEVs induced IL-6 and IL-8 secretion. Secretory proteins downregulated cytokine responses. Both BEVs and secretory proteins induced neutrophil activation, chemotaxis and respiratory burst. However, secretory proteins attenuated neutrophil bacterial killing. **Conclusions:** BEVs and secretory proteins exhibited unique proteomic profiles with virulence proteins enriched in BEVs. This led to differential functional effects on innate immune responses in corneal epithelial cells and neutrophils during PA keratitis.

***C. burnetii*downregulates IL-17 signaling in macrophages to block neutrophil recruitment**

T. Mordente Clemente, L. Augusto, S. D. Gilk; University of Nebraska Medical Center, Omaha, NE

Coxiella burnetii is a highly infectious pathogen that causes human Q fever, a flu-like acute illness that can develop into a chronic life-threatening endocarditis. *C. burnetii* first targets alveolar macrophages and promotes formation of a phagolysosome-like vacuole called the *Coxiella* Containing Vacuole (CCV). Successful host cell infection requires the Type 4B Secretion System (T4BSS), which translocates bacterial effector proteins across the CCV membrane into the host cytoplasm, where they manipulate a

variety of cell processes. We recently demonstrated that the *C. burnetii* T4BSS downregulates expression of IL-17 target genes as well as IL-17-stimulated chemokine secretion, and confers protection against IL-17 mediated killing by the macrophage. Given that IL-17 is known to protect against pulmonary pathogens, we hypothesize that *C. burnetii* T4BSS effector proteins downregulate intracellular IL-17 signaling pathways in order to evade the host innate immune response and promote bacterial pathogenesis. To further determine whether *C. burnetii* blocks IL-17-induced gene transcription, we utilized a stable IL-17 promoter reporter cell line which expresses secreted embryonic alkaline phosphatase (SEAP) under the control of one NF-kB and five AP-1 promoter elements. While there was a robust induction of SEAP following IL-17 activation in both mock and cells infected with the *C. burnetii* T4BSS mutant *dotA,* infection with wild type *C. burnetii* decreased SEAP by 75%, indicating that *C. burnetii* blocks IL-17-induced transcriptional activation. In addition, by assessing the phosphorylation state of NF-kB, MAPK, and JNK in mock- or *C. burnetii*-infected alveolar macrophages treated with IL-17, we confirmed that *C. burnetii* downregulates activation of these proteins. To determine whether the IL17RA-ACT1-TRAF6 pathway is required for IL-17-mediated killing of *C. burnetii*, we generated IL-17-RA and TRAF6 knockouts in macrophages. IL-17 stimulation decreased *C. burnetii* viability in WT cells, but not in the knockout cells, indicating that the IL17RA-ACT1-TRAF6 pathway is essential for the IL-17 bactericidal effect. Because IL-17 plays a critical role in recruiting neutrophils, we tested whether *C. burnetii* blocks IL-17-induced neutrophil chemotaxis using migration assays of neutrophils in the presence of supernatants from untreated and IL-17 treated infected macrophages. We found that *C. burnetii* actively inhibits IL-17-mediated neutrophil recruitment, and we identified CXCL5/LIX as an IL-17 induced neutrophil-chemoattractant downregulated in *C. burnetii*-infected macrophages. Together, our findings indicate that *C. burnetii* blocks IL-17 signaling to avoid direct killing by the macrophages and to decrease neutrophil recruitment to the infection site.

***Toxoplama* exploits the host autophagy to acquire amino acids to persist in the brain.**

E. Funke[1], **L. Augusto**[2]; [1]University of Nebraska Omaha, Omaha, NE, [2]University of Nebraska Medical Center, Omaha, NE

Toxoplasma gondii is one of the most prevalent parasites worldwide. It is estimated that nearly 2 million people in the world have been infected with this pathogen. Given that healthy individuals usually can control parasite replication, they typically remain asymptomatic or present mild flu-like symptoms during acute infection. However, parasites that escape from immune response encyst in the brain, becoming resistant to both immune response and available drugs. One of the reasons for this successful infection is *Toxoplasma*'s ability to infect virtually any nucleated cell in warm-blooded vertebrates. However, the parasite relies on host cells' nutrients, especially amino acids and fatty acids, to chronically persist in the brain, which is associated with neurological alterations. The currently recommended therapy for toxoplasmosis causes severe adverse effects and only targets acute forms of *Toxoplasma*. Therefore, one of the highest priorities in the field is elucidating how latent parasites persist in the brain in order to identify potential drug targets against chronic forms. Curiously, upon infection *Toxoplasma* recruits the host cell's endoplasmic reticulum (ER) into close proximity to the parasitophorous vacuole (PV), although the reasons for these high affinity interactions are not completely understood. Here, we show that *Toxoplasma* exploits ER-phagy in infected cells, which culminates in lysosomal amino acid accumulation. Remarkably, the viability of chronic forms is drastically decreased when this accumulation of amino acids is blocked, and the ER function and homeostasis are restored. Finally, by restricting the

amino acid intake in chronically infected mice, the number of chronic forms in the brain was significantly decreased and neurological alterations caused by infection were restored. Our findings identified the underlying mechanisms used by *Toxoplasma* to exploit host ER and lysosomal pathways to acquire nutrients during chronic infection in the brain. These findings provide new insights into strategies for the treatment of toxoplasmosis.

Evidence that a Palladin-VASP interaction influences Enteropathogenic *E.coli* (EPEC) actin-rich pedestal height

K. M. Bruzzini, S. Mann, J. A. Guttman; Simon Fraser University, Burnaby, BC, Canada

Enteropathogenic *E.coli* (EPEC) generate actin-rich protrusions at sites where the bacteria bind to their host cells. These structures enable the bacteria to rise off of the membrane surface onto "actin pedestals" that provide motility to the bacteria when docked to their host cells. The actin and VASP-associated protein palladin has been previously found to be important for actin structure formation in other systems and can functionally replace the Arp2/3 complex at branched actin comet tails generated by *Listeria monocytogenes*. Here we examined the role of palladin during EPEC infections. We found that palladin colocalized with actin throughout the stalk of EPEC pedestals. When an actin-binding mutant of palladin was transfected into host cells, pedestals appeared normal. However, when a VASP binding mutant form of Palladin was examined, pedestal height was impaired suggesting that a Palladin-VASP interaction may be needed for efficient pedestal height.

The role of Myristoylated, Alanine-rich C-kinase Substrate (MARCKS) in Macrophages upon stimulation of Toll-like receptor 4.

J. Issara-Amphorn[1,2], V. Sjoelund[2], A. Nita-lazar[2]; [1]National Institute of Allergy and Infectious Diseases, NIH, Bethesda, MD, [2]Functional Cellular Networks Section, Laboratory of Immune System Biology, National Institute of Allergy and Infectious Diseases, National Institute of Health, Bethesda, MD

MARCKS (Myristoylated Alanine-rich C-kinase Substrate) is a membrane protein expressed in many cell types including macrophages and functionally related to cell adhesion, phagocytosis and inflammatory responses. LPS (lipopolysaccharide), one of the strongest PAMPs (Pathogen-associated molecular patterns), triggers inflammation via TLR4 (Toll like receptor 4). During TLR4 stimulation, MARCKS is phosphorylated by PKC (Protein kinase C) resulting in its release to the cytosol followed by activation of inflammatory signal transduction pathways. The phosphorylation site of MARCKS (phospho-MARCKS) on serine (S163) may have a regulatory role, since we found it changes upon TLR stimulation. Serine phosphorylation serves as a key regulator of many physiological processes including innate and adaptive immune responses. Although MARCKS and the formation of phospho-MARCKS in macrophages have been described, the cellular role(s) of MARCKS and phospho-MARCKS in regulating macrophage functions remain unclear. As a proof-of-concept study, we activated macrophages with LPS with or without addition of a PKC inhibitor. We found that PKC inhibition substantially decreased macrophage IL6 and TNF cytokine production. In addition, confocal microscopy showed that MARCKS and phospho-MARCKS increased localization to endosomes in response to LPS stimulation. Moreover, CRISPR-CAS9 mediated knockout of MARCKS in macrophages downregulated TNF and IL6 cytokine production following LPS stimulation, suggesting a role for MARCKS in inflammatory responses. Our comprehensive

proteomics analysis comparing LPS-stimulation of WT and CRISPR-CAS9 MARCKS knock-out macrophages provides insight into the involvement of MARCKS in specific biological processes including inflammatory responses and cytokine-mediate signaling pathways, uncovering the specific proteins involved in regulating MARCKS activity upon LPS stimulation. The discovery of the mechanism by which MARCKS contributes to the inflammatory response may provide new strategies to manipulate inflammation-related diseases.
This research was supported by the Intramural Research Program of NIAID, NIH.

***Legionella pneumophila* effector Lpg2409 binds PI(3)P and targets host mitochondria**

M. Grossi, C. Pike, M. Neunuebel; University of Delaware, Newark, DE

Mitochondria are dynamic organelles in both their constant energy turnover and in regulation of their structure through elongation/fission and mitophagy. *L. pneumophila* effectors can exploit these functions by fragmenting mitochondria to promote its survival. Here we present evidence that Lpg2409 targets mitochondrial components. HEK293T lysate pulldowns followed by mass spectrometry revealed that mCherry-Lpg2409 associates with Mic60, a protein that regulates mitochondrial structure, and ubiquitin ligase scaffolding proteins. In HeLa cells, EmGFP-Lpg2409 colocalized with endogenous Mic60 and induced cytosolic cytochrome C, yet no cell death occurred. Lpg2409 bound PI(3)P *in vitro,* and mCherry-Lpg2409 colocalized with EGFP-2xFYVE, indicating that Lpg2409 localized to PI(3)P-enriched vesicles such as autophagosomes. Indeed, Lpg2409 colocalized with endogenous autophagy markers p62 and ubiquitin in transfected HeLa cells. Lastly, immunostaining of host cells infected with *L. pneumophila* expressing HaloTag-Lpg2409 demonstrate that Lpg2409 likely accumulates later during infection. These findings suggest Lpg2409 targets key components involved in mitochondrial architecture and autophagy.

B707/P3083

Human B-lymphoblastoid Cells Exhibit Vastly Different Susceptibility to Shigatoxin 2

G. J. Chaudry[1], A. K. Strickland[1], O. N. Tran[1], S. N. Asin[1], A. Melton-Celsa[2]; [1]Science & Technology, 59th Medical Wing, San Antonio, TX, [2]School of Medicine, Uniformed Services University of the Health Sciences, Bethesda, MD

Diarrheal infections are typically food-borne and occur globally. Two bacteria that can cause hemorrhagic colitis (HC) are *Shigella dysenteriae* and Shigatoxigenic strains of *Escherichia coli* (STEC) such as serotype O157:H7. The pathologic and clinical severity of diarrheal disease due to STEC is quite variable, but in extreme forms it involves the potentially fatal hemolytic uremic syndrome (HUS). Shiga toxins produced by *S. dysenteriae* and STEC are crucially important in HUS pathogenesis. STEC strains produce Shiga toxin 1 (Stx1), Shiga toxin 2 (Stx2), or both. Stx1 is essentially identical to the Shiga toxin produced by *S. dysenteriae* type 1. Stx2 has the same mode of action as Stx1, but there is significant amino acid divergence from Stx1. In addition, Stx2 is more frequently associated with HC and HUS. Both Stx1 and Stx2 are AB5 toxins with potent cytotoxic activity. The toxins bind to the cellular receptor globotriaosylceramide (Gb3) via the B pentamer, then are trafficked in a retrograde manner to the endoplasmic reticulum (ER). From the ER the toxin enzymatic moiety (A subunit) enters the cytosol. The Stx1 and Stx2 A subunits are N-glycosidases that target the 28S rRNA. This action renders the 28S rRNA nonfunctional, arrests protein synthesis, and kills the cell. The work reported here aimed to assess

susceptibility of 90 individual-specific human B-lymphoblastoid cell lines to Stx2. Toxicity assays were done at 37°C for 72 hours. Of the cell lines evaluated, many showed complete resistance to Stx2 (IC_{50} > 500 ng/mL), while others showed very high sensitivity (IC_{50} ~ 0.007 ng/mL). To discern gene expression and other genetic differences between the highly sensitive and resistant cell lines, we performed RNA seq in triplicate on 15 of these cell lines. The RNA seq results revealed that in the Stx2-resistant group 37 genes had >5-fold increased expression compared to Stx2-sensitive group. Conversely, 34 genes showed >5-fold increased expression in Stx2-sensitive group. There were 25,506 transcripts with no expression difference between resistant and sensitive cells ($P > 0.05$). We hypothesize that some of the gene expression differences account for the differential Stx2 sensitivity and resistance phenotypes in these lymphoblastoid cells. Work is now in progress to elucidate the steps where there are blocks to Stx2 toxicity in the resistant cell lines.

Identification of bacterial species present in a concrete Pennsylvania bridge

P. Tadley, K. Hansen, J. Colosi, L. K. Goudsouzian; Biology, DeSales University, Center Valley, PA.

Concrete is the most prevalent material used in the construction of roads and bridges. Concrete corrosion is a leading cause of structural damage that can lead to bridge failure. While concrete contains low biomass, some bacteria can survive and even grow in the low oxygen, highly alkaline environment. There is little understanding of the microbial communities present in concrete, and whether those microorganisms present contribute to its degradation. The Pennsylvania Department of Transportation supplied a concrete sample collected from Pier 8 of the Minsi Trail Bridge (PennDOT #48-3007-0022-0071) in Bethlehem, Pennsylvania during renovation. Under stringent aseptic conditions, DNA was extracted from the interior of the sample using a silica suspension. A control sample (washed glass beads) was extracted alongside the concrete sample, to identify and rule out contaminant taxa which were introduced by the laboratory environment. A surface sample of the concrete was collected to determine the effectiveness of sterilization before collection of the interior sample. The V3-V4 region of the 16S gene was amplified in all samples and sequenced using massive parallel sequencing (next generation sequencing) with modifications for low-biomass samples. *Firmicutes*, *Proteobacteria*, and *Actinobacteriota* were the three most abundant phyla found in the Minsi Trail Bridge sample. The three most abundant individual bacterial genera were *Streptococcus*, *Corynebacterium*, and *Pajaroellobacter*. Eleven of the bacteria sequenced contained the gene *narG*, a subunit of nitrate reductase alpha. This enzyme causes the degradation of nitrogen used in concrete, thus contributing to its corrosion. Remarkably, 18S sequencing of the concrete surface sample yielded multiple examples of a DNA sequence identified as the eukaryotic midge, *Belgica antarctica*. This insect's range is limited to Antarctica, which leads us to believe that the eukaryote detected during sequencing is, in fact, a novel species of midge with a genome most closely related to that of *Belgica antarctica,* or a species of midge never characterized by genetic means.

***Sulfolobus acidocaldarius* adhesion pili power twitching motility in the absence of a dedicated retraction ATPase**

A. Charles-Orszag[1], M. van Wolferen[2], S. J. Lord[1], S. Albers[2], D. Mullins[1]; [1]University of California, San Francisco, San Francisco, CA, [2]University of Freiburg, Freiburg, GERMANY.

Type IV pili are ancient and widespread filamentous organelles found in most bacterial and archaeal phyla. They support a wide range of fundamental functions including adhesion to substrates, DNA uptake, self aggregation and motility. In particular, disassembly of type IV pili mediated by PilT-family ATPases allows pilus retraction, which is responsible for twitching motility that is important for surface colonization in bacteria. Archaea do not possess homologs of a PilT retraction ATPase, and it was therefore hypothesized that archaeal cells are not capable of twitching motility. Yet, recent microscopic observations of live Sulfolobus acidocaldarius showed that cells exhibit short-range surface-motility that resembles bacterial twitching motility. S. acidocaldarius is a thermoacidophilic crenarcheon that encodes three different type IV pili systems with non-redundant functions. While archaella are rotating type IV pili that allow swimming motility, UV-inducible pili promote cell aggregation and DNA exchange upon exposure to UV light, and adhesion pili are responsible for surface attachment and biofilm formation. Here, using a combination of automated single cell tracking at high temperature, high-temperature fluorescence imaging, and genetic manipulations, we demonstrate that S. acidocaldarius exhibits bona fide twitching motility, and that this behavior depends specifically on adhesion pili. Our results show that adhesion pili are capable of retraction in the absence of a PilT retraction ATPase. While PilT-independent pilus retraction was previously observed in bacteria such as C. crescentus, our study suggests that in archaea, which do not encode a dedicated retraction ATPase, this might be a common mechanism for pilus retraction. Our results also suggest that the ancestral type IV pilus machinery was capable of dynamic retraction and extension cycles in the absence of a dedicated retraction ATPase.

Cellular dynamics of early stages of *P.aeruginosa* infection by giant bacteriophages

O. S. Sokolova[1], A. Moiseenko[2], Y. Danilova[2], D. Antonova[3], I. Vishnyakov[3], M. V. Yakunina[3]; [1]Biology, MSU-BIT University, Shenzhen, CHINA, [2]Biology, Moscow M.V.Lomonosov University, Moscow, RUSSIAN FEDERATION, [3]Peter the Great St. Petersburg Polytechnic University, St. Petersburg, RUSSIAN FEDERATION.

The large-scale use of antibiotics in medicine and agriculture has led to the emergence and rapid spread of antibiotic-resistant strains of pathogenic bacteria. The problem is complicated by the fact that 1) the spread of antibiotic-resistant strains is faster than the development of new antibiotics; 2) numerous strains resistant to several antibiotics at once (multidrug-resistant strains) are emerging; 3) antibiotics used to fight a number of bacteria are highly toxic to humans. The natural enemies of bacteria, lytic bacteriophages, have evolved many molecular mechanisms over the course of evolution that allow them to successfully and rapidly infect bacteria, evolve in them, suppressing or modifying important cellular processes, and ultimately destroying infected bacteria. PhiKZ-related phages infect a wide range of bacteria, including clinically important pathogens of the genera Pseudomonas, Yersinia and Salmonella, which are characterized by resistance to antibiotics. In this regard, phiKZ and related phages are considered components of phage cocktails for the treatment of infections caused by these bacteria. To develop more effective and safe antibacterial agents based on these phages and the proteins encoded

by them, it is necessary to study the development of phage infection within bacterial pathogens. Here, we used RT-PCR, fluorescent *in situ* hybridization (FISH), cryo-electron microscopy and electron tomography to study the morphology of early stages of bacteriophage infection of Pseudomonas *aeruginosa* cells. The maturation of the pseudo-nucleus was traced in short intervals for 40 min after infection and revealed the continuous spatial separation of the phage and host DNA. Immediately after ejection, phage DNA was located inside the new-identified round compartments (RC); we used cryo-EM to demonstrate how the RC are organized. At a later infection stage, phage DNA was replicated inside the pseudo-nucleus; in the mature pseudo-nucleus, a saturated internal network of filaments was observed. This network consisted of DNA bundles in complex with DNA-binding proteins. On the other hand, the bacterial nucleoid underwent significant rearrangements during phage infection, yet the host DNA did not completely degrade until at least 40 min after phage application. Energy dispersive x-ray spectroscopy (EDX) analysis revealed that, during the infection, the sulfur content in the bacterial cytoplasm increased, which suggests an increase of methionine-rich DNA-binding protein synthesis, whose role is to protect the bacterial DNA from stress caused by infection. Analytical EM was supported by the Innovation Committee of Science and Technology of Shenzhen, China (20200828172651001) and cryo-EM by the Russian Science Foundation (20-04-60258).

***Legionella pneumophila* infection of human macrophages retains golgi structure but reduces o-glycans**

R. E. Heineman[1], Y. Fu[2], V. Macwan[2], M. R. Terebiznik[2], R. E. Harrison[2]; [1]Cells and Systems Biology, University of Toronto, Toronto, ON, CANADA, [2]University of Toronto, Toronto, ON, CANADA.

Legionella pneumophila is an accidental pathogen that replicates intracellularly within the *Legionella*-containing vacuole (LCV) in macrophages. Within an hour of infection, *L. pneumophila* secretes effectors to manipulate Rab1 and intercept ER-derived vesicles to the LCV. The downstream consequences of interrupted ER trafficking on the Golgi of macrophages are not clear. We examined the Golgi structure and function in *L. pneumophila*-infected human U937 macrophages. Intriguingly, the size of the Golgi in infected macrophages remained similar to uninfected macrophages. Furthermore, TEM analysis also did not reveal any significant changes in the ultrastructure of the Golgi in *L. pneumophila*-infected cells. Drug-induced Golgi disruption impacted bacterial replication in human macrophages, suggesting that an intact organelle is important for bacteria growth. To probe for Golgi functionality after *L. pneumophila* infection, we assayed glycosylation levels using fluorescent lectins. Golgi O-glycosylation levels, visualized by the fluorescent cis-Golgi lectin, *Helix pomatia* agglutinin (HPA), significantly decreased over time as infection progressed, compared to control cells. N-glycosylation levels in the Golgi, as measured by L-PHA lectin staining, were not impacted by *L. pneumophila* infection. To understand the mechanism of reduced O-glycans in the Golgi we monitored UDP-GalNAc transporter levels in infected macrophages. The solute carrier family 35 membrane A2 (SLC35A2) protein levels were significantly reduced in *L. pneumophila*-infected U937 and HeLa cells and *L. pneumophila*growth in human macrophages benefitted from GalNAc supplementation. The pronounced reduction in Golgi HPA levels was dependent on the translocation apparatus DotA expression in bacteria and occurred in a ubiquitin-independent manner. Thus, *L. pneumophila* infection of human macrophages maintains and requires an intact host Golgi ultrastructure despite known interference of ER-Golgi trafficking. Finally, *L. pneumophila* infection blocks the formation of O-linked glycans and reduces SLC35A2 protein levels in infected human macrophages.

Characterization of a putative trehalose biosynthetic pathway in *Salmonella typhimurium*

C. J. Larmore, A. R. Storm; Western Carolina University, Cullowhee, NC.

Trehalose is a non-reducing disaccharide composed of two glucose monomers. In living organisms, this sugar is predominantly connected by an α-1,1-glycosidic linkage. Trehalose has been shown to benefit many bacterial species by protecting biomolecules from denaturation, increasing cell wall stability, and serving as a carbon source. Genes believed to encode a trehalose biosynthetic pathway, including the enzymes maltooligosyl trehalose synthase (StMTSase) and maltooligosyl trehalose trehalohydrolase (StMTHase), have been identified and shown by knock-out studies to be essential in *Salmonella typhimurium*. However, the protein products have yet to be experimentally characterized. Because *S. typhimurium* is of medical concern and becoming increasingly antibiotic resistant, better understanding these essential genes will improve our understanding of potential targets for treatment. The objective of this study was to characterize the putative StMTSase and StMTHase enzymes to determine if this pathway is functional. Comparative sequence analysis revealed that both StMTSase and StMTHase are highly conserved with homologous proteins that have been previously characterized and retain amino acid residues known to be both catalytic and involved in substrate binding. The enzymatic activity of StMTSase was experimentally tested using the Nelson-Somogyi (NS) method for detection of reducing sugars, as MTSase enzymes convert reducing maltooligosaccharides into the non-reducing sugar maltooligosyl trehalose. StMTSase was shown to utilize maltohexaose as a substrate and function optimally at 40°C and a pH of 7.0. Overall, our results suggest that the putative trehalose biosynthetic pathway identified in *S. typhimurium* is functional and that StMTSase behaves optimally under similar conditions to MTSase enzymes in other bacterial species. Moving forward, enzyme activity assays will be performed across increasing substrate concentrations to determine the maximum rate at which StMTSase catalyzes its reaction (V_{max}) and its affinity for maltohexaose (K_m). Once these key parameters have been determined, the activity of two mutant StMTSase enzymes will be evaluated. One mutant lacks a key catalytic residue (E279), while the other contains substitutions of tyrosine at two positions (M460 and V464) to match binding site residues identified in known functional MTSases.

Multiple ParA/MinD ATPases Coordinate the Positioning of Disparate Cargos in a Bacterial Cell

L. T. Pulianmackal, J. I. Limcaoco, K. Ravi, S. Yang, J. Zhang, M. K. Tran, M. J. O'Meara, A. G. Vecchiarelli; University of Michigan, Ann Arbor, MI.

In eukaryotes, linear motor proteins govern intracellular transport and organization. In bacteria, where linear motors are absent, the ParA/MinD (A/D) family of ATPases spatially organize an array of genetic- and protein-based cellular cargos. ParA is well known to segregate plasmids and chromosomes, as is MinD for its role in divisome positioning. Less studied is the growing list of ParA/MinD-like ATPases found across prokaryotes and involved in the spatial organization of diverse protein-based organelles, such as Bacterial Microcompartments (BMCs), flagella, chemotaxis clusters, and conjugation machinery. Given the fundamental nature of these processes in both cell survival and pathogenesis, it is unsurprising that the positioning of these cargos has been independently investigated to varying degrees in several organisms. However, it remains unknown whether multiple A/D ATPases can coexist and coordinate the positioning of such a diverse set of fundamental cargos in the same cell. If so, what are the mechanistic commonalities, variation, and specificity determinants that govern the positioning

reaction for each cargo? Here, we find that over a third of sequenced bacteria encode multiple A/D ATPases. Among these bacteria, we identified several human pathogens as well as the experimentally tractable organism, *Halothiobacillus neapolitanus*, which encodes seven A/D ATPases. We directly demonstrate that five of these A/D ATPases are each dedicated to the spatial regulation of a single cellular cargo: the chromosome, the divisome, the carboxysome BMC, the flagellum, and the chemotaxis cluster. We identify putative specificity determinants that allow each A/D ATPase to position its respective cargo. Finally, we show how the deletion of one A/D ATPase can have indirect effects on the inheritance of a cargo actively positioned by another A/D ATPase, stressing the importance of understanding how organelle trafficking, chromosome segregation, and cell division are coordinated in bacterial cells. Together, our data show how multiple A/D ATPases coexist and function to position a diverse set of fundamental cargos in the same bacterial cell. With this knowledge, we anticipate the design of minimal autonomous positioning systems for natural- and synthetic-cargos in bacteria for synthetic biology and biomedical applications.

Dynamic heterogeneity inside the bacterial cytoplasm

A. Papagiannakis, C. Jacobs-Wagner; Stanford University, Stanford, CA.

When thinking of the bacterial cytoplasm, the nucleoid (DNA with its associated proteins) and the polysomes (mRNAs with their associated ribosomes) come to mind. In *Escherichia coli*, the nucleoid has been shown to spread through more than half of the cell volume[1], whereas the actively translating ribosomes account for about one fifth of the total proteome in fast growing cells[2]. Yet, despite their size and abundance, little is known about the biophysical interactions between these two macromolecules during the cell division cycle of *E. coli*.

Using quantitative epi-fluorescence microscopy in combination with microfluidics for long-term observation of single *E. coli* cells, we found that in this seemingly symmetric rod-shaped organism, the ribosomes and the DNA exhibit remarkable spatial and temporal heterogeneity which cannot be explained by free cytoplasmic diffusion and equilibrium processes. Our work proposes a self-organizing biophysical mechanism for chromosome segregation and positioning at the expense of ribosomal homeostasis in bacterial cells, which lack cytoskeleton mediated systems for these essential processes.

Regulation of sporulation by proteolysis in *Bacillus subtilis*: mechanisms of the adaptor protein YjbA

J. A. Lyda, E. P. Riley, J. D. Tibocha-Bonilla, K. Zengler, K. Pogliano; UCSD/SDSC, NIST, La Jolla, CA

Previous studies in the Pogliano lab have demonstrated that the adaptor protein YjbA is responsible for the metabolic reprogramming of the forespore during sporulation in *Bacillus subtilis* however, the targeting mechanisms of this adaptor protein and the benefits of the metabolic reprograming are still unknown. Here we examine the function of an N-terminal sequence of one such substrate CitZ, which is conserved in CitZ homologues from endospore forming bacteria. *B. subtilis* responds to severe nutrient limitation using a process called sporulation wherein the vegetative cell differentiates into 2 cell types, eventually producing a spore resistant to oxidative stress and antibiotics. This highly durable spore

makes it difficult to treat infections created by other similar bacterial pathogens that also produce spores. During the sporulation process, the vegetative cell divides at one pole, giving rise to the smaller forespore and the larger mother cell. The mother cell then engulfs the forespore in the process called engulfment, nurturing it in its cytoplasm until maturation. Once the spore is mature, the mother cell lyses, releasing the spore. Research from the Pogliano lab has shown that the forespore and mother cell become metabolically differentiated, with metabolic enzymes including the TCA cycle and enzymes required to produce metabolic building blocks being lost from the forespore, which thereby depends on the mother cell for macromolecular synthesis. We have shown that these enzymes are degraded from the forespore during development by one of the cell's core proteases, ClpCP, and identified a forespore expressed adaptor protein, YjbA. To identify the targeting mechanisms of YjbA we made use of chimeras of CitZ, a degraded metabolic enzyme from the TCA cycle, and the bacterial-two-hybrid assay. We also employed a metabolic model of a sporulating cell to simulate the consequences of the metabolic reprogramming of the forespore. Our results suggest that YjbA does not recognize a specific pattern on its substrates but rather likely activates or enhances ClpCP activity in the developing forespore, thereby initiating metabolic differentiation.

Green Syntheses and Characterizations of Silver Nanoparticles for Food Safety Applications

J. Gonzales[1], A. Geremew[2], L. Carson[2]; [1]Prairie View A&M University, Prairie View, TX, [2]Cooperative Agriculture Research Center, Prairie View A&M University, Prairie View, TX.

There is a growing demand and application of nanoparticles in various industries such as electronics, cosmetics, food safety, optics, and medicine. Green synthesis of silver nanoparticles (AgNPs) using medicinal plants has been investigated due to the presence of phytochemicals that play a role in the reduction process. Thus, this study aimed to synthesize and characterize AgNPs using aqueous leaf extracts of *Salvia blepharophylla* and *Salvia greggii*, and to assess their antimicrobial activity on the multidrug-resistant species of bacteria, *Escherichia coli, Salmonella typhimurium, Listeria*, and *Staphylococcus aureus*. The formation of AgNPs was confirmed using UV-vis spectroscopy as the reaction solution changed from a light brown to a darker brown. The particle stability and sizes were determined using the Anton Paar Litesizer. Agar well diffusion method was used to measure zones of inhibition (ZOI) to determine the antimicrobial properties of the AgNPs. Preliminary data indicated that AgNPs sizes were between 80-92 nm, and 80-84 nm, using extract of *S. blepharophylla* and *S. greggii*, respectively. Additionally, zeta potentials of AgNPs synthesized using *S. blepharophylla* ranged from -23 to -26 mV, and -20 to -25 mV using *S. greggii.* Overall results showed that *E. coli, S. typhimurium, Listeria,* and *S. aureus* were inhibited by AgNPs synthesized using the extract of *S. blepharophylla* with ZOIs were 0.9-1.2 mm, 0.9-1.1 mm, 0.3-1.3 mm, and 0.95-1.25 mm, respectively. Additionally, *E. coli, S. typhimurium, Listeria,* and *S. aureus* were inhibited by AgNPs synthesized using the extract of *S. greggii* ZOIs were 1-1.15 mm, 0.9-1.3 mm, 1-1.4 mm, and 1-1.3 mm, correspondingly. *S. aureus* seemed to be the most sensitive bacteria overall, against both plant-based AgNPs.

Characterization of Multidrug Resistant Bacteria from the Lane College Soil

J. Wright, L. Allen, M. Van Stry; Lane College, Jackson, TN

Antibiotics are substances that eliminate or slow down the growth of bacteria. Beta-lactam antibiotics, such as penicillin, are antibiotics that contain a beta-lactam ring that inhibits bacterial cell wall biosynthesis. Bacteria are becoming resistant to antibiotics being that antibiotics are highly prescribed when people seek health care. My goal for this project is to isolate and characterize soil bacteria that are resistant to antibiotics. I hypothesize that the bacteria present in the soil on Lane College campus is resistant to beta-lactams. Furthermore, I hypothesize that these bacteria have a beta-lactamase gene, which is an enzyme that inactivates the bacteria by cleaving the beta-lactam ring. I collected soil samples from Lane College campus and cultured the bacteria on two nutrient agar plates with ampicillin and cultured over night at room temperature. For further characterization, I then chose 3 different colonies from the plates (S1A, S1B, and S2A) and streaked them on to new nutrient agar plates with ampicillin. The strains were tested for drug resistance using the Kirby-Bauer method. They were incubated overnight at room temperature. I then streaked separate nutrient agar plates from all 3 colonies and added antibiotic disks to each plate (ampicillin, penicillin, amoxicillin, and streptomycin) with E. coli as a control group. Strains S1A, S1B, and S2A were resistant to ampicillin, penicillin, and amoxicillin, but were sensitive to streptomycin. We then further characterized by Gram staining and morphological observation. All samples were Gram negative and the cells were a coccus shape. I am planning to use the 16S rDNA gene to identify the bacteria using Nanopore next generation sequencing, and to look for the presence of beta-lactamase genes by whole genome sequencing.

Muscle Structure, Function, and Disease

A small internal deletion in Titin yields transient cardiogenic defects followed by ion channel-dependent cardiomyopathy and arrhythmia

X. Jiang[1,2], O. T. Ly[3,4], H. Chen[3], Z. Zhang[5], B. A. Ibarra[1,2], M. A. Pavel[3], A. Sridhar[3,6], D. Tofovic[3], A. Swick[1,2], R. Marszalek[6], F. Navales[1,2], Y. Gao[5], D. Darbar[3,6], A. Saxena[1,2]; [1]Department of Biological Sciences, University of Illinois at Chicago, Chicago, IL, [2]University of Illinois Cancer Center, Chicago, IL, [3]Division of Cardiology, University of Illinois at Chicago, Chicago, IL, [4]Department of Biomedical Engineering, University of Illinois at Chicago, Chicago, IL, [5]Department of Pharmaceutical Sciences, University of Illinois at Chicago, Chicago, IL, [6]Department of Physiology, University of Illinois at Chicago, Chicago, IL.

Atrial fibrillation, the most common arrhythmia, has been occasionally shown to correlate with congenital heart defects, but causal relationships are not well-defined. Additionally, it is unclear how adult cardiac function might compensate for developmental defects and, in doing so, mask the potential for adult atrial fibrillation. Here, we deleted just 9 amino acids (Δ9) within the structural protein Titin in both zebrafish and human induced pluripotent stem cell-derived atrial cardiomyocytes (hiPSC-aCMs), revealing new connections between cardiac development and disease. We found that *ttna*$^{\Delta 9/\Delta 9}$ homozygous zebrafish embryos' atrial morphology is perturbed and accompanied by reduced cardiac function. Surprisingly, this function recovers within a few days of embryonic development, and most *ttna*$^{\Delta 9/\Delta 9}$ embryos reach adulthood and are externally indistinguishable from wild-type clutchmates. However, *ttna*$^{\Delta 9/\Delta 9}$ adults exhibit persistent atrial enlargement and weak atrial contraction, and a subset

of adults demonstrate atrial fibrillation with a near-absence of fibrosis. Patch-clamp assays and shotgun proteomics revealed that *ttna*$^{\Delta 9/\Delta 9}$ adult hearts have substantial ion channel remodeling in response to the Δ9 deletion, and inhibiting the function of potassium channel Kv7.1 in *ttna*$^{\Delta 9/\Delta 9}$ embryos accelerates developmental recovery of atrial contraction. Upon recapitulating the Δ9 deletion in hiPSC-aCMs, we found increased expression of Kv7.1 and impaired interactions between Kv7.1 and its regulatory subunit KCNE1, resulting in increased I_{Ks} current. Suppression of I_{Ks} rescues arrhythmia and partially restores contractility. Taken together, these findings reveal how a small deletion in Titin unexpectedly contributes to ion channel dysfunction, demonstrating how subtle developmental abnormalities can recover functionally yet increase the risk of subsequent adult cardiac disease.

Visualizing sarcomere and cellular dynamics to improve cell transplantation and fusion in striated muscle

M. Gotthardt[1], J. Hüttemeister[1], M. Radke[1], F. Rudolph[1], C. Fink[1], S. Lehnart[2], E. Wagner[2]; [1]Max-Delbrueck Center, Berlin, GERMANY, [2]University Medical Center Göttingen, Goettingen, GERMANY.

The giant striated muscle protein titin integrates into the developing sarcomere to form a stable myofilament system that is extended as cells fuse. The logistics underlying myofilament assembly and disassembly have started to emerge with the possibility to follow labeled sarcomeric components. Here, we generated the mCherry knock-in at titin's Z-disk to study skeletal muscle development and remodeling. We find that titin integration into the sarcomere is tightly regulated and its unexpected mobility facilitates a homogenous distribution of titin after cell fusion - an integral part of syncytium formation and maturation of skeletal muscle. Implantation of titin-eGFP myoblasts into the muscle of mCherry-titin mice reveals how cells fuse and contribute to the continuous myofilament system across cell boundaries. Unlike in immature primary cultures, titin proteins are retained at the proximal nucleus and do not diffuse across the whole syncytium. These findings have implications for future cell-based therapies of skeletal muscle disease.

Identification of PAKAP as a Novel Regulator of Myoblast Fusion in Vertebrates

A. Hazak, S. Sinha, G. Zarfati, K. Huk, E. Ozer-Partuk, O. Avinoam; Department of Biomolecular Sciences, Weizmann Institute Of Science, Rehovot, ISRAEL.

Myoblast cell fusion is an essential process in skeletal muscle development and regeneration. However, the molecular machinery that drives membrane fusion in myoblasts remains incompletely understood. One of the challenges in studying cell fusion is that it is a rare and transient event, making it difficult to identify the proteins involved. We have recently found that ERK1/2 inhibition induces synchronous myoblast differentiation and fusion in culture, making it possible to capture large amounts of fusing myoblasts. Additionally, we found that simultaneous inhibition of ERK1/2, which is required for primary myoblast proliferation, and P38, which is required for myoblast differentiation, uncouples differentiation and fusion, leading to the accumulation of differentiated unfused cells. I used mass spectrometry proteomics mapping to identify proteins that are specifically enriched during cell-to-cell fusion, comparing the differentiated unfused and fused cells. This analysis pointed to Paralemmin A-kinase anchor protein (PAKAP), a protein of unknown function, as a potential regulator of myoblast fusion. PAKAP is expressed as a natural fusion protein between Paralemmin-2 (PALM2) and the

downstream gene A-kinase anchor protein 2 (AKAP2). Interestingly, paralemmins are involved in membrane dynamics and filopodia formation, while AKAPs can bind to the regulatory subunit of protein kinase A (PKA) and direct it to a specific cellular location. Filopodia formation and PKA signaling are known to be involved during myoblast fusion. However, the exact mechanism remains unknown. To test whether PAKAP is essential for myoblast fusion, we generated a PAKAP knockout (KO) in C2C12 myoblast cell line and found that KO cells have a severe fusion failure phenotype. Immunofluorescence and membrane proteomics experiments showed that PALM2 and PAKAP localize to membrane protrusions on the surface of fusing cells. Taken together, these experiments suggest that PAKAP is specifically involved in myoblast fusion, possibly by directing PKA signaling to the plasma membrane, where it might activate PALM2 to generate fusogenic filopodia. We are currently testing this exciting hypothesis by live-cell imaging. Hence, our work will provide new insight into the mechanism of myoblast fusion as a paradigm for other cell fusion processes.

B722/P3097

Klhl41 plays a critical role in er homeostasis in skeletal muscle

T. Moretti, J. Essner, J. Kim; Iowa State University, Ames, IA.

Nemaline myopathy (NM) is a congenital skeletal muscle disorder characterized by hypotonia, muscle weakness, and atrophy. Thirteen genes have been linked to NM, the majority encoding the components of the sarcomeric thin filament. Within the NM genes, KLHL40, KLHL41, and KBTBD13 belong to the Kelch-like gene family whose gene products affect protein turnover, bringing a different mechanistic perspective to the disease. The Kelch-like proteins are involved in ubiquitination of target proteins as a substrate-recognizing component of a cullin3 RING ubiquitin ligase. Here we report a novel role of KLHL41 in ER homeostasis. When we knocked down the expression of KLHL41 in C2C12 myotubes, it led to an increase in several ER proteins. In particular, levels of Sarco/endoplasmic reticulum Ca2+-ATPase 1 (SERCA1) and ryanodine receptor (RYR) increased several folds. Overexpression of a recombinant KLHL41 reduced SERCA1 levels considerably, suggesting that KLHL41 is critical for maintaining SERCA1 levels. We generated zebrafish klhl41 knockout animals using CRISPR-Cas9 technology. There are two klhl41 orthologs (klhl41a and klhl41b) in zebrafish. klhl41a knockout (KO) alone caused no evident phenotype, while klhl41b or klhl41a/b KO caused strong phenotypes. The klhl41b and klhl41a/b mutants presented with disorganized and thinner myofibers, actin aggregation, reduced muscle integrity, and smaller somite size. In addition, levels of SERCA1 increased over three folds in klhl41 KO embryos. Furthermore, the cisternae of the sarcoplasmic reticulum (SR) were enlarged in the mutants. We conclude that KLHL41 is crucial for the organization of the sarcomeric thin filament as well as the homeostasis of the SR. Our experiments now focus on understanding the molecular mechanism by which KLHL41 affects SERCA1 and other SR proteins in skeletal muscle.

B723/P3098

Defining the differential function, localization, and protein interaction partners of wild type and expanded PABPN1, an RNA binding protein associated with a late onset muscle disease

A. T. Mezzell, K. E. Vest; Molecular Genetics, Biochemistry, and Microbiology, University of Cincinnati, Cincinnati, OH.

The polyadenylate binding protein nuclear 1 (PABPN1) is an RNA binding protein that facilitates multiple steps in RNA processing. PABPN1 protein contains an amino-terminal alanine tract of unknown function.

Small expansions of the polyalanine tract cause the late-onset disease oculopharyngeal muscular dystrophy (OPMD), which affects craniofacial and proximal limb muscles and causes drooping eyelids, trouble swallowing, and loss of mobility. OPMD pathology remains poorly understood and no pharmacologic treatments are available. Therefore, a deeper understanding of the function, localization, and protein binding partners of both wild type and expanded PABPN1 is needed. Expanded PABPN1 forms nuclear aggregates, which have been implicated in OPMD pathology. However, soluble alanine-expanded PABPN1 interacts with a different subset of proteins than wild type PABPN1, suggesting that alanine expansion impacts PABPN1 function. We aim to define the protein binding partners of wild type and expanded PABPN1. Most previous models used to study PABPN1 and expanded PABPN1 over expressed the proteins, which can impair RNA binding protein function. We have generated stable muscle cell lines containing PABPN1 fused with the promiscuous biotin ligase TurboID under the control of an inducible promoter to allow for native levels of expression. PABPN1 is predominantly nuclear, with a small fraction located in the cytoplasm. We found that overexpression of TurboID fusion constructs results in mislocalization of both wild type and expanded PABPN1 to the cytoplasm. When we expressed the wild type PABPN1-TurboID fusion at endogenous levels, the protein localized normally and labeled known PABPN1 binding partners. When we expressed expanded PABPN1 at endogenous levels, we found that it is not detected in the cytoplasm suggesting that it is mislocalized to another compartment. Our future studies will focus on comparing wild type PABPN1 to alanine expanded PABPN1. We will extend our assays to explore aberrant localization of expanded PABPN1 and determine how mislocalization affects interaction with PABPN1 protein binding partners. Our findings will expand the knowledge of PABPN1 function and provide additional insight into the mechanisms that cause OPMD.

Defining Therapeutic Targets and New Therapeutics-for Diverse Diseases

Laser Delivery of Optogenetic Therapy in Murine Pain Models

A. Fijany[1,2], D. Narcisse[3], R. Benkowski[2], A. Tripathy[3], N. Al-Adli[1], S. Mohanty[3]; [1]TCU School of Medicine, Fort Worth, TX, [2]Designplex Biomedical, LLC, Fort Worth, TX, [3]Nanoscope Technologies, LLC, Bedford, TX.

Introduction: Pain is an essential sensation that occurs due to tissue damage. However, it can occur chronically and become debilitating for individuals. Therapies for pain conditions are costly and complicated by adverse events (often related to off-target effects). Targeted treatments to areas involved in pain perception with a specific and easily modulated therapy can avoid these pitfalls. Optogenetics allows site-specific and temporally precise modulation of genetically targeted cells expressing an opsin protein. Traditionally, gene therapies have been delivered by viral vectors. However, previous studies have demonstrated that viral vectors can induce a maladaptive immunologic response that may be responsible for tissue degeneration in a dose-dependent manner.[1] In our own experience, we have experienced greater control with laser gene delivery in a manner that is superior to that seen in the viral vector studies.

Methods: Nanoscope Technologies developed an opsin with high sensitivity to red light and a significant depolarizing effect when activated named Multi-Characteristic Opsin (MCO). Using an injection of functionalized gold nanorods (fGNRs) and MCO-encoding DNA, we were able to induce the expression of MCO in target areas of the nervous system by illuminating them with concentrated bursts of attuned light. We then used the wireless Optogenetic Pain Modulator (OPM) device developed by Designplex Biomedical to stimulate the newly expressed MCO with precise control of the frequency, intensity, and

repetition rate of optogenetic stimulation in experimental models of pain. We used a model of acute inflammatory pain in the form of a formalin test in which optogenetic stimulation was used to mitigate pain in stereotyped pain behaviors. Sciatic nerve ligation served as a model of chronic neuropathic pain; we stimulated neurons related to pain information processing and measured the changes in the reflex response of a mice's hind paws to mechanical allodynia.
Results: We demonstrated that optogenetic stimulation of MCO-sensitized inhibitory neurons in the CNS leads to a significant reduction in acute pain reactions and a significant increase in the applied force threshold for paw withdrawal in previously hypersensitive limbs secondary to nerve ligation.
Conclusion: Our results support modulation of the inhibitory pathways within the CNS as a viable alternative for inhibiting chronic neuropathic pain. Given the need for reliability, portability, and convenience for pain treatment to be therapeutically effective and advantageous, the ease of application and easily customized optogenetic stimulation inherent to our approach make it ideal for future application in the field of neuromodulation.

B725/P3100

Peroxisome Proliferator Activated Receptor Alpha Regulates Interplay between Senescence, Mitochondrial Functions and Autophagy in Retinal Cells

J. Blasiak[1], M. Hytti[2], A. Koskela[2], S. Felszeghy[2], K. Kaarniranta[2]; [1]University of Lodz, Lodz, POLAND, [2]University of Eastern Finland, Kuopio, FINLAND.

Age-related macular degeneration (AMD), an eye disease is a world-wide emerging problem, but exact mechanisms of its pathogenesis is poorly known. Peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1α) encoded by the *PPARG1* gene is a master regulator of mitochondrial biogenesis and an important factor in antioxidant defense. We have created a model to study mechanisms of AMD pathogenesis including mice with knockout in the *PPARG1* gene and a series of lines of retinal pigment epithelium (RPE) cells derived from induced pluripotent stem cells (iPSCs) obtained from AMD patients. The aim of our study was to determine the expression of genes involved in mitochondrial functions, autophagy and senescence in *PPARG1*-KO mice and RPE-iPSCs as compared with respective controls. We also assessed the influence of age on the observed effects. Gene expression was evaluated by RT-PCR, immunochemistry and immunoblotting. Mitochondrial metabolism was evaluated by the Seahorse FX test. Bafilomycin a1 (Baf1) and MG-132 were used as autophagy inhibitor and inducer, respectively. The 3-months- or 1-year-old *PPARG1*-KO mice were derived from the C57BL/6J strain. We observed difference between the expression of *HMGB1* (*High Mobility Group Box 1*) and *CDKN2A (Cyclin Dependent Kinase Inhibitor 2A*) (senescence), *SDH* (*Succinate Dehydrogenase Complex Subunit D), MT-CO1* (*Mitochondrially Encoded Cytochrome C Oxidase I*) (mitochondria)*, MTOR* (*Mechanistic Target of Rapamycin Kinase*)*, MAP1LC3B* (*Microtubule Associated Protein 1 Light Chain 3 Beta*)*, SQSTM1* (*Sequestosome 1*) and *PRKN (Parkin RBR E3 Ubiquitin Protein Ligase*) (macroautophagy and mitophagy) genes in the RPE cells from KO animals and AMD patients. Observed effects were more pronounced in 1-year- than in 3-months-old animals. The PGC-1α deficiency results in altered mitochondrial metabolism, accelerated decline of the expression of autophagy-related genes with age and alterations in mitochondria- and senescence-related genes in RPE cells. The mice with knockout in the PGC-1α-encoding gene and RPE-iPSCs obtained from AMD patients can be a useful complex model to investigate the role of impaired mitochondrial and autophagic functions associated with cellular senescence in AMD pathogenesis.

***Maackia amurensis* Seed Lectin (MASL) Increases Movement Velocity of Mice with TNFα Induced Rheumatoid Arthritis**

K. L. Hamilton[1], A. A. Greenspan[2], C. M. Laugier[2], A. J. Shienbaum[3], B. Fischer[4], A. Bottaro[4], G. S. Goldberg[2]; [1]Georgetown University, Washington, DC, [2]Rowan University, Stratford, NJ, [3]Keystone Medical Laboratories, Throop, PA, [4]Rowan University, Camden, NJ.

Up to 70 million people around the world suffer from rheumatoid arthritis. Current treatment options have varied efficacy and can cause unwanted side effects. New approaches are needed to treat this condition. Sialic acid modifications on chondrocyte receptors have been associated with arthritic inflammation and joint destruction. The transmembrane mucin receptor protein podoplanin (PDPN) has been identified as a functionally relevant receptor that presents extracellular sialic acid motifs. PDPN signaling promotes inflammation and invasion associated with arthritis and, therefore, has emerged as a target that can be used to inhibit arthritic inflammation. *Maackia amurensis* seed lectin (MASL) can target PDPN on chondrocytes to decrease inflammatory signaling cascades and reduce cartilage destruction in a lipopolysaccharide induced osteoarthritis mouse model. Here, we investigated the effects of MASL on rheumatoid arthritis progression in a TNFα transgenic (TNF-Tg) mouse model. Results from this study indicate that MASL can be administered orally to ameliorate joint malformation and increase velocity of movement exhibited by these TNF-Tg mice. These data support the consideration of MASL as a potential treatment for rheumatoid arthritis.

B727/P3102

Potential antioxidant, cytotoxic, antiviral, and antibacterial activities of extracts from three species of *Piper*, an African pepper

A. Meyer[1], S. Akbar[2], D. Sheridan[1], H. Cogburn[1], J. A. Fernandez Romero[1], B. Rafferty[1], A. Koroch[1], C. Priano[1]; [1]Borough of Manhattan Community College, New York, NY, [2]Brooklyn College, Brooklyn, NY.

Peppers of the genus *Piper* are commonly used as spices and traditional medicines in Africa. The aim of this study was to identify total phenolic content and antioxidant, cytotoxic, antiviral, and antibacterial activities of extracts from seven commercial sources of *P. nigrum, P. guineense,* and *P. borbonense.* Crude extracts were prepared in different solvents from dried crushed seeds for each sample. Total phenolic compounds and antioxidant capacities were determined using the Folin-Ciocalteu assay and the 2,2'-azino-bis -ABTS assay. The cytotoxicity in different cell lines and viral entry inhibition by aqueous extracts were explored using the XTT colorimetric assay and the SARS-CoV-2 Delta variant pseudoviral model. Antibacterial activity was determined by growing *Escherichia coli* and *Bacillis subtilis* in microplate cultures in the presence or absence of each aqueous extract and monitoring growth by spectrophotometry. Variations in total phenolic content and antioxidant capacity between samples and extraction solvents were observed. Samples with high total phenolics exhibited the highest antioxidant capacity. The SARS-CoV-2 Delta variant pseudoviral model in HeLa ACE-2 cells showed half-maximal effective concentrations (EC_{50} values) between 0.7 and 3.7 mg/mL. The half-maximal cytotoxic concentration and EC_{50} ratio (selective index) showed promising viral entry inhibition in four of seven extracts with selective indexes between 8.2 and 14.9. Aqueous extracts from *P. borbonense* showed the best antiviral selectivity. The cytotoxicity in Caco-2 cells showed that most of the aqueous extracts did not decrease cell viability, with no dose-response observed. Whereas *P. guineense* and *P. borbonense*

extracts inhibited growth of *B. subtilis*, there was no activity observed against *E. coli*. Differential results are possibly due to differences in bacterial cell wall structure. Samples of *P. borbonense* that exhibited the highest suppression of *B. subtilis* growth had relatively high phenolic content and antiviral activity. The data collectively support a scientific basis for traditional health benefits of *Piper* extracts and warrant further investigation into the actions of specific phenolic compounds present in these extracts and their potential biological activities.

Reduction of senescence of chondrogenic progenitor cells by Fisetin in knee osteoarthritis

A. Aggarwal[1], J. Jacob[1], A. Aggarwal[2]; [1]Postgraduate Institute of Medical Education & Research Chandigarh India, Chandigarh, INDIA, [2]Postgraduate Institute of Medical Education & Research Chandigarh India, CHANDIGARH, INDIA.

Introduction: Knee osteoarthritis is a debilitating disorder that results in the degradation of articular cartilage. Not only chondrocytes are affected, but the stem cells are also prone to oxidative stress and cellular senescence. Not only the senescence is restricted to the cells but is propagated via Senescence associated secretory phenotype (SASP) that contributes to overall degradation of the cellular matrix. The Objective was to study the effect of Fisetin, the natural flavonoid on the cellular senescence in the chondrogenic progenitor cells (CPCs) and the impact on the overall regeneration of articular cartilage. **Methods**: Chondrogenic progenitor cells were isolated and cultured from the medial tibial plateaus of knee osteoarthritis patients that were clinically and radiologically diagnosed according to the American College of Rheumatology criteria. The cells were evaluated for the cellular senescence using SA-β galactosidase assay. IC_{50} value was calculated using MTT assay and cells were treated with fisetin for 24 hours. Senotherapeutic activity of fisetin was assessed post treatment by staining the cells with SA-β galactosidase and evaluating the cellular senescence genes using real time PCR (p16, p21, p53, and p38MAPK) and proteins using Western Blot. In addition, the matrix degradation enzymes MMP-9 and MMP-13 as well as IL-1 β was evaluated at both gene and protein levels. **Results**: Determination of cell viability upon 24 hours treatment with natural drug fisetin, using a concentration ranging from 5µM-100µM revealed that fisetin was not cytotoxic and safe in this range of concentration (99.5%-86.03% viability; p=0.61). Treatment of CPCs with fisetin at a concentration of 100µM significantly decreased the senescence index compared to the untreated control (42.93%, p=0.01). With higher doses of fisetin treatment i.e., 50µM and 100µM, gene expression of p53 (50µM: p=0.005, 100µM: p<0.0001) and p38 (50µM: p=0.04, 100µM: p<0.007) was significantly downregulated. Protein expression of p53 and p38 was further verified by western immunoblots supported the decline in the cellular senescence proteins post treatment. Similarly, SASP related gene expression of MMP-9, MMP-13 and IL-1β was significantly downregulated at high dose of fisetin. However, significant downregulation of protein expression of MMP-9 (p=0.04) and IL-1β (p=0.03) was observed at 100 µM. **Conclusion**: Overall, fisetin was found to be effective in reducing the burden of senescence in CPCs and SASP including proteases MMP9 and MMP13 associated with cartilage matrix degradation and inflammatory cytokine IL-1β.

Arctiin attenuates high cholesterol-induced bone loss by decreasing oxidative stress in osteoclasts

G. Li, **H. Choi**; Biological Sciences, University of Ulsan, Ulsan, KOREA, REPUBLIC OF.

Arctiin, arctigenin glycoside is a bioactive ingredients of *Arctium lappa L* that has been used as a medicininal herb in Asia. Arctiin-containing plants has been considered to be effective to treat rheumatic arthritis, inflammatory disease, and infection in traditional oriental medicine. Our previous studies demonstrated that high cholesterol diet induced bone loss in mice along with oxidative stress. We hypothesized arctiin may protect high cholesterol diet-induce bone loss via decreasing oxidative stress. To investigate action mechanism of arctiin to protect from cholesterol-induced bone loss, arctiin was orally treated at a dose of 10 mg/kg in atherogenic diet-fed C57BL/6 male mice for 6 weeks. In vitro, the anti-oxidant effects of arctiin was evaluated in osteoclasts (OCs) that was stimulated by 7-ketocholesterol (7-KC). Arctiin decreased the number and activity of 7-KC stimulated OCs and inhibited autophagy via disruption transcription factor EB (TFEB) nuclear localization by reducing oxidized TFEB signaling pathway. Arctiin decreased cytosolic ROS to decrease its effects on OCs. These findings provide a therapeutic potential of arctiin to prevent from cholesterol-induced bone loss by decreasing oxidative stress. Insulin like growth factor -binding protein 2 ameliorates glucose imblanced state by regulating Amp-activated kinase signal pathway in Thioacetamide injured rat ovary model

D. Lee[1,2], H. Park[1,2], K. Na[1], J. Seok[3], Y. Kim[4], G. Kim[1,2]; [1]CHA University, Seongnam-si, KOREA, REPUBLIC OF, [2]PLABiologics.Co.Ltd, Seongnam-si, KOREA, REPUBLIC OF, [3]University of Chicago, Chicago, MD, [4]CHA Bundang Medical Center, Seongnam-si, KOREA, REPUBLIC OF.

Glucose is an important energy substrate for the generation of ATP for the metabolic and physiological functions of the ovary. However, impaired glucose metabolism, insulin resistance is an important cause of ovarian dysfunction and mitochondrial dysfunction due to the central importance of glucose as a source of energy. Glucose dysregulation can interfere with reproductive hormones and cause reproductive diseases including polycystic ovary syndrome and ovarian insufficiency. PD-MSCs could have therapeutic effects on metabolic dysfunction and ovarian function via activating AMPK signaling pathway. The objectives of this study are to analyze the therapeutic effects of PD-MSCs on glucose metabolism in TAA-injured rat model and to investigate the correlation between glucose metabolism and ovarian function through AMPK signaling.The expression of glucose metabolism factors (e.g.,AMPK,SIRT1,GLUT4,IR,IRS1,PI3K,AKT) were significantly increased in PD-MSCs compared to TAA group (*$p<0.05$). The follicular development hormones, AMH, FSH and E2 levels were also higher than TAA group. In addition, the expressions of mitochondrial dynamics factors and ATP uptake were significantly increased in PD-MSCs transplanted group than TAA group (*$p<0.05$). Ex vivo cocultivation of TAA treated ovaries and PD-MSCs or treatment with recombinant IGFBP2(100ng/ml) and IGF-1 inhibitor(100ng/ml) increased glucose metabolism marker and ovarian function and insulin signal and Autophagy marker. Notably, the mRNA expression of AMPK,SIRT1,GLUT4,IGFBP2,IGF-1,IRS1,IR was significantly increased in cocultivation with PD-MSCs group and recombinant treat group (*$p<0.05$). In addition, the protein level of AMPK,GLUT4 was significantly increased in PD-MSCs group and IGFBP2 treated group(*$p<0.05$). Also, the mRNA expression of Autophagy marker(BECN1,LC3b) was significantly

increased in PD-MSCs group and IGFBP2 treaed group but mTOR expression was opposite. These findings suggest that secreting IGFBP2/IGF-1 by PD-MSCs plays an important role in glucose metabolism, mitochondrial dysfunction,ovarian function,Autophagy and offer new insight into the effects of stem cell therapy for reproductive systems.

Comparative analysis of co-cultured amniotic cell conditioned media with cell-free amniotic fluid reveals differential effects on epithelial-mesenchymal transition and myofibroblast activation

N. Liu[1], C. M. Bowen[1], M. M. Shoja[1], K. L. Castro de Pereira[1], L. P. Dongur[1], S. Antonio[1], W. K. Russell[1], T. C. Broderick[2], J. H. Fair[1], **W. S. Fagg**[1]; [1]University of Texas Medical Branch, Galveston, TX, [2]Merakris Therapeutics, Research Triangle Park, NC

Myofibroblast activation is a cellular response elicited by a variety of physiological or pathological insults whereby cells initiate a coordinated response intended to eradicate the insult and then revert back to a basal state. However, an underlying theme in various disease states is persistent myofibroblast activation that fails to resolve. Based on multiple observations, we hypothesized that the secreted factors harvested from co-culturing amniotic stem cells might mimic the anti-inflammatory state that cell-free amniotic fluid (AF) elicits. We optimized an amnion epithelial and amniotic fluid cell co-culture system, and tested this hypothesis in the context of myofibroblast activation. However, we discovered that co-cultured amniotic cell conditioned media (coACCM) and AF have opposing effects on myofibroblast activation: coACCM activates the epithelial-mesenchymal transition (EMT) and stimulates gene expression patterns associated with myofibroblast activation, while AF does the opposite. Intriguingly, extracellular vesicles (EVs) purified from AF are necessary and sufficient to activate EMT and inflammatory gene expression patterns, while the EV-depleted AF potently represses these responses. In summary, these data indicate that coACCM stimulates myofibroblast activation, while AF represses it. We interpret these findings to suggest that coACCM, AF, and fractionated AF represent unique biologics that elicit different cellular responses that are correlated with a wide variety of pathological states, and therefore could have broad utility in the clinic and the lab.

Purinosome assembly in various biological models of DNPS disorders

V. Barešová, O. Součková, V. Škopová, S. Kmoch, M. Zikánová; Charles University in Prague and General University Hospital in Prague, Prague, Czech Republic

Purinosome assembly in various biological models of DNPS disordersObjectives: Purine metabolism is an integral part of human life, as purines are essential compounds that provide energy to the body and make up our genetic code. Purines are synthesized in de novo purine synthesis (DNPS) by coordinated action of six enzymes to catalyze ten consecutive reactions. These enzymes are organized in a multi-enzyme structure, the purinosome, which is transiently and reversibly assembled in the cell cytoplasm as the demand for purines changes. Disorders of purine metabolism include rheumatological, neurodevelopmental, immunological or renal diseases. Their pathogenesis is not fully understood.Methods: We investigated purinosome formation in a purine-depleted media by immunofluorescence labeling of endogenous proteins involved in the DNPS pathway in skin fibroblasts from patients with DNPS disorders. We then performed knockout of genes encoding DNPS enzymes in HeLa cells using GeneArt® CRISPR Nuclease Vector with OFP Reporter Kit and analyzed the ability of

knockout cells to form the purinosome in the same manner. To observe dynamic purinosome formation, we prepared a transgenic C. elegans model carrying the fluorescently tagged DNPS proteins PPAT-1:GFP and F38B6.4 (GART):mCherry.Results: We demonstrated that mutations in skin fibroblasts derived from patients with DNPS, AICAribosiduria and ADSL, PAICS and PFAS deficiencies disrupt purinosome assembly. Purinosome formation was also impaired in HeLa cells where DNPS enzymes were knocked out. Fibroblasts from patients with Lesch-Nyhan syndrome form the purinosome not only in a purine-depleted but also in a purine-rich medium. A similar observation was seen in the HGPRT enzyme knockout HeLa cell line. The purinosome formation was normalized by transfection of wt protein. In the C. elegans model purinosomes colocalized with mitochondria and were strongly formed in the dauer state. We did not observe purinosome formation in L1 and adult states.Conclusion: The mechanism of purinosome assembly and the contribution of various biological, genetic and metabolic factors have not been fully investigated. The aim of our study was to describe the purinosome in different pathological conditions. This characterization will improve our understanding of purine synthesis and regulation and provide better insight into the pathophysiology and possible treatment of purine disorders.

A Macromolecular Complex of CFTR, NHERF2, and LPA_2 in Intestinal Epithelium and Its Role in the Pathological Process of Secretory Diarrhea

W. Zhang[1,2,3], S. Kong[2], Y. Zhang[4], A. P. Naren[5]; [1]USDA-ARS, Stoneville, MS, [2]Departments of Pediatrics, University of Tennessee Health Science Center, Memphis, TN, [3]Departments of Physiology, University of Tennessee Health Science Center, Memphis, TN, [4]Department of Bioscience Research, University of Tennessee Health Science Center, Memphis, TN, [5]Department of Medicine, Cedars-Sinai Medical Center, Los Angeles, CA.

Background: Diarrhea is the second leading cause of death in children under five years old and the leading cause of malnutrition in this age group. The hyperactivation of the cystic fibrosis transmembrane conductance regulator (CFTR) channels in the gastrointestinal tract plays a central role in the pathogenic process of some secretory diarrheas. CFTR forms a macromolecular complex with Na^+/H^+ exchanger regulatory factor 2 (NHERF2) and lysophosphatidic acid receptor 2 (LPA_2) at the apical plasma membrane of intestinal epithelial cells. This study aimed to investigate the roles of CFTR-NHERF2-LPA_2 complex in fluid homeostasis and inflammatory responses in the gut. **Methods:** (1) Study models: Intestinal epithelial cells (human HT29-CL19A cells, mouse m-ICc12 cells), mouse intestinal epithelial tissues, mouse intestine fluid secretion models. (2) Techniques: immunofluorescence imaging, Western blotting, PCR, proximity ligation assay, ELISA, Ussing chamber, etc. **Results:** (1) LPA_2 is a major LPA receptor in human and mouse intestinal epithelial cells. (2) CFTR complexes with NHERF2 and LPA_2 at the plasma membrane of HT29-CL19A cells and m-ICc12 cells. (3) LPA inhibits CFTR channel function through an LPA_2-mediated G_i pathway. LPA substantially reduced the cholera toxin (CTX)-induced and CFTR-mediated intestinal fluid secretion in mice. (4) GRI977143 (a specific LPA_2 agonist) inhibited the forskolin-induced CFTR channel activity in polarized HT29-CL19A cells and mouse intestinal epithelial tissues. GRI977143 significantly decreased the CTX-induced closed-loop intestinal fluid secretion in mice. (5) Knock-down of LPA_2 in HT29-CL19A cells and m-ICc12 cells significantly reduced the gene and protein level of IL-8. GRI977143 also inhibited IL-8 secretion. (6) IL-8 level is decreased in the intestines of LPA_2 knockout mice compared to wild type mice. **Conclusion:** CFTR-NHERF2-LPA_2 complex plays a critical role

in the pathological process of certain secretory diarrheas. In addition to modulating the CFTR-mediated fluid secretion, it also regulates IL-8 secretion from intestinal epithelial cells which could contribute to excessive inflammatory responses in the gut. Specific and potent anti-secretory agents can be useful additions to oral rehydration therapy for secretory diarrheas. **Acknowledgment:** Supported in part by NIH grant R01HL147351.

Bile Inhibits Bacterial Toxin Activity by Instigating Structural Destabilization and Oxidation

J. E. S. Taylor[1], D. Heisler[1,2], E. Kudryashova[1], D. Kudryashov[1]; [1]Department of Chemistry and Biochemistry, Ohio State University, Columbus, OH, [2]University of Texas Southwestern Medical Center, Dallas, TX.

While bile primarily solubilizes fat in the gut, it also regulates the colonization of the gut microbiome. To counteract this, some bacteria have evolved to modulate the production of virulence factors in response to bile. We speculate that due to their typically high conformational plasticity and low stability, virulence factors are easy targets for the denaturing activities of bile salts. If confirmed, toxin denaturation by bile salts may influence the pathogenic potential of bacteria and justify bile-related adjustments in the expression of virulence factors. In this work, we explored the effects of reconstituted bovine bile, sodium deoxycholate (DOCh), and sodium taurocholate (TCh) on the stability and activity of effector domains of multifunctional auto-processing repeats-in-toxin (MARTX) from *V. cholerae* and *A. hydrophila*. We assessed changes in protein structure and stability using collisional quenching of intrinsic Trp residues and pelleting. Most toxins responded to bile and DOCh treatments by enhanced quenching of Trp fluorescence by acrylamide. We observed increased precipitation of toxins in the presence of DOCh. The effects of bile on solubility were milder and more discriminative, slightly promoting precipitation of some toxins, showing no effect on others, and even improving the solubility of yet others, e.g., actin crosslinking domain (ACD) toxin from psychrophilic *A. hydrophila*, when added above its melting temperature. Upon entry of the host cell cytoplasm, MARTX domains are separated by activation of the cysteine protease domain (CPD). Cleavage of the CPD-containing four- and two-domain constructs was unaffected by DOCh and TCh but was inhibited by whole bile. This inhibition was accompanied by the formation of a high molecular weight protein species that could be reversed by the addition of a reducing agent, as revealed by non-reducing SDS-PAGE. Overall, these observations suggest that bile can compromise the structural integrity of the tested bacterial toxins, instigate their precipitation, and induce oligomerization via reversible cysteine oxidation, justifying the need for bacteria to tune toxin expression levels.

Basigin is expressed in mouse intestines and feces

J. D. Ochrietor[1], A. Preciado[1], V. J. Ochrietor[1], J. Gelsleichter[1], A. Arikawa[2]; [1]Biology, University of North Florida, Jacksonville, FL, [2]Nutrition and Dietetics, University of North Florida, Jacksonville, FL.

Basigin is a cell-adhesion protein belonging to the immunoglobulin superfamily (IgSF). This ubiquitously expressed protein plays roles in metabolism and immunity, with its most notable functions related to vision, cancer, and COVID-19. Recent studies by this research group showed that Basigin expression in blood vessel endothelial cells of the mouse brain is altered in response to ex vivo exposure to lipopolysaccharide (LPS), which is a component of the Gram negative bacterial outer membrane. Blood

vessel endothelial cells of the brain contribute to the blood-brain barrier (BBB), which may be functionally altered in response to an inflammatory stimulus. Because the intestinal epithelium also forms a barrier, the expression of Basigin in that tissue may also be altered in response to LPS. Therefore, expression of Basigin in mouse intestine, specifically the colon and rectum, was analyzed as a first step in understanding the potential role of the IgSF molecule in acute and chronic inflammation of the tissue. Mouse feces was also assessed because it may serve as a non-invasive method for assessing colon health. Colorectal samples from male and female mice at various post-natal ages were obtained and the contents were removed and served as the fecal sample analyses. Protein lysates were generated from the intestine and feces samples for subsequent quantitative ELISA analyses. In addition, intestines containing feces were fixed in 4% paraformaldehyde and subjected to immunohistochemical analyses. It was determined that male and female intestine samples were similar in expression of Basigin, with the highest concentration expressed at post-natal day 14. Basigin was observed on intestinal epithelial cells, with less prominent expression near the caecum and more prominent expression near the rectum. Basigin was detected in the fecal samples as well, with the highest concentration at post-natal day 21. No correlation between Basigin concentrations in the fecal and intestinal samples was observed. Because of the differential expression of Basigin through the length of the colon, future studies will examine specific regions of the intestine to better understand the gradient of expression within the tissue. Additionally, it would be useful to analyze external fecal pellets, rather than samples isolated from the intestines themselves, as samples isolated from regions near the caecum had less exposure to Basigin-expressing epithelial cells. It can be concluded that Basigin is expressed on both male and female mouse epithelial cells. The usefulness of fecal samples to assess Basigin expression in the colon, and hence the health of the tissue, has yet to be determined.
